[According to Laennec, an attack of purely nervous asthma is rarely fatal, and indeed is hardly ever so, without previously giving rise to congestions of blood, and other consequences of the disorder of the respiration and circulation induced by it: and, in these consequences, he observes, prejudiced minds may see the causes of the disease. He has met with many cases, however, in which it was impossible, after the most minute research, to find any organic lesion whatsoever, to which the asthma could be attributed. An instance of this is given by M. Andral in the case of a fatal suffocation, following the suppression of a discharge from an ulcerated leg.—(*Clin. Méd.*, tom. ii., obs. 20.) M. Guersent records the cases of two children who died in a few days of a remitting dyspnœa, attended with dry cough and præcordial anxiety, in whose bodies no obvious lesion could be found after death.—(*Dict. de Méd.*, tom. iii., p. 126.) Laennec is convinced that, in the greater number of asthmatic cases, depending on dry catarrh and pulmonary emphysema, the asthmatic paroxysm can be induced equally by the super-vention of a fresh catarrh, and by a deranged state of the nervous influence, occasioning pulmonary spasm, or an increase of the necessity of respiration, and sometimes by both causes at once. He believes, in fact, that few cases are owing to any one of these causes; and that, in old men particularly, several are frequently concerned. Of this kind are debility; ossification of the cartilages, and immobility of the ribs; rheumatism affecting the walls of the chest; and, perhaps, also, the tenuity of the air-cells, and of all the pulmonary vessels in advanced life. With the exception of the different kinds of catarrh, the occasional causes of the attacks of asthma are almost always such as are calculated to produce immediate and evident disturbance of the nerves; a strong mental emotion; venereal excesses; the influence of light and darkness; retrocession of gout; certain odours, such as those of tuberoses, heliotrope, stored apples, &c.; changes of the atmospheric electricity, and other less appreciable conditions of the atmosphere. We find that the greater number of asthmatic patients cannot remain with impunity in a low, close apartment, although containing much more air than they could consume in twenty-four hours; and although it is constantly, but insensibly renewed by the doors and chimneys. Some cannot bear any person to go before them, or any thing to be brought close to them, without experiencing a sense of suffocation; while others are never more subject to dyspnœa than in the midst of a large plain.*]

* See Laennec on Diseases of the Chest, &c., 2d edit., p. 412. Dr. Henderson notices a disorder in India, exactly corresponding to our spasmodic asthma, and which appears to attack poor individuals, whom accident has deprived of their usual daily allowance of opium. The disorder

Cases of the species of asthma before us, and even of humid asthma, occurring upon a SUDDEN DISAPPEARANCE OF scabid, herpetic, and other CUTANEOUS ERUPTIONS, are so common, that it is hardly worth while to dwell upon them. They are especially noticed by Sir John Floyer, and have rarely escaped the attention of any pathologist since his day. And that this is an actual cause of the disease, is perfectly manifest from the subsidence of the latter as soon as such eruption has been re-excited. A sudden disappearance of gout in the hand or foot, or of an habitual discharge, as that of the hemorrhoidal vessels, has operated in the same manner, while a renewal of these affections has proved an equal remedy.

But those of relaxed and PHLEGMATIC HABITS are peculiarly affected by such transfers of morbid action, particularly when the feet and ankles are habitually œdematous, and accustomed to enlarge towards night. Chronic or exacerbating dyspnœa is a frequent attendant upon such a state of corporeal debility; and hence we have reason to expect asthma also: for further information upon which subject the reader may turn to what has already been observed under *dyspnœa chronica*.

It is not surprising that asthma should be produced by the INHALED FUMES OF METALS, and other mineral substances, since we see it also frequently occasioned in constitutions prone to the complaint, by clouds of common smoke or dust. And Dr. Percival informs me that he has met with two cases in which slight apoplexies were concomitants of asthma, produced by concentrated fumes of nitrous acid; here again leading to the same train of causes we have already noticed, as laying a foundation for chronic dyspnœa.

To this subdivision, also, belong such cases of asthma as proceed from fogs and mists, especially those of populous and extensive towns, which many asthmatics are obliged to abandon, as soon as November makes its appearance, for a drier and less hazy atmosphere. The coats of the bronchiæ seem to be constricted by the inhaled vapour; and hence the suffocating feeling. Where, however, the internal tunic of the bronchiæ is habitually dry and irritable, the moisture of such an atmosphere cools and softens the harsh membrane, and the patient longs for such a situation, instead of flying from it. And hence the reason why fogs are poisonous to some asthmatics, and healthy to others. It is also probable that the altered gravity of the atmosphere, in these cases, and the larger and smaller doses of oxygen inhaled in every inspiration, produce some influence that proves beneficial or injurious, according to the habit or actual state of the air-vessels. And hence again, while some asthmatics can only

live in a mountainous situation, others find their only relief in lowlands and valleys.

An impregnation of the atmosphere with odorous essences, has also been found in a few cases of uncommon idiosyncrasy, or where the air-vessels have been peculiarly sensible, a sufficient cause of the asthmatic paroxysm; which has hence been produced by the smell of musk, and in one instance, related by Timæus, by that of roses.—(*Cas.* 216.) And, in consequence, it is not to be wondered at, that more pungent, and perhaps acuated corpuscles should produce a like effect. Dr. Scott, of Northumberland, has given cases of the greatest danger and extremity, occasioned by accidentally inhaling the effluvia of ipecacuanha while pulverizing.—(*Edin. Med. Comment.*, vol. iv., p. 75.)

Another and a very frequent cause of both species of asthma, but more particularly the *asthma sicccum*, is some organic derangement of the walls or contents of the chest. Gibbosity is one of the most common of the present group of causes. Lommius asserts, after Hippocrates (*Aph.* xlv., sect. 6), that if a person become gibbous before puberty, in consequence of asthma, he dies.—(*Obs. Med.*, lib. ii., p. 146.) On which Dr. Bree has well observed, that the authors have here substituted cause for effect (*Inquiry*, &c., p. 24), since it is rather the gibbosity that produces the asthma, than the asthma that produces the gibbosity. An osseous, and consequently rigid condition of the cartilaginous extremities of the ribs and sternum; ossifications of the pericardium, the valves of the heart, or the coronary arteries; pressure upon the lungs produced by a dropsy of the chest, or of the pericardium; by an empyema; by vomica or indurated tumours of whatever kind in the substance of the lungs; an inordinate magnitude of the lungs themselves; have all been found occasional causes of asthma, and are among the most formidable to be attacked. Haller, Bonet, Morgagni, and others, who have been peculiarly attentive to structural diseases and their effects, have recorded numerous instances of this kind. And the later examinations of M. Rostan have added other morbid changes to those already noticed, in the heart indeed as well as in the lungs. In the first of these, he has very frequently found that particular kind of thickening of the left ventricle of the heart, to which the French have given the name of active aneurism: and, in the second, besides the morbid lesions already noticed, adhesions between the lungs and the pleura; effusions of serum into the cavity of the chest; and a general change of structure in the lungs, giving them a semblance of the organ of the liver. Several of these appearances are most probably effects of the disease, though by M. Rostan uniformly regarded as causes.

{It was strongly suspected by Laennec (*Op. cit.*, p. 404), that in some rare instances of asthmatic dyspnœa, an imperfect paralysis of the diaphragm* and other muscles of inspiration

attacks them with such violence, that, unless a sufficient quantity of this narcotic be provided for them, they die in a few hours.—(*Edinb. Med. and Surg. Journ.*) This fact amounts to a convincing proof of the correctness of the term nervous asthma.—*Ed.*

* When asthma is combined with some material imperfection or disease of the organs of circula-

was concerned. Rostan gives an instance of asthma connected with ossification of the diaphragm.]

The general treatment of this distressing affection is still a matter of discussion. A considerable distinction is necessary in the two species under which it makes its appearance; and hence it will be more advantageous to defer the consideration of this subject, till we have noticed somewhat more at large the history of humid asthma, so that the plan proper for the one may stand in contrast with that proper for the other.

SPECIES II.

ASTHMA HUMIDUM.

HUMID ASTHMA. COMMON ASTHMA.

PAROXYSM GRADUAL; INGRAVESCENT, PROTRACTED; CONSTRICTION HEAVY, HUMID, LABORIOUS; COUGH SEVERE; EXPECTORATION COMMENCING EARLY; AT FIRST SCANTY AND VISCID, AFTERWARD COPIOUS, AND AFFORDING GREAT RELIEF.

This is the ordinary form under which the asthmatic paroxysm shows itself; and the trivial name of humid or humoral was given to it by earlier writers, most of them advocates of the humoral pathology, from an idea that an acrid humour was hereby discharged from the general mass of the blood, and consequently that the expuition was to be encouraged as much as possible; the suffocative struggle being regarded as an instinctive or remedial effort of nature to restore the system to a state of health.

Like the preceding species, it very generally appears without any obvious cause or connexion with any other affection. In some cases, however, it seems to be the result of a plethora, or, as Dr. Cullen expresses himself, a "turgescence of the blood, or any other cause of an unusual fulness and distention of the vessels of the lungs."—(*Pract. of Phys.*, part ii., book iii., chap. vi., sect. 1384.) And sometimes, as in old age, or after long-continued and repeated catarrhs, it is produced by an excess of serum or mucus flowing inordinately from a weakened and relaxed state of the bronchial exhalants or mucous glands: thus offering us three varieties as follow:

a Simplex.

Simple humid asthma. Without any manifest cause or combination with any other affection.

tion and respiration, it is often difficult to offer a positive opinion whether the latter circumstance is not consecutive, and gradually induced by the repeated attacks of the asthma. Then, we may also conceive that various morbid affections and organic diseases in asthma, are sometimes accidental attendants on it—not at all concerned with it either as a cause or an effect. Questions of this kind, as M. Jolly has well observed, are sometimes involved in difficulties which have not yet been obviated by pathological anatomy.—(*Dict. de Méd. et de Chir. Pratiques*, art. *ASTHME*.) No doubt, in a vast number of examples, in by far the greater number of cases, asthma is only a symptomatic disorder.—Ed.

β Plethoricum.

From plethora.

From plethora, or the suppression of some accustomed sanguineous evacuation.

γ Atonicum.

From local atony.

From a debilitated and relaxed condition of the excretories of the air-vessels, as a consequence of chronic and neglected catarrhs, or of old age.

We also meet with examples of the humid as well as of the dry asthma, as a symptom or sequel of many other diseases: as gout, hypochondrias, hysteria, parabsysma, and syphilis.

I have already observed that the attack of the present species is more severe, as well as of longer duration than the preceding; as though the patient were contending with two hostile forces instead of with one—a diminished diameter of the vessels, and infarction from a surplus of viscid mucus: and thus both the exciting causes co-operate, which have been contended for singly by the leaders of opposite principles. I am much disposed to think that this is frequently the case; and that, to a certain extent, both hypotheses are correct. That asthma occurs as in the preceding species without any increased discharge of mucus, is unquestionable; that it occurs with such increased discharge, is equally incontrovertible.

But whatever be the source of the aggravated distress endured in humid asthma, after some hours of suffering the patient feels less anxiety, breathes more leisurely and with less labour, and, with a growing freedom of expectoration, acquires general relief and tranquillity. Yet such is the irritable state of the affected organs, that even on the second day "no change of posture is made with impunity, and particular distress affects him if he engage in the fatigue of dressing while the stomach is empty. During the day, if no particular hurry occur, the breathing becomes generally more free till the evening: an inexperienced asthmatic even flatters himself that his disease is leaving him; but he finds at the approach of night that he must sustain a new attack. The paroxysm recommences with the usual symptoms, and the night is passed nearly as the former; but the sleep is more perfect, and productive of more relief. The third day the remission is more complete, there is some additional expectoration, and bodily motion is performed with less distress, but still with great inconvenience. After the paroxysm has been renewed in this manner for three nights, the expectoration generally becomes free; but there is no certain termination of the fit at a fixed period. However, except in particular cases, it goes off after a few days; and as the daily remissions become more perfect, the urine is higher coloured, and in smaller quantities: the expectorated mucus is more copious and digested; strength of pulse and vigour of action increase; and good-humour again enlivens the mind."—(*Bree, Inquiry*, &c., sect. iv., p. 48.)

In treating asthma, our attention must be

directed to the paroxysm itself, and to the nature of the constitution after the paroxysm has ceased; and even during the paroxysm, to the character of the particular species under which the disease shows itself.*

Dr. Cullen, who, as we have already seen, regarded plethora and turgescence of the blood-vessels as the usual cause, recommends blood-letting in the first attack, and especially in young persons; with the use of acids and neutral salts, as employed by Sir John Floyer, for the purpose of taking off the congestion of the blood. Nevertheless, bleeding demands a nice discrimination, and is rarely to be recommended in either species. The relief it affords, even in dry or convulsive asthma, is very temporary; and Dr. Cullen allows that it cannot be persevered in without undermining the constitution, and laying a foundation for dropsy.

Dr. Bree regards it as a doubtful operation in the first species, or that, to adopt his own language, produced by aerial irritation, and as always imprudent in the second. In this last, "I have repeatedly," says he, "directed it; but I have never had reason to think that the paroxysm was shortened an hour by the loss of blood: and I have often been convinced that the expectation was delayed, and that more dyspnea remained in the intermission, than was common after former paroxysms. In old people, who have been long used to the disorder, it is certainly injurious."†

Purging, beyond the intention of keeping the bowels regularly open, has seldom proved beneficial. When, indeed, the disease is secondary, and depends evidently upon an overloaded liver or stomach, or some suppressed evacuation, active cathartics, and especially such as operate simply, will be of great use: and the increased action excited in the alvine canal will often take off the irregular action in the chest; but where the asthma is idiopathic, and especially where the constitution is infirm, as in old age, a powerful alvine irritation will exacerbate the spasm of the chest, instead of diminishing it.

* "The treatment of asthma, like that of all periodical diseases, consists of two parts; that proper in the paroxysm, and that in the interval."—(Forbes, in *Cyclop. of Pract. Med.*, art. *ASTHMA*.) As the same physician justly observes, when the treatment of asthma is spoken of, that of its chronic forms is generally signified; for what is called acute asthma is either a variety of bronchitis, or a violent congestion of the pulmonary mucous membrane, both cases requiring to be treated on principles applicable to such pathological states, with little regard to the spasm which complicates it. These are truths to which all practitioners must subscribe.—*Ed.*

† Inquiry, &c., p. 245. According to Dr. Forbes (*Cyclop. of Pract. Med.*), it never puts an end to the paroxysm, much less does it cure the disease; and its habitual employment, in an affection of frequent recurrence, cannot fail to be highly injurious. It is indicated in the early attacks of young and robust subjects; in cases of great general plethora; in fits of great violence, in which the pulmonary circulation is much impeded, and the brain, or other important organs, are likely to suffer in consequence.—*Ed.*

In exciting nausea or vomiting, however, we may be less cautious; for each has been found highly advantageous in both species of idiopathic asthma. The first, by diminishing generally the living power, and hereby relaxing the convulsive action; and the second, by changing the seat of the convulsive action, and at the same time determining to the surface. [This practice has the sanction of Riverius, Akenside, Sir John Floyer, and Laennec, who says, that it acts on the nervous system, and is often followed by an immediate alleviation of the paroxysm.*]

Blistering may also be made use of, but, like setons or issues, can only be of ulterior advantage, for the fit must be of far more than ordinary length if it continue till the blister has produced vesication. It may, however, go far to prevent or shorten a relapse on the ensuing night; and especially when the disease is connected with an asthmatic habit.

Sir John Floyer is said, during his residence at Lichfield, to have found great benefit in his own case by the use of very strong coffee. And the practice was afterward followed by Sir John Pringle, as he informs us, with equal success. "On reading the section on coffee, in the second volume of your *Essays*," says he, in a letter to Dr. Percival, "one quality occurred to me, which I had observed of that liquor, confirming what you had said of its sedative powers. It is the best abater of the periodic asthma that I have seen. The coffee ought to be of the best Mocha, newly burnt, and made very strong, immediately after grinding it. I have commonly ordered an ounce for one dish, which is to be repeated fresh after the interval of a quarter or half an hour, and which I direct to be taken without milk or sugar."

Sedatives and antispasmodics, given alone, have rarely been attended with any decisive advantage. They have occasionally afforded relief in the first species, but have had little effect in the second; and, by heating the system unnecessarily, have often augmented and prolonged the paroxysm. Dr. Bree, in relating his own case, which was that of humid asthma, tells us, that, in the access of a paroxysm, he took four grains of solid opium, which produced nearly an apoplectic stupor for two days. A few hours after trying the opium, a most debilitating sickness supervened, with incessant efforts to puke. The labour of the respiratory muscles abated, but the wheezing evidently increased, accompanied with an intense headache and a

* Laennec on Diseases of the Chest, &c., p. 418, 2d edit. Dr. Forbes approves of a dose of ipecacuanha when the paroxysm supervenes to a full meal, or occurs in a person having an habitually sluggish and loaded stomach; but he does not consider emetics generally useful. (*Cyclop. of Pract. Med.*) Akenside's practice consisted in giving ℥j. of ipecacuanha in the paroxysm to induce vomiting, which, he assures us, gave great relief; and, in the intervals, he gave gr. v. every morning, or gr. x. every alternate morning, these doses proving equally useful, whether they excited vomiting or merely nausea.—*Med. Trans.*, vol. i.

countenance more turgid than usual; the pulse being at first strong and quick, and afterward sinking into great weakness. The paroxysm showed itself four hours earlier than usual the next day. He tried it in smaller doses during several subsequent fits, but in no instance without great general mischief, and with little or no local benefit.*

Much of this deleterious effect may have depended on idiosyncrasy. Sedatives and narcotics, if employed at all, should be combined with diaphoretics. In this form, they often prove a very powerful remedy: and one of the best preparations of this kind is the compound powder of ipecacuanha. A universal glow and diapnoë, as it has been called, or breathing moisture on the surface, are among the most favourable symptoms of the disease, under whatever form it makes its appearance. Antispasmodics and narcotics, as musk, castor, valerian, cardamine, camphire, and the fetid gums, may, perhaps, be employed successfully when the disease is chiefly dependant upon a morbid habit; but even here they will derive a great advantage from a union with diaphoretics, as the neutral salts, and small doses of ipecacuanha, or antimonial powder.

The hyoscyamus has often succeeded, as a narcotic, where opium has failed: but, like the latter, it should not be trusted to by itself in either species of the complaint.

[Laennec conceives, that narcotics may act, not merely by lessening the necessity of respiration, but also by overcoming the spasm of the lungs. The following, he says, have been particularly approved of: opium, belladonna, phellandrium aquaticum, aconitum, napellus, colchicum, tobacco smoked or taken internally, cicuta, dulcamara, hyoscyamus, and the smoking of stramonium. The cases in which he particularly recommends narcotics, are those seemingly attended with an extraordinary necessity for respiration, and a spasm of the lungs.

Besides narcotics, certain substances which act powerfully on the stomach, or nervous system, have been tried, as the distilled water of lauro-cerasus, the nux vomica, tincture of cantharides, the arsenical solution, and the prussic acid. Laennec found the laurel-cherry water and diluted prussic acid ease the breathing, though less certainly than narcotics. The same, he says, is true of the nitric, sulphuric, and acetic ethers.—(Op. cit., p. 416, 417.) With respect to the lobelia inflata, so much commended in America (*Eberle's Mat. Med.*, Philadelphia, 1822; *Dr. Andrew, Glasgow Journ.*, vol. i.), Dr. Forbes has found it temporarily

successful in certain spurious cases, produced by hydrothorax and disease of the heart; and even in the catarrhal asthma, he has known it check the paroxysm, if given at the commencement of the attack; yet he estimates its claim to efficacy below that of stramonium.

Where the urine is small in quantity, and of a pale hue, and particularly where the disease is connected with a pituitous or phlegmatic habit, diuretics have been found serviceable. Dr. Ferriar combined them with opium.

But as there is no discharge that promises such direct benefit as that from the excretories of the bronchial vessels themselves, so is there no tribe of medicines on which we can place so much dependance as the expectorants, when judiciously selected and administered. In every kind of idiopathic asthma, these may be employed with advantage.

Among the fetid gums which have been employed for this purpose, ammoniac has acquired the greatest degree of popularity: but, its power is inferior to that of asafoetida, the virtue of which is to be judged of by the degree of its offensive odour. Both these, however, are apt to be too heating, except in very flaccid and phlegmatic habits; and it will hence be often necessary to soften their pungency by a saline medium, taking care not to irritate the bowels unduly. And where there is a considerable degree of irritability and much quickness of pulse, we may prefer several of the oleraceous, and especially the mucilaginous demulcents: but oily demulcents are always to be avoided.

Of all the medicines, however, which act on the excrements of the lungs, the squill is the most to be depended upon. It is indeed a stimulant of the excrement system generally; for there is no part of this system capable of resisting its power: and it is hence necessary to watch its effects upon the kidneys and intestinal canal, and to attempt it with opium or some other guard, if it produce much influence in either of these ways; except, indeed, in the case of asthma connected with the phlegmatic habit, which is the only modification of the disease in which this collateral influence is found to be of advantage. Squills have also a peculiar tendency to stimulate the stomach, and produce nausea or vomiting; and it rarely shows much of an expectorating power till it has occasioned the former. But as these are advantageous to the disease in both species, and especially in humid asthma, we are not to discontinue it on this account, but only to moderate its use. Many practitioners, indeed, employ it directly as an emetic medicine, and prefer it to ipecacuanha. In asthma it may, in some habits, be allowed to supersede it; but in no other disease that I recollect; for it is rougher in its action, and more offensive in its taste.

Where, however, the lungs seem to be affected only secondarily, and the source of the disease lies in an infarcted and torpid state of the liver or some other abdominal organ, squills, and indeed expectorants in general,

* Many cases of asthma being connected with a state of the bronchial membrane, analogous to inflammation, do not seem likely to admit of benefit from narcotics. Hence, Dr. Forbes is of opinion, that it is only in cases of pure nervous asthma, or in those symptomatic dyspnoeas, simulating asthma, which depend on organic disease of the heart, &c., that opium and other narcotics and antispasmodics are at all likely to prove useful. In the hysteric asthma, the good effects of opium were long ago recognised by Willis.—See Cyclop. of Pract. Med., art. АСТМА.—ED.

will be found less serviceable, than in idiopathic cases. And hence we should prefer the seneka-root, which has often been found of great success, after calomel, or whatever other cathartic may be judged most proper, has been previously made use of. Seneka-root, indeed, is in itself a sort of general evacuant; for while it increases very largely the discharge of mucus, it increases also the flow of perspiration and urine, and sometimes acts as an emetic and purgative.

There is a tribe of medicines, which are also found of essential benefit in many cases of both species of asthma, but, with whose mode of action we are so little acquainted, that it has been explained on very different principles by different pathologists; I mean the acids, both mineral and vegetable. These principles we have not room to examine; nor is it necessary; since, if they be really beneficial, it is of little moment whether they act as sedatives in allaying irritation, or as tonics in invigorating the relaxed bronchial exhalants. The vegetable seem more efficacious than the mineral acids, probably because, in consequence of their being less corrosive, the patient can take them in larger quantity; and the vegetable acids obtained by fermentation, seem more useful than the native.

Yet these have rarely been given alone; for, by uniting them with diaphoretics, as small doses of ipecacuanha, or with narcotics, the remedial power of each has been augmented; and the latter are not only rendered more efficacious, but are borne with less mischief afterward. Sir John Floyer was in the habit of uniting the acetous acid with squills, and hence, indeed, the popularity which the vinegar of squills has preserved to the present day. Dr. Bree has employed both the vegetable and the mineral acids, but always in union with some other preparation. Thus in humid asthma, after emetics, he prescribes a draught composed of an ounce of distilled vinegar, and from one to three grains of ipecacuanha, in a sufficient quantity of pure water, to be taken every four hours, as a means of determining to the surface of the body, and of promoting absorption and exhalation. And as a means of taking off irritation and exciting the secretions of the bronchiæ, it may be also employed in nervous or dry asthma, and often with as good effect.

In like manner, Dr. Bree has made use of the nitric acid in union with squills and extract of henbane; giving three grains of the henbane with six minims of the acid and ten of tincture of squills in the form of a draught, and repeating it every three or four hours during the paroxysm. And he tells us that "Many patients, who had taken the most powerful antispasmodics, have assured me, that none had been so useful; and two gentlemen now under my direction inform me, that it is the only medicine that has ever given them relief in the paroxysms."—(*Inquiry*, &c., p. 285.) I cannot say that I have found it thus pre-eminently serviceable; but it has often been of decided benefit. And I know of no medicine that suc-

Vol. I.—T

ceeds so well in preventing the mischievous effects of opium, and even in adding to its sedative power; or that is so valuable an adjunct in almost all antispasmodic preparations, and especially where ether, camphire, and other terebinthines are employed; or that tends so effectually to take off all excess of pungency from the more heating expectorants.

As simple relaxants are always hurtful in this disease, and only add to the debility, it is not to be wondered at that warm bathing should be also injurious. Cold bathing, as a tonic between the intervals, has much more to be said in its favour. Dr. Bree tried it in his own person, but did not obtain success. His was a case of humid asthma. But in the first species, and particularly where habit has given inveteracy to the recurrence of the paroxysms, and where the general constitution is vigorous, there is no single remedy likely to be of more value.

[In Dr. Wilson Philip's "Inquiry into the Laws of the Vital Functions," will be found various observations, tending to prove the utility of galvanism in one form of asthma.]

Wherever asthma may be supposed to be dependant upon plethora, tonics can have no claim to be employed till after such a condition has been removed; and then, perhaps, the best medicine will be the mineral acids.

[When the asthmatic paroxysms have a strongly-marked periodical character, cinchona, according to Laennec, frequently diminishes their severity, and sometimes stops them altogether.]

Peruvian bark is often found to overload the stomach, especially in dyspeptic patients, with whom I have found columbo agree better, occasionally combined with carbonate of soda.* But the best tonics are the metallic oxydes, [and of these the subcarbonate of iron, given in doses from a scruple to a drachm, is praised by Dr. Bree and Laennec. The latter speaks particularly of its benefit in pallid relaxed habits, and both in the dry asthma and the nervous.—(*On Diseases of the Chest*, &c., p. 418.)]

Inhalations cannot well be tried during the paroxysms, but they have been very generally had recourse to in the intervals, and have consisted of very different vapours. When pneumatic medicine was at the height of its popularity, much benefit was supposed to be derived from the use of oxygen and hydrogen, and dilute chlorine gases. Dr. Beddoes was peculiarly attached to the former, and thus describes its effects with his constitutional warmth of expression;—"No sooner does it touch the lungs, than the livid colour of the countenance disappears, the laborious respiration ceases, and the functions of all the thoracic organs go on easily and pleasantly again." Yet, with all this high recommendation, few patients choose

* Dr. Forbes believes that bark possesses no specific powers in checking the return of the common asthmatic paroxysm; but, that it occasionally acts beneficially in two classes of cases; first, when the asthma is complicated with ague; and secondly, when the stomach or general system is in a state in which a tonic of this kind is beneficial.—*Ed.*

to be cured in this manner in the present day ; oxygen gas is now rarely adverted to by asthmatics or their medical attendants ; and the remedy, from having been extolled beyond its proper level, has fallen back into an unmerited disregard. Dr. Ferriar has spoken in more sober terms of the benefit of hydrogen in the first species ; and I am induced to believe that a long perseverance in the use of this gas may often produce the effects he has ascribed to it ; but it is rarely that I have seen it so decidedly useful as to ascribe the patient's recovery to this remedy, rather than to other means he had been employing at the same time.

Warm aromatic fumes have been also tried ; as prophylactics, obtained from various substances. The smoking of tobacco has very extensively been recommended ; the leaves of the *scandix odorata* were at one time in still higher repute ; but both have of late years given way to those of the *datura stramonium*, or thorn-apple. Most of these contain a narcotic power, and whatever benefit they produce is hence, perhaps, chiefly derived ; but either this narcotic power, or the stimulating power with which it is so intimately united, has at times been found to bring on a difficulty of swallowing.

Another process has lately been adopted in France, but of the issue of which we have not yet received any satisfactory information. It consists in a revival of the impregnated aqueous injections of Stephen Hales (*Hæmostatics*, ii., 74, 75), with a view of determining how far such impregnating materials may reach the lungs and be thrown off by the bronchial exhalants. Magendie (*Physiologie*, tom. ii., p. 291) and Nysten have been chiefly engaged in these researches, and they have ascertained that alcohol, ether, camphire, and most of the other volatile antispasmodics, together with the gases, are in this manner conveyed to the lungs, and transpire from the surface of their air-cells.

Issues, setons, and even cauteries, have been long in repute as useful drains or revellents ; and under this character, are highly successful in the relief of asthma. And where the disease has appeared upon a sudden check of the cutaneous eruption, or a sudden cessation of any habitual evacuation, I can unite in this recommendation of Macbride (*Med. Observ. and Inq.*, vol. vi., art. ii.) and Reidlin.—(*Lin. Med.*, 1695, p. 91.) Issues to this end, and, indeed, for all others, are most conveniently kept open, and produce the most salutary irritations, by small pieces of the bark of spurge-laurel, or mezereum, both of which contain a very acrid matter ; and the latter of which, more especially, has for this purpose been very generally employed in France, under the name of *écorce de Garou*.—(*Essai sur l'Usage et les Effets de l'Écorce de Garou*, par M. Archange le Noi, Paris, 1767.) A lady, between fifty and sixty years of age, whom I have long been in the habit of attending, had several very severe fits of asthma, about three years ago, at the distance of ten days or a fortnight from each other. I discovered that she had been formerly

subject, though at irregular periods, to slight bleedings from the hemorrhoidal vessels, which, for some months, had ceased to be renewed. With a view of exciting a vicarious action, I opened an issue in one of the arms, and irritated the rectum by small doses of aloetic cathartics. The issue discharged copiously for six weeks, during which time the patient continued free from all attack : I then suffered it to heal slowly, still continuing the aloes ; and about a month afterward was informed, that the habitual discharge had returned. She had no paroxysm after this for upwards of two years.

Pontifex relates a case, in which a corpulent asthmatic patient, who suffered severely from frequent fits of this disease, was accidentally infected with the itch. As the eruption extended, his breathing became every day more easy ; and, from the time that the contagion took place, he had no return of a paroxysm whatever. He was then desirous of being cured of the itch, and, for this purpose, went for several days successively into a cold bath. The eruption was hereby repelled ; but he was immediately attacked with an asthmatic fit, which returned twice within the space of a month. M. Pontifex advised him to have recourse to his former cure, by using the bed-clothes of one infected with the itch. This advice he followed ; a few days after which the scabid eruption made its appearance, when he was again perfectly liberated from his asthma.*

The diet should be light and cordial, without being stimulant, and the food be of a solid, rather than of a liquid kind. All flatulent fruits and vegetables should be avoided ; but oranges, the alliaceous esculents, and the aromata may be allowed in moderation. Hot liquors should be sedulously abstained from ; and the beverage consist chiefly of coffee, ginger-tea, and acidulated waters.

Where asthma is dependant upon some primary affection of another kind, it can only be effectually treated by removing, or palliating, the original disorder.†

* Recueil d'Obs. de Médecine des Hôpitaux Militaires, par M. Richard de Hautesierck, &c., tom. ii., 4to., Paris, 1774.

† The most recent pathological views of this disorder sustain the opinion that its dominant cause is often an emphysematous condition of the lungs. In regard to the treatment of this disease, regard must always be paid to the doctrines of plethora. Several American writers, as Thatcher, Eberle, and others, agree as to the value of the *datura stramonium* in lessening the violence of the paroxysms of asthma. Very lately, an ointment, made from veratria, has been used with great success against neuralgic irritation and spasmodic distress, and in controlling difficult respiration, accompanied with cough : clinical results may prove veratria to be efficacious in the treatment of asthma.—See Turnbull, on the External Application of Veratria. As asthma appears in paroxysms, much may be done in the way of preventing its attacks. For this purpose, cold bathing and cold affusions, and a strict attention to diet, will be found very beneficial. Finally, in many cases, where remedies are of little avail, a change of air and scene will often relieve the patient.—D.

GENUS V.
EPHIALTES.
INCUBUS.

SIGHING, SUFFOCATIVE ANHELATION, WITH INTERCEPTED UTTERANCE, AND A SENSE OF SOME EXTERNAL WEIGHT PRESSING HEAVILY ON THE CHEST; TRANSITORY.

EPHIALTES, incubus, nightmare, which are the common names in Greek, Latin, and English, for the present genus of diseases, though not exactly of the same meaning, import a sudden sense of an oppressive and suffocative weight on the chest, threatening strangulation, and rendering the person attacked incapable of changing his position. Ephialtes, from ἐπάλ-λαμαι, signifies "to leap upon;" incubus, from incubo, "to lie upon;" and the term *mare*, in our compound nightmare, inbodies the looser idea contained in the Greek and Latin denominations, and signifies a hag, goblin, demon, or spectre; as though the oppressive weight were occasioned by some such hideous monster's abruptly leaping or lying on the chest; whence our old Anglo-Saxon name for the disease, *Elf-sidenne*, or elf-squatting; which is as significant as any of them.

The character of the genus will be found sufficiently expressed in the foregoing definition.

If the generic definition be correct, as I trust it is, there can be no doubt that ephialtes belongs to, or should be ranged in close connexion with, the family of anhelations, under which it was usually classed by the earlier writers; and, indeed, continued to be so till the time of Dr. Cullen, who has strangely removed it to that of *vesania*, or mental derangements, putting it immediately after mania; reducing it from a generic to a specific station; and as singularly uniting it with *sleep-walking*, with which it has little or no connexion in cause or symptoms, as will be sufficiently obvious from comparing the account about to be given of the one disease with that of the other.

The history of the affection will easily lead us to the nature of its production. It appears most frequently in persons of an irritable or nervous temperament, and of a weakly constitution; particularly among those who are predisposed to hypochondriasis or low spirits. Others, indeed, are occasionally affected by it, but more rarely, and perhaps in a less degree. It usually, though not always, occurs in the night, during a reclined position, and after great fatigue of body or mind, or a stomach disordered by indigestible food, or food taken in excess.

Although, therefore, the symptoms of this complaint are to be taken from the actual state of the muscles and other organs of respiration, the exciting cause is to be ascribed, for the most part, to the actual state of the stomach, or the sensorium, or both:—more generally, indeed, to both, as the brain and the stomach are so much in the habit of associating in the same action.

Yet how comes it that the organs of respiration should be thus singularly affected by the state of the stomach and the sensorium, and

chiefly so in the night, rather than in the day? The solution of the question may be found in the reasons we have already offered, why the paroxysms of asthma, or of exacerbating dyspnoea, should mostly recur under similar circumstances, and at the same period.

Respiration is a semi-voluntary action. In firm health, the will, indeed, is seldom applied to for its aid: but the moment the moving powers of the chest labour under any degree of debility, the will instantly interferes, and by its stimulus compensates for the deficient energy.

Something like this applies to the state of the stomach, during the process of digestion. In healthful digestion, the ordinary action of the stomach is equal to its own demand: but the moment it labours under any degree of debility, or, in consequence of its being overloaded, or loaded with indigestible materials, its ordinary action is not sufficient, it becomes necessary that it should be supplied, not indeed by the will, but instinctively, or by the remedial aid of the living principle, with an additional flow of nervous energy to enable it to meet the excess of duty hereby imposed upon it.

The surplus of sensorial power, under such circumstances bestowed upon the stomach, is taken from the general supply to the system at large, as from a common stock; every organ contributing its proportion, and among others, the lungs. And if this demand, on the part of a feeble or overloaded stomach, should occur in a system, in which the general weakness of the respiratory organs is considerable; if it should take place in a recumbent position, in which they have, at all times, less power of action than in an upright posture; and if, moreover, it should be exhibited during sleep, in which the will itself, and most, sometimes indeed all, of the faculties of the mind are in a state of suspension, from a cause I shall hereafter have occasion to explain; almost every thing will co-operate to impede respiration, to lower the tone of the respiratory muscles, and consequently to excite in them irregular and spasmodic action; in one word, to lay a foundation for all the symptoms which characterize ephialtes: the mind, sympathetically disturbed and hurried in the midst of sleep, imaging to itself, at the moment, from the terrible sensation induced, as terrible a cause for its production, and giving full credulity to the presence of a huge and hideous spectre, tyrannically squatted upon the chest, and striving to take away the breath.

Now, in reverie, the will, as indeed all the faculties of the mind, may be as abstracted during the day, as they are suspended in sleep during the night: and from the peculiar strength and vivacity of the train of ideas or mental emotions that constitute the reverie, the same sudden exhaustion may take place, and the same inordinate demand upon the common stock of sensorial power, distributed throughout the system at large, may be made upon every organ acting under a common bond of sympathy, as we have just contemplated during the influence of sleep. And the respiratory organs being

thus, in the same manner, mulcted of a part of their ordinary influx of nervous power, the same complaint may take place in the one period as in the other; though, the body not being recumbent in the day, the lungs will not sustain so violent a struggle; and the intellect, from its being less passive than in sleep, not so strongly imposed upon. [Although the foregoing hypothesis, respecting the cause of incubus, displays much ingenuity, the editor need scarcely observe, that what is stated amounts to nothing more than conjecture, liable to the very same objections which have subverted most other theories on the subject. Were it true, hardly any dyspeptic person with weak lungs, who eats too freely, could ever escape an attack of nightmare after going to bed.

Yet this is quite repugnant to common experience. The disorder has sometimes been imagined to proceed from a stagnation of the blood in the sinuses of the brain, or in the vessels of the lungs, or from too great a determination of blood to the head. The horizontal posture during sleep, and the pressure of the stomach upon the aorta in a supine position, have been fancied to be sufficient to produce an unusual distention of the vessels of the brain; while, by others, the weight of the heart pressing on the left auricle and large pulmonary veins, has been suspected to produce the oppression and sense of weight and suffocation in the breast.—(See *Bond, on Incubus*, 1753.) As Dr. Whytt has observed (*On Nervous Disorders*, chap. 6), however, if these opinions were true, every person that lies upon his back, especially after a full meal, ought to suffer a degree of nightmare. Dr. Bateman considered it probable, that the seat of nightmare was chiefly in the stomach. The sympathy of this organ with the head, heart, lungs, and diaphragm, he says, is so remarkable, that there can be no difficulty in referring the several symptoms of incubus to a disagreeable irritation of the nerves of the stomach. A heavy or flatulent supper undoubtedly aggravates the nightmare in persons predisposed to it. Persons are mostly attacked while lying upon their back, because in this position the viscera make greater pressure on the diaphragm, and inspiration is less easy. The nightmare takes place only in sleep, because the strange ideas excited in the mind, in consequence of the disordered feelings of the stomach, are not then corrected by the external senses; nor do we then, by an increased respiration, or other motions of the body, endeavour to shake off any beginning uneasiness about the stomach or breast. The nightmare generally occurs in the first sleep, and seldom towards the morning, because at the earlier period the stomach is more loaded with food, and digestion is less advanced. It may be remarked, however, that neither a horizontal posture, sleep, nor heavy suppers ever produce the nightmare, at least, in any considerable degree, unless the person be already predisposed to the complaint by the particular condition of the nerves of the stomach. As far as practical considerations are concerned, there may not be

any very important difference between our author's views and those of Drs. Whytt and Bateman, since he represents the imposition of too much work on the stomach as the exciting cause. And it is only in his *rationale*, that he lets his imagination take a random flight. With respect to his hypothesis of the cause of the daymare, it may be noticed, that the case which he has inserted as an illustration of it, could not be connected with rcvery or abstraction of the mind, as it always took place suddenly, and at regular periods. Be this as it may, our author describes the two following species of the affection:]

- | | |
|---------------------------|------------|
| 1. Ephialtes Vigilantium. | Daymare. |
| 2. ——— Nocturnus. | Nightmare. |

SPECIES I. EPHIALTES VIGILANTIUM. DAYMARE.

PRODUCED DURING WAKEFULNESS; THE PRESSURE SEVERE, AND EXTENDING OVER THE ABDOMEN; RESPIRATION FREQUENT, LABORIOUS, CONSTRICTED; EYES FIXED; SIGHING DEEP AND VIOLENT; INTELLECT UNDISTURBED.

This species is less frequently described by pathological writers than the ephialtes of the night season. Rhodius (Cent i., observ. 54.) however, Forestus (Lib. x., obs. 52), and Sauvages (Class v., ord. i., *Anhelationes Spasmodica*, gen. i.), have distinctly marked it; and a striking example of it occurred some years ago in my own practice.

Forestus gives a case that returned periodically every third day, like an intermittent fever. The patient was a girl nine years of age, and, at these times, was suddenly attacked with great terror, a constriction of both the upper and lower belly, with urgent difficulty of breathing. Her eyes continued open, and were permanently turned to one spot; with her hands she forcibly grasped hold of things, that she might breathe the more easily. When spoken to, she returned no answer. In the meantime, the mind seemed to be collected; she was without sleep; sighed repeatedly; the abdomen was elevated, the thorax still violently constricted, and oppressed with laborious respiration and heavy panting; she was incapable of utterance.

This case seems to be founded upon a highly irritable or spastic diathesis, and makes some approach towards ecstasis and catalepsy; but, with that intolerable weight on the chest which peculiarly marks ephialtes. No exciting cause is stated. A predisposing cause I have already hinted at, and shall briefly advert to the treatment under the ensuing species.

SPECIES II. EPHIALTES NOCTURNUS. NIGHTMARE.

PRODUCED DURING SLEEP, AND INTERRUPTING IT WITH VIOLENT STRUGGLE AND TREMOR: THE PRESSURE ON THE CHEST SEEMING TO

BE THAT OF SOME HIDEOUS MONSTER, OR PHANTOM.

THE sensation is said to be frequently preceded by some fearful dream, as that of an implacable enemy, known or unknown, in close pursuit of the dreamer, from whose grasp he feels incapable of escaping; or of exposure to some overwhelming danger by sea or land, as that of falling from a steep precipice; or struggling, amid the ruins of a shipwreck, with rocks and breakers that threaten to dash him to pieces every moment. This I believe is often the case; and particularly when the state of the brain, rather than that of the stomach, forms the exciting cause.

The attack, however, appears to be sometimes slighter, and unaccompanied with such fearful scenes of desperate adventure, or the machinery of hideous and appalling demons or monsters; for Fortis gives the case of a young woman, who, during the paroxysm, supposed herself to be pressed upon by a man who was very far from being disagreeable to her; yet awoke from this imaginary concubinage with the usual sense of oppression, the voice and breath interrupted, great anxiety, and the face covered with sweat.—(*Sauv. Nosol.*, Meth. i., 631.) And similar cases, according to Craanen, Heurnius, and Forestus, have occurred to men as well as to women. While we are told by Pliny, that the oppression, in his day, was ascribed to the sports of fauns, an idea rather pleasing than hateful to the imagination; and that the disease was hence denominated faungambols, *ludibria fauni*.

The treatment may be stated in a few words. The mind and body should be kept free from all undue fatigue and commotion, and the diet be light, especially towards the evening. The action of the bowels should be kept regular; and, perhaps, as Dr. Darwin recommends, a mattress or harder bed than usual should be used, and an alarm clock hung up in the room, so that the sleep may be interrupted at short intervals. [The patient should sleep with his head raised on high pillows, and lie on his side. If the functions of the stomach be much disordered, the directions already given for the relief of dyspepsy and other affections of this organ should be followed.] These plans will supersede the use of the feeble medicines which were formerly in vogue for the cure of nightmare, as saffron and peony, and will render superfluous all further inquiry into a subject which once exercised the pen of the learned, whether the latter was or was not a specific in the form of an amulet.

GENUS VI.

STERNALGIA.

SUFFOCATIVE BREAST-PANG.

VIOLENT PAIN ABOUT THE STERNUM, EXTENDING TOWARDS THE ARMS; ANXIETY, DIFFICULTY OF BREATHING, AND SENSE OF SUFFOCATION.

THIS disease is described by modern writers under the names of *angina pectoris*, *syncope*

anginosa, *asthma dolorificum* or *arthriticum*, *orthopnea cardiaca*, and various others of a similar import, that clearly discover its relationship to the genera which have just passed in review before us. It has characters, however, sufficiently marked to separate it from all of them, and particularly from those under which it has hitherto been ranked as a species or subdivision. And I have, in consequence, been under the necessity of giving it a new denomination, as well as of assigning it a new place: and hence the above name of STERNALGIA (ΣΤΕΡΝΑΛΓΙΑ); a compound importing "pain about the sternum," which is a striking pathognomonic symptom, if not the leading feature of the affection. It is here it differs essentially from syncope and asthma, neither of which terms, therefore, ought to have been appropriated to it; while it has still less connexion with angina, in its common sense of quinsy, although this is the name by which, from the time of Dr. Heberden, it has been most frequently denominated.

M. Brera, an Italian physician of deserved eminence, but whose work (*Della Sternocardia*, Verona, 1810) the author was unacquainted with till after the first edition of the present, has entitled it *sternocardia*, and M. Portal has preferred this term to *angina pectoris*. Its chief objection is a derivation from two distinct organs, as the seat of disease.

The genus offers us two species:—

1. Sternalgia Ambulans— Acute Breast-pang.
tium.
2. ——— Chronica. Chronic Breast-pang.

SPECIES I.

STERNALGIA AMBULANTIUM.

ACUTE BREAST-PANG.

SUPERVENING SUDDENLY DURING EXERCISE; WITH TENDENCY TO SYNCOPE: RELIEVED BY REST.

It is singular that there is no description which will fairly apply to this genus under either of its species, in any of the writings of the Greek, Roman, or Arabian authors that have descended to us. Some few passages have been quoted as possibly referring to it; but, on examination, they will be found too general for the purpose, or evidently intended for some other affection. Such particularly is the *asthma pneumodes* of Aretæus, referred to by Svediaur, who has distinguished the disease in his Nosology by the name of *pniogophobia*. And hence, considering the minuteness with which many of the writers thus adverted to have followed up all the morbid affections of the human frame, and the accuracy with which they have described them, the most reasonable conclusion is, that, like rickets and several other diseases, it was not known to them, or, in other words, was not in existence.

The first glances at it which we are anywhere capable of tracing, are to be met with occasionally in the works of Morgagni (see especially *Epist.* xxiii., art. 8, 9), and somewhat

more distinctly in the *Consultationes Medicae* of Hoffmann. Dr. Letherland has followed up the inquiry with a curious spirit of research in the Edinburgh Medical Commentaries (vol. iii., p. 180), and has quoted a passage from the works of Poter, which renders it highly probable that this writer was well acquainted with, at least, the first species of the genus, and was aware of its being often fatal. Poter's description of the disease is as follows:—"Respirandi difficultas quæ per intervalla deambulantibus incidit; sic ut plurimum derepente moriuntur."—(*Poterii Op.*, Cent. 3, No. 22.) But it is to the late Dr. Heberden that we are indebted for the first full and perspicuous account of sternalgia, or, as he calls it, *angina pectoris*.—(See *Med. Trans.*, vols. ii. and iii.)

Dr. Cullen has not noticed the complaint, either in his Nosology or in his First Lines; but he has entered it with the unsatisfactory name of *angina pectoris* in his "Catalogue of Omitted Diseases."

It has, however, been minutely described and well illustrated, both historically and practically, by many modern writers of established reputation, as Dr. Fothergill, Dr. Duncan, Dr. Percival, Dr. Darwin, Dr. Macbride, Dr. Hamilton, Dr. Haygarth, and Dr. Parry, most of whom have accompanied their descriptions with a speculative inquiry into the causes of the complaint.

Sternalgia rarely attacks the young, or those who are under five-and-forty or fifty years of age. Persons with short necks, inclined to corpulence, or of a gouty temperament, and especially when indulging a sedative life, are peculiarly predisposed to it. The form it first assumes is commonly that of the present species, by far the most severe, and, as Poter correctly observes, the most frequently fatal: for when the constitution has been for some time habituated to the paroxysms, though it often becomes greatly debilitated by them, and the paroxysms themselves increase in duration, it passes through the attack with less violence and immediate danger.

The incipient assault is usually felt while the patient is walking, and especially if he happen to be walking soon after eating, or during the process of digestion. He complains of a new and painful sensation in his breast, spreading up to his arms. At first, perhaps, this extends no farther than to the insertion of the deltoid muscle, and more commonly on the left side than on the right; but it soon winds its way to the elbow, wrist, and fingers' ends. In this incipient state, he sometimes loses the pain suddenly and entirely by merely standing still. Yet it rarely continues more than from half an hour to an hour, even under its most severe assault, and where it proves fatal. There is sometimes connected with it a strong feeling of flatulence at the stomach, with momentary ease on eructation. The face, moreover, is often pale, and the body bathed in perspiration.

Whatever exercise the person is engaged in when the paroxysm attacks him, he feels that a perseverance in it would produce a total suspension of living power; and hence, if he be walk-

ing, and especially against the wind, he turns from the wind and stands still; when, if the complaint be slight, and in its infancy, it soon vanishes.

In one instance, a patient thus attacked, and who was distinguished for great firmness of mind, had the resolution to continue walking, and found the pain go off after it had affected him from five to ten minutes.—(*Parry, Treatise on Angina Pectoris.*) If, by a like degree of courageous effort, the patient, in struggling for breath, be able to overcome the constriction, he will continue able through the remainder of the fit to make a deep inspiration, though accompanied perhaps with sighing and some difficulty of expiring his breath. In other instances, however, an equal degree of firmness has been exerted in vain. In most cases, the pulse, during this contest, varies but little, yet it is sometimes quickened, and sometimes intermits; while, in a few instances, the heart palpitates considerably, though less so than in the chronic species.

A habit of return is soon induced after a few fits have paved the way; and when this is effected, the action of walking is not necessary for its production, for it will sometimes be brought on by the most trivial circumstances, as coughing, swallowing, going to stool, or a slight disturbance of the mind. And, in this case, the first species becomes converted into the second. "One," says Dr. Heberden (*Med. Trans.*, vol. ii., p. 61), "has told me that this complaint was greatest in winter; another, that it was aggravated by warm weather; in the rest, the seasons were not suspected of making any difference." The pulse is not only little affected, as already observed, during the paroxysm, but even in the intervals; being, for the most part, only a little quickened, and seldom exceeding eighty strokes in a minute; in one instance, even where the semilunar valves of the heart were afterward found ossified, and the ossification had extended to the aorta itself, the pulse, though small, never exhibited irregularity.—(*Med. Trans.*, vol. iii., p. 16.) Yet, in a few instances, I have found it not only irregular, but intermittent; and intermittent for some weeks after the paroxysm had ceased to return. In others, it has been strong and vibratory.

The cause is very obscure, and the more so as the disease has often been found in persons labouring under different sorts of structural derangement about the heart, or in one or more of the organs of respiration, to which it has been ascribed, as soon as such derangements have been discovered; while, in other cases, nothing of the kind seems to have existed. Thus, the cartilaginous portions of the ribs have sometimes appeared ossified on examination after death; sometimes the semilunar valves of the heart; and sometimes the coronary arteries: and hence Dr. Wall (*Med. Trans.*, vol. iii., art. ii.) has ascribed the disease to the first or second of these morbid changes, and Drs. Heberden and Parry to the third (*Treatise on the Syncope Anginosa*, commonly called *Angina Pectoris*), who have been followed by Burns

and Kreysig. Dr. Cuming found the heart itself double its natural size, with some kind of morbid change in several of the surrounding organs—(*Case of Diseased Heart, &c.*, *Dublin Reports*, vol. iii.) Dr. Haygarth, on one occasion, found the mediastinum in a state of suppurative inflammation, and has hence regarded this as the cause (*Med. Trans.*, vol. iii., art. vi.); while, as the pericardium has sometimes evinced concretions of blood, Dr. Hooper and others have referred the disease to this affection.—(*Mem. of the Med. Soc. of Lond.*, vol. i., p. 19, 21.) Dr. Hosack conceives (*Americ. Med. and Phil. Regist.*, vol. ii., p. 366), “that it most frequently arises from a plethoric state of the bloodvessels, more especially from a disproportionate accumulation of blood in the heart and large vessels;” an opinion more in accordance with the observation of Dr. John Forbes than any of the others.—(See note in *transl. of Laennec on Diseases of the Chest*, 2d edit., p. 692.) Dr. Darwin mentions it as a sort of asthma, producing a cramp of a peculiar kind in the diaphragm, or the other muscles of respiration; while a very large number of pathologists, among whom may be mentioned Elsner (*Abhandlung über die Brustbränne*, Königsburg), Bengel (*Algem. Deutsche Bibl.*, xxxvi., p. 125), Dr. Butler (*Treatise on the Disease commonly called Angina Pectoris*, London, 1791), and Dr. Macqueen (*London Medical Journal*, vol. v.), have endeavoured to account for it as a particular species of gout: and hence Dr. Berger attacked it with gum guaiacum, which, in his paper upon this subject in the *Copenhagen Transactions*, he asserts to have been particularly serviceable. Dr. Latham has, in various instances, found it in persons who, possessed of sound chests and apparently untainted constitutions (*Med. Trans.*, vol. iv., art. xvi.), were affected with enlargements of the abdominal viscera, or other diseases seated in these organs.*

That there is a violent and painful constriction of some of the muscles about the sternum during the existence of the paroxysm, and that respiration is hence greatly impeded, is unquestionable; and that many of the above misformations of structure, or constitutional habits, may occasion a predisposition to sternalgia, is highly probable; but they give us little or no information concerning the cause that immedi-

ately produces it; while it is by no means unlikely, that several of these morbid changes, thus brought forward as causes, are themselves only effects of so laborious and perilous a struggle. And hence we cannot, I am afraid, in our present defective knowledge of the physiology of the disease, do more than adopt the modest opinion of Dr. Bergius and Dr. Heberden, and regard it as dependant upon a cause that has not yet been traced out, but which does not seem to originate necessarily in any structural derangement of the organs affected.

The variable state of the pulse, and the occasional palpitation of the heart, are best accounted for by supposing some such structural disease as we have just seen occasionally exists there. Yet even these symptoms may depend upon the habit or idiosyncrasy, and appear to have occurred, in a few instances, in which dissection has discovered no such manifest local cause. So far as I have witnessed the disease, it has commenced in the respiratory muscles with a suffocative struggle, and tense constrictive pain: and it has not been till a minute or two afterward, and where the spastic action has extended in different directions, that the pulse has varied, or palpitation ensued: as though the primary seat of disease was in these muscles, and the heart was only affected secondarily.

[Laennec considers *angina pectoris* as a variety of neuralgia of the heart. The doctrine of the disease being always the effect of some organic affection of this viscus, he says, is far from being correct. He has known many individuals, who suffered a few very severe but short attacks of it, and then had no further return of it. On the other hand, he admits, that it frequently accompanies organic diseases of the heart. He has examined several subjects, whose cases were attended either with hypertrophy, or dilatation of the heart; but in none of these instances were the coronary arteries ossified. Andral relates a case, in which, after death, no appreciable morbid change was detected in the heart, but there were tubercles in the lungs. He takes the opportunity to observe, that the suspicion of *angina pectoris* being dependant upon an ossified state of the coronary arteries, is destitute of proof; and the disorder is set down by him as an impairment of, what he calls, the *innervation* of the heart.—(*Andral, Précis d'Anat. Pathol.*, tom. ii., p. 345.) Laennec conceives (*Op. cit.*, p. 690), that the site of the disorder may vary. When there is pain both in the heart and lungs, the affection may be chiefly situated in the pneumogastric nerve; when there is merely a sense of stricture in the heart, the disorder may be in the nervous filaments, which the heart receives from the great sympathetic nerve. Other nerves are also simultaneously affected by sympathy, or direct anastomosis.]

When the real nature of the disease is thus doubtful, and its causes thus obscure or variable, its best mode of treatment must be equally uncertain; and though I willingly join with Dr. Heberden in thinking, that we ought not to

* Dr. John Warren, of Boston, states (*New-England Journal*, vol. i., p. 11) that *angina pectoris* may probably be the effect of an incapacity of the heart to empty itself of blood (forced into it in an accelerated circulation) sufficiently fast to maintain the vital functions. Prof. Chapman, of Philadelphia, remarks, “that the disease is a species of neuralgia, we are entirely persuaded, commencing, for the most part, in the pneumogastric nerve, and spreading in different directions as other nerves may become involved. That it is, in many instances at least, derived from irregular gout, which, misplaced thus, operates as an irritant to the nerves, and probably first to those of the stomach, seems highly probable.”—See Hays’ *Cycloped. of Pract. Med. and Surgery*, Art. *Angina Pectoris*.—D.

despair of finding a cure, I am afraid we have not yet found it.

Where the temperament is plethoric, or the heart is evidently implicated in the affection, bleeding will often afford some relief. But, in the simplest cases of the complaint, where the pulse is little disturbed, and the heart without palpitation, the use of the lancet has proved injurious, rather than beneficial; and purging has been of as little avail. Antispasmodics and cordials, and especially wine, palliate the symptoms for a few minutes, but afterward lose their virtue.

The mode of treatment which I have found most successful consists in putting the patient immediately in an inclined, rather than a recumbent position, with his head raised high. He should instantly take an emetic of whatever may be given most expeditiously, though the antimonial preparations form the best medicine for this purpose, as producing a longer action. As soon as the patient rejects, he may be allowed a little warm water, administered to him sparingly. The diaphoresis, hereby induced, should be assisted by a moderate warmth of bedclothes, and particularly by placing the patient between blankets; and, if the constrictive pain or difficulty of respiration still outlast the sickness, opium, intermixed with ether, camphire, or other diffusible antispasmodics, should be employed pretty freely. And I may here observe, as a general rule, that, where the common forms of opium, as the extract, wine, or tincture, are found to affect the head, the Lancashire or Cheshire preparation of it, known by the name of *black drop*, which is a solution of this drug, in verjuice, with, apparently, 'some portion of rectified spirit, and, certainly, a liberal combination of aromatics, seems to have less tendency to excite nausea and headache afterward: and, from its being nearly double the strength of the ordinary laudanum, may be used in a much smaller quantity. Mr. Batley's well-known form will also, in many cases, succeed as well.*

But it is in the intervals of the fits that medical skill and ingenuity are likely to be most efficacious. If we find the complaint connected, as it often is, with a morbid diathesis of any kind, as that of gout, with the sudden suppression of any habitual discharge, as that of the hemorrhoidal vessels, or a chronic affection of any other organ, as the heart, the stomach, or the liver, our attention must be immediately directed to what may thus prove a predisposing cause, which we must endeavour to palliate or remove, according to the nature of the cause we may be fortunate enough to detect. The bowels, in the meantime, must be kept gently open, and a freedom from relapse be secured at night for a week or a fortnight by an opiate pill, or the extract of henbane.

As the disease is greatly dependant upon a morbid mobility and weakness of the muscular

fibres, either general or local, a tonic course of medicine and regimen should be instantly commenced, and unswervingly persevered in. The diet should be light; all flatulent foods and drinks be cautiously avoided; the hours be early, and the exercise indulged in be of the gentlest kind.

Arsenic, in small doses, is said to have been tried with advantage (*Alexander, Med. Comm.*, Edinb., vol. v., p. 99); but I know nothing of its effects from my own practice; and should prefer the oxydes of many other metals, and particularly those of bismuth, copper, and iron, as more likely to afford a permanent and radical cure. Sir Gilbert Blane has briefly noted a case, in which the disease yielded to arsenic in combination with digitalis and mercury.—(*Medico-Chir. Trans.*, vol. iv. p. 136.)

Where the complaint is strictly idiopathic and uncombined, it has often been found to give way to some local irritation or vicarious drain. A sudden flow of blood from the anus has completely removed it. An ichorous or serous discharge from the same organ has proved equally successful; as has also an obstinate gleet. And it is hence not to be wondered at, that setons or issues should have been productive of equal service. The latter are to be preferred as the least troublesome; one should be opened in each thigh, and each incision should be large enough to contain two peas; which it would be better at first to make of the mezereon bark, as already recommended for the same purpose in asthma.

[The prussic or hydrocyanic acid, prepared according to Scheele's formula, and given during the paroxysm, has sometimes proved rapidly successful; and this, probably, from its power of augmenting action, while it diminishes irritability.

Laennec has a high opinion of the usefulness of magnetism, with leeches, blisters to the forepart of the chest, the cherry-laurel infusion, digitalis, or the fetid gums; a mild regimen, and the warm or cold bath, according to the season of the year.]

SPECIES II.

STERNALGIA CHRONICA. CHRONIC BREAST-PANG.

THE PAROXYSMS LESS VIOLENT, BUT OF LONGER CONTINUANCE; RECURRING FREQUENTLY WITH GREAT PALPITATION OF THE HEART, EXCITED BY SLIGHT AND OFTEN UNKNOWN CAUSES, AND NOT RELIEVED BY REST.

FROM the observations which have been thrown out at some length in treating of epialtes and asthma, it is not to be wondered at that sternalgia should in many habits, where it has once taken a hold, be peculiarly disposed to recur when the body is recumbent, and particularly during sleep: nor even that, in some idiosyncrasies, it should, like the two complaints just alluded to, often originate in such a state of body.

If, however, the first attacks do not prove fatal, the disease is often apt to become chronic;

* At the present time we should commonly prefer the acetate or muriate of morphia; preparations of opium freed from narcotine.—ED.

and to exhibit the symptoms that characterize the present species. The attack is now not only more easily brought on, but requires a longer period of time for its removal. Rest, even if it commence during exercise, has little or no effect, and the paroxysm has at times been protracted not only for some hours, but even for several days, without remission, and occasionally with a considerable degree of danger through the whole period. Yet it has occasionally continued to harass and weaken the constitution, without actually destroying it, for twenty years; and in a few instances, has been known to cease spontaneously. In this species of the disease, we meet with far more instances of palpitation of the heart and irregular pulse than in the preceding: and not unfrequently these catenating symptoms become more manifest and distressing as the disease becomes more inveterate; as though the morbid state of the heart or its appendages were a result of sternalgia, instead of sternalgia being a result of the former. In Sir Gilbert Blane's valuable Table of Medical Cases occurring in his private practice, as contradistinguished from the diary of his public duty as physician to St. Thomas's Hospital, under the head of "Palpitation of the Heart and Angina Pectoris," we have the following remark:—"In one of these cases, there was an extreme distress of breathing for five years, and the pulse fluctuated from 20 to 32, never falling below the former, nor exceeding the latter. Nothing gave material relief. Leave was not obtained to open the body after death."* Dr. Fothergill, in like manner, asserts, not only that the pulse, in his practice, has been irregular and intermitting during the exacerbations, but that it has continued irregular, and even intermittent, when the patient has been free from pain and at rest.

* Med.-Chir. Trans., vol. iv., p. 136. The late Mr. Robert Bligh, who was attended by Dr. Pinckard and the editor, was attacked in bed nearly every night, for some months previous to his death, with such pain about the heart, palpitations, and difficulty of respiration, that he was always obliged to get up immediately, and walk about, to prevent suffocation. His pulse was generally between 28 and 36, regular and strong, but with a vibratory motion in it. One afternoon he fell down dead. The editor examined his body, assisted by Mr. Hooper, of the London Road. The auriculo-ventricular opening of the left side of the heart, and the mitral valves, were much thickened. The lungs were healthy, with the exception of some adhesions to the inside of the chest. In the right bag of the pleura, about a pint of bloody serum was discovered. The liver was prodigiously enlarged, hardened, and of a dark purple ink colour. In the gall-bladder there were about twenty calculi; and, in the left kidney, a good deal of gravel. Experience certainly does not at present justify the inference, that angina pectoris is a distinct disorder, depending upon any determinate series of morbid appearances; though, in opposition to the conclusion of Laennec and Andral, it may be safely asserted, that it is undoubtedly, in many instances, not simply a functional disorder of the nerves of the heart, but actually connected with organic disease, as exemplified by dissections.—Ed.

Of the medical treatment and regimen, I have already spoken under the preceding species.

GENUS VII.

PLEURALGIA.

PAIN IN THE SIDE.

PUNGENT PAIN IN THE SIDE; DIFFICULTY OF BREATHING; WITHOUT FEVER OR INFLAMMATION.

THE last genus of diseases which occurs under the present order, is that which has been usually denominated pleurodyne, for which pleuralgia is here adopted in its stead for the sake of simplicity. Both terms import pain or ache in the side; but as *algia* is a more common medical termination than *odyne*, and one alone is sufficient, a preference has been given to the former. On a nice and critical examination, it would not be difficult to point out a shade of difference between *άλγος* and *όδύνη*, but no such critical distinction has been ever attended to by professional writers, and, as terminations to medical compounds, they are used convertibly, or as direct synonymes.—(See the Author's Prelim. Dissert. to his Nosology, p. 59.)

The difficulty of breathing, noticed in the generic definition, depends altogether upon the acute ache produced by every attempt to inflate the lungs; and though negative characters ought to be avoided as much as possible, both in generic and specific definitions, it is necessary in the present instance to add, "without fever or inflammation;" since this is the chief feature by which pleuralgia, or "stich in the pleura" is distinguished from "pleuritis, or inflammation of the pleura."

Pleuralgia, or pleurodyne, is no more to be found in Dr. Cullen's Nosology than sternalgia. Pain in the side is, in his opinion, never any thing more than a mere symptom of some other complaint, most commonly rheumatism; and the example which Dr. Cullen has thus set has been followed by most of the later writers of our own country. There are two species, however, that have a fair claim to be regarded as strictly idiopathic. They do not often, indeed, constitute alarming diseases, but so long as they continue, are peculiarly distressing; while the latter is often of long duration, and demands a considerable range of medical treatment.

Sauvages, therefore, is fully justified in forming a distinct genus of the complaints before us; and Macbride is more to be commended in following his example than Cullen in departing from it. The two species are as follow:—

1. Pleuralgia Acuta. Stich.
2. ——— Chronica. Chronic pain in the side.

SPECIES I.

PLEURALGIA ACUTA.

STITCH.

PAIN SUDDEN AND TEMPORARY: SUPERVENING ON MUSCULAR EXERCISE: RELIEVED BY PRESSURE.

This species is found most frequent among

boys, who are engaged in any violent exertion, and particularly in hard running. It is produced by too great and sudden a distention of the fine bloodvessels of the pleura, from undue propulsion of the blood.

It is relieved by a handkerchief, or any other tight bandage. It gradually subsides on rest, or even slackening the pace. When this is not the case, bleeding and other evacuations are instantly necessary; together with warm relaxing liniments, and anodyne fomentations.

It is from this forcible distention of the minute vessels of the pleura that Van Swieten, Sauvages, and Macbride distinguish this species by the name of pleurodyne à spasme; thus making a distinction between spasma and spasmus; and understanding by the former, that voluntary stretching or straining which takes place in any vehement exertion, contraction, or extension of a muscle, as in striving, bearing heavy burdens, or running. In the language of M. de Sauvages (*Nosol. Method.*, Cl. v., Ord. ii., Gen. xi), "*Spasma non est spasmus, sed distractio, divulsio, qualis accidere solet à vehementi musculi nisu, contractione, extensione; ut inter luctandum, onera gestanda, currendum.*"

This species is occasionally met with as a symptom in flatulence, hysteria, and hypochondrias: in all these cases, however, though the disease or symptoms are the same, the exciting cause is very different. There is here evidently a nervous or irritable temperament, and a tendency to spastic action.

[With regard to the hypothesis of stitch depending upon an immoderate propulsion of the blood into the vessels of the pleura, it seems to be unsupported by any kind of evidence; nor is the editor aware that mere distention of bloodvessels will in any other instance satisfactorily account for an attack of acute pain. The stitch, which is so common to young persons in their active sports, is generally a pain fixed nearly to a point either within one of the hypochondria, or under the false ribs, and is too circumscribed to admit of being explained by the supposed immoderate distention of the bloodvessels of the pleura, even if such distention could account for the sudden pain.]

SPECIES II.

PLEURALGIA CHRONICA.

CHRONIC PAIN IN THE SIDE.

PAIN PERMANENT: AUGMENTED BY PRESSURE:
INABILITY OF LYING ON THE SIDE AFFECTED.

This species is more diffused than the first, and accompanied with a considerable degree of irritation; whence pressure, instead of diminishing, augments the pain. The cause is therefore of a different kind from any of those already noticed, and is perhaps most frequently to be found in adhesions of the folds of the pleura to each other, or to the intercostal muscles, or a thickening in some part of its extent, whereby the play of the respiratory organs is impeded, and a state of perpetual irritation, or a ceaseless tendency to irritation, is kept up.

This species has also often been produced

by a fractured rib, or some other lesion of the chest; or by some internal malformation, or other structural disease in the organs of the same cavity. Dr. Percival, in a note upon this species, appended to the volume of Nosology, refers to a case which once occurred to him, of pain in the left side, acute and obstinate, that baffled all remedies, local and general; and which was at length found to have originated from an aneurism of the aorta.

Chronic pleuralgia may also follow from an inflammation of the pleura; or from transferréd gout or rheumatism. It is peculiarly apt to take place under every disease, which, by lowering the tone of the system, renders it generally irritable and subject to irregularity of action; as is the case in worms, syphilis, and phthisis. The opposite extreme of plethora has, moreover, not unfrequently been found to produce it.

Most of these, however, may be regarded as mere symptomatic affections. Among the genuine idiopathic cases may be mentioned, in the first place, those produced by external pressure, as habitually forcing the chest, in writing against the hard edge of a desk; or, which still more frequently occurs, and is productive of far severer effects, by the absurd, though fashionable use of tight stays, which, while they undermine the health, generally coop up and distort the chest into a shape equally ungraceful and unnatural. This barbarous custom cannot be too strongly inveighed against: for though the imprisoned young female may, by dint of habit, and where little exercise or exertion is required, be able to obtain a sort of triumph over the primary mischief of adhesions hereby produced, yet may she pave the way for an obstinate cough, phthisis, and lateral curvature of the spine; and, should she escape these, she will still have other inconveniences to suffer as soon as she reaches a state of pregnancy.

In attempting either to cure or to palliate the present species of pleuralgia, we must direct our eye as nearly as possible to its cause. If the affection be symptomatic, we must combat the original disease. If idiopathic, bleeding from the arm will generally be found requisite, and freely, if we suspect plethora; but locally by cupping or leeches, if it be from the mischievous habit of dress we have just reprobated, and the constitution, as is mostly the case, be relaxed and delicate. Here also dry cupping has been frequently found serviceable. Under all circumstances, a loose dress should be insisted upon. Blistering will often afford relief, and the discharge should be rendered permanent; but a seton or an issue will generally succeed better than a blister. Electricity by drawing sparks, has also proved frequently of use. [Laennec's opinion of magnetism has been noticed under the first species, where the other remedies in which he confides are also briefly mentioned.] Quiet rather than exercise is demanded, and the ablest course of internal medicines will be that which is best calculated to take off irritating and irregular action, as bark, valerian, snake-root, conium, and the various preparations of the hop.

CLASS III. HÆMATIC A.

DISEASES OF THE SANGUINEOUS FUNCTION.

ORDER I.

PYRECTICA.

FEVERS.

“ II.

PHLOGOTICA.

INFLAMMATIONS.

“ III.

EXANTHEMATICA.

ERUPTIVE FEVERS.

“ IV.

DYSTHETICA.

CACHEXIES.

CLASS III.

PHYSIOLOGICAL PROEM.

In treating of the very important and extensive range of diseases included under the present class, let us first take a brief survey of the sanguineous function, which is the immediate theatre of their operation, and the means and instruments by which it is maintained.

This comprehensive subject may be most conveniently discussed under the three following divisions:—

- I. The Machinery of the Sanguineous System.
- II. Its Moving powers.
- III. The Nature of the Fluid Conveyed.

I. The importance of the blood to the general health of the animal system, and its existence in every part of almost every organ, have been known in every country in which medicine has been studied, from the first dawn of its cultivation. It is not necessary to retrace the wild and idle hypotheses, that were started in ancient times to account for the means by which this universal fluid travels from one part to another, and appears in every quarter. It is enough to observe, that till the great and transcendent doctrine of the circulation of the blood was completely established, the acutest physiologists wandered about in darkness and uncertainty, seldom satisfying themselves, and still more rarely the world around them.

The opinion, indeed, of a circulation of the blood through the system, was loosely started by various writers, even of very early times; but, under every modification, it was found to be accompanied with so many difficulties, as always to be dropped almost as soon as it was revived,

and rarely, till the middle of the seventeenth century, to show itself to any effective purpose. Hippocrates guessed at it; Aristotle assented to it; Servetus, or Servede, who was burnt as a heretic in 1553, imperfectly taught it by pointing out the smaller circulation, or that through the lungs; and our own illustrious countryman, Harvey, about a century afterward, gave a finish to the inquiry, by establishing the larger circulation, or that over the whole frame.*

The principal proofs of a circulation of the blood offered by Harvey, and those, indeed, on which we chiefly rely in the present day, are deduced from the disposition of the valves at the origin of the two great arteries; from the mechanism of the valves in the veins; and from the arrangement of those of the heart; from the possibility of draining an animal of its blood by opening either an artery or a vein; from the range of the arteries and the veins, and from what occurs when either the arteries or veins are opened, compressed, tied, or injected. All the valvular contrivances, to which a reference

* Dr. J. R. Coxe, of Philadelphia, has lately examined Harvey's claims, with a view to show that instead of discovering the circulation of the blood, he merely "attached more firmly the cementing links of an extensive chain which time had rusted, and possibly, also, has added slightly to its more full perfection." Dr. Coxe supports his views by numerous quotations, from authors existing prior to Harvey, which evince much learned research.—See his *Inquiry into the Claims of Dr. Wm. Harvey to the Discovery of the Circulation of the Blood*, &c., Philadelphia, 1831.—D.

has been made, prevent the blood from taking any other course than what the present doctrine of the circulation inculcates. If we open an artery, the blood that jets from the puncture flows in a direction from the heart : and in a direction to the heart if we open a vein. A compression or ligature upon an artery, puts a stop to the blood that flows from above the ligature ; but the same upon a vein puts a stop to the blood from below it, in which direction the vein immediately becomes distended. In like manner, an acid liquor, injected into the veins, coagulates the blood in the direction towards the heart, proving that the venous blood is everywhere travelling in this course. While an examination by the microscope of the vessels of the half-transparent textures of frogs, and other cold-blooded animals, confirms the view laid open by these phenomena, and shows to us a continual flow of the blood from the heart into the arteries, thence into the veins, and thence to the heart again ; thus completing the circular career.

The arteries, therefore, generally speaking, terminate in veins ; but by no means the whole of them, for many are exhalant or secretory, and terminate on the surface of membranes and other organs by minute orifices ; which no microscope, however, has yet discovered, but whose existence we have every reason to believe, as we perceive a perpetual oozing of fluids, whose flow we cannot otherwise account for, into all the cavities of the body ; which keeps their surfaces moist, and makes motion easy. While, according to M. Magendie, whose experiments, however, seem to want confirmation, other minute arteries terminate in lymphatics, which he makes as much a part of the sanguiferous system as the veins ; the lymphatics conveying the more attenuate part of the arterial blood, slightly tinged of an opaline or rose-coloured hue, though sometimes of a madder-red ; such as the fluid which oozes upon puncturing the lymphatics, or the thoracic duct, after a long fast. It is not necessary to examine into the correctness of this hypothesis in the present place, as we shall have occasion to notice it more at large when treating of the excrement system, which will be found to embrace both the absorbent and secretory vessels. It should be remarked, however, that, in M. Magendie's hypothesis, the veins, and not the lymphatics, are the absorbents of the body. —(*Précis Élémentaire de Physiologie*, tom. ii.)

Omitting then, for the present, the consideration of the lymphatics, the machinery, by which the circulation of the blood is principally effected, consists of the heart itself, the arteries, and the veins.

The heart, in the more perfect classes of animals, as mammals, birds, and most, though not all, amphibians, is a very compound organ ; for in all these the blood, when received from the veins, is first sent from this central organ to the lungs to be duly aerated, or, according to Mr. Ellis's hypothesis, to be unloaded of its excess of carbon, and is afterward returned from the lungs to the same organ before its general circulation over the system commences. These classes, therefore, are said to possess a double

circulation. And as the heart itself consists of four cavities, a pair, composing what is called an auricle and a ventricle, belonging to each of the two circulations ; and as each of these pairs is divided from the other by a partition, these classes are also said to have not only a double circulation, but a double heart ; a pulmonary and corporeal circulation and a pulmonary and corporeal heart.

[The division of the circulation into two parts, the *great aortic, systemic, or corporeal*, and the *less, or pulmonary* one, has generally been adopted since the time of the illustrious Harvey. Bichat conceived, however, that a division, founded on another principle, was preferable for the purpose of illustrating the objects of the blood's motion. The blood in one portion of its course is remarkable for its bright scarlet hue ; in another, for its dark colour. In the first, it is flowing from the lungs to all parts of the body ; in the second, it is returning from these parts to the lungs. The first is Bichat's *circulation of red blood* ; the second, his *circulation of black blood* (*Anat. Gén.*, tom. ii.) ; a distinction, that at once gives a prompt introduction to the knowledge of the purposes of the circulation.]

The heart, in which the chief impelling power of the two vascular systems resides, is situated in the chest, between the lungs, and upon the diaphragm, by all the motions of which it is influenced. [The texture of the heart is fleshy, but very dense and compact, consisting of packets of fibres, more or less oblique, and variously contorted. The lesser ventricle, which has to propel the blood to a much greater distance than the right, is more fleshy and strong than the latter, which has merely to send the blood through the lesser or pulmonary circulation. When the chest and pericardium are opened in a living animal, the heart may be seen beating ; the action of the auricles and ventricles alternating ; that is to say, the two auricles contract together, and then the two ventricles. When the stethoscope is applied to the region of the heart, the distinct sounds of the action of the ventricles and auricles may be heard. At the instant when the pulse is perceptible in the arteries, a dull sound is audible, and directly afterward a clearer sound, similar to the noise of a valve. The former arises from the action of the ventricles ; the latter from that of the auricles.*

* See Laennec, *Traité de l'Auscultation*, &c., tom. ii., p. 403, edit. 2. Some experiments made by Dr. Stokes and Mr. Hart, and of which an account is given in the *Edin. Med. and Surgical Journal* for October, 1830, p. 269, led them to conclude that Laennec was mistaken in his opinions respecting the impulse of the heart. "It is not, as he states, produced during the systole, but during the diastole of the ventricle. In point of fact, the pulse in the extremities, and the impulse of the heart, arise from one and the same cause ; in the artery from its diastole, and, in the ventricular portion of the heart, from the same cause. This explains satisfactorily the want of coincidence between the impulse of the heart and the pulse at the wrist."—(*Op. cit.*, p. 271.) The observations of the same experimenters lead to the following

The blood is returned from the greater circulation by the two large venæ cavæ into the right auricle. At the same moment, it is poured into the left auricle from the pulmonary circulation by the four pulmonary veins. The auricles being thus filled with blood, contract, when the blood, partly thrown back into the veins, produces by its reflux from the right auricle, a pulse, sometimes visible in the internal jugular veins of thin persons (*Magendie's Physiology by Miligan*, p. 360; and *Mayo's Outlines*, p. 67), but the main part of it is propelled into the right ventricle. The auricles then become relaxed, and the ventricles act, and drive back into the auricles such blood as happens to be situated behind the tricuspid and mitral valves, the valves placed at the communications between the auricles and ventricles, while the rest is thrown by the right ventricle into the pulmonary artery, and by the left into the aorta. All regurgitation from these two great trunks is now impeded by the operation of the semilunar valves, placed at their commencement.]

The heart is loosely surrounded by a dense and fibrous membrane, named from its situation, pericardium, possessing little sensibility, closely connected with the diaphragm, and reflected over the heart and its large vessels. Physiologists commonly represent its use to be that of confining the heart in its proper post; and of lubricating it, in its state of unceasing activity, with a peculiar fluid, denominated liquor pericardii, secreted from the capillary arteries of its internal surface. In a state of health, this fluid is small in quantity and of a reddish hue, some portion of the red parts of the blood being intermixed with it; but, in a morbid state of the membrane, it is apt to accumulate, change its properties, and lay a foundation for various complaints.—(See *Bostock's Elem. System of Physiology*, vol. i., p. 363, 8vo., 1824.)

[With respect to the considerable effect imputed to the pericardium in regulating the motions of the heart, and preventing this organ from leaping out of its place, as the expression is, one or two facts, brought to light by dissection, have materially weakened, if not quite subverted the hypothesis. A few instances have occurred of the heart being found without any pericardium whatever, or any device to answer its purpose. Dr. Baillie has recorded a singular instance of this in a man, aged about forty, who died of an accidental complaint, without seeming to have suffered from the deficiency.—(See *Baillie's*

Works by Wardrop, vol. i., p. 44.) Many examples are met with, where the bag of the pericardium and its reflected layer on the heart are completely adherent together, without any particular effect on the action of the latter viscus. A similar case to that in Dr. Baillie's works, is reported by M. Littere.—(*Hist. de l'Acad. des Sciences*, 1712, p. 37.) The circumstances which have most influence in fixing this organ, are, its situation between the two lungs, which enclose it nearly on every side; and its connexion with the large bloodvessels.

When, as an able physiologist has observed, we take into consideration the relative importance of the heart and brain, as far as regards mere animal existence, we shall be led to decide in favour of the former. In incubation, as the immortal Harvey pointed out, a beating point, a "punctum saliens," as he expresses it, which is the rudiment of the future heart, precedes the formation of other parts of the body, and is visible for some time before any trace of the brain can be distinguished. Acephalous fœtuses have been known to attain their full size in the womb, and even to have lived for a short time after birth, and then died from not being able to effect those changes, which are incidentally necessary to an existence of any duration. For example, a regular supply of nutritious matter is essential to the support of life; this can only be supplied by the introduction of food into the stomach by the act of deglutition; but this act, at least in the higher animals, cannot be performed without the intervention of the nervous system.—(See *Bostock's Physiology*, vol. i., p. 335.)

The sides of arteries are divisible into several strata of dissimilar substances, technically named *coats* or *tunics*. Mascagni, like the older anatomists who preceded him, represents both the arteries and veins as having four coats (*Prodromo*, pp. 61-64); but, his external one (*ascitizia*) is merely the cellular membrane that connects the vessels to the adjoining parts.—(*K. A. Rudolphi, Elem. of Physiol.*, vol. i., p. 90.) According to Rudolphi, and the generality of modern anatomists, all vessels have at least two coats, and the arteries three. Some writers, indeed, reckon only two proper arterial coats, and describe every arterial tube, exceeding one line in diameter, as visibly composed of one adventitious and two essential substances.—(See *Edinb. Med. Journ.*, vol. xviii., p. 258.) The three arterial coats are

results:—1. That, in a state of health, the impulse of the heart precedes that of the arteries. 2. That the interval between the impulse of the heart and the pulse in the arteries is in the direct ratio of the distance of the vessels from the centre of the circulation. 3. The pulsations of arteries in different parts, but at equal distances from the heart, are synchronous. 4. The greater the distance, the longer will be the interval. 5. That, although the actual pulsations depend on the systole of the left ventricle, yet the diastole of the vessels does not occur synchronously in all parts of the body, but is progressive. In the production of the sounds of the heart, as audible with the stethoscope, Dr. Stokes and Mr. Hart consider that two causes are

concerned. If, as they endeavour to show, Laennec's first sound, or that coinciding with the impulse, be produced during the diastole of the ventricle, it must be produced by this cause, and the contraction of the auricle. To the production of the second, on the other hand, attributed by Laennec to the contraction of the auricles, the contraction of the auricles and the dilatation of the ventricles appear necessary. With respect to the phrase *diastole of the vessels*, employed by Dr. Stokes and Mr. Hart, it would perhaps have been better to have substituted the term *pulsation*, as the experiments of Dr. Parry tend to prove, that there is no true dilatation or diastole in the arteries accompanying the pulse as will be presently noticed.

now generally called *external*, *middle*, and *internal*; denominations adopted by Dr. Jones, in his excellent work on hemorrhage; or *elastic*, *muscular*, or *fibrous*, and *membranous*. By Bichat, the latter tunic was styled the *common membrane of the system of red blood*, as it is not restricted to the arteries, but extends over the inner surface of the left ventricle and auricle of the heart, and lines the pulmonary veins, and, in short, the whole track of the scarlet blood.

In examining arteries, one of the first things observable is, that the sides of the large arteries are thick and elastic, so that, when these vessels are transversely divided, the section presents a regularly circular aperture.—(Haller, *Elem. Physiol.*, tom. i., p. 37.) Elasticity is rather obscure in the greater number of the textures of the animal body, a more prevalent feature of which is softness; yet it is very conspicuous in the arteries, and one thing that particularly marks their difference from veins, keeping their sides apart, even when they are empty. In fact, the arteries and some cartilaginous passages, like the windpipe, and the meatus auditorius of the fœtus, are the only tubes which are sufficiently elastic to remain open of themselves. It is to the elasticity of the arterial parietes that must be ascribed the sudden return of their naturally pervious condition, after their cavity has been momentarily effaced by compression, and the quickness with which an artery that has been bent straightens itself again. According to Bichat, this property is also manifestly concerned in the sort of locomotion which the arteries undergo from the influx of blood into them. If a tortuous arterial trunk be exposed in a living animal, the whole of it will be seen to rise up at each pulsation, quit its place, and straighten itself. As soon as an anatomical injection is thrown into the vessels of a very thin, diminutive subject, a locomotion of all the tortuous branches of the face becomes perceptible through the integuments. If the arteries had not a firm, elastic texture, they could not thus yield to the impulse communicated to them. The abdominal branches of the vena portæ, having no valves, may be injected like the arteries; but nothing resembling the above locomotion, is observable when the fluid is impelled into them. Bichat frequently made arterial blood circulate in veins by means of curved pipes, adapted to the vessels of a living animal; for instance, to the carotid and external jugular vein; yet, though a kind of pulsation, synchronous with that of the heart,—an evident rustling,—could be felt in the veins, thus injected with arterial blood, no real locomotion was discernible.—(Bichat, *Anat. Gén.*, tom. i., p. 289.)

The *internal coat* of the arteries, though extremely thin, and even semitransparent, is very close in its texture, endued with little elasticity (Hunter on the Blood, p. 117), and gives to those vessels their smooth polished lining. It does not exhibit the dun yellow colour of the middle coat; nor has it any fibrous appearance, being everywhere perfectly level and slippery.—(Soemmerring, *De Corp. Hum. Fab.*, tom. v.,

p. 57.) According to the experiments of Dr. Jones, it is elastic and firm in the *longitudinal direction*; but so *weak in the circular*, as to be very easily torn by a force applied in that direction.—(On the Process of Nature in suppressing Hemorrhage, &c., 8vo., Lond., 1805.) In the dead body, Bichat noticed that it seemed to have an unctuous fluid upon it, which he conceived, however, might not be the case in the living subject. It is of folds of the internal coat of the arteries, that the semilunar and sigmoid valves are formed at the origins of the aorta and pulmonary artery, the important uses of which valves have been already cursorily stated. The same membrane also forms the various ridges at the commencement of the arterial branches. It is very feebly united to the middle coat; and, according to Bichat, there is no cellular tissue between them. The morbid changes to which it is subject, prove its vascularity. Indeed, during life, it is particularly connected with arterial diseases. Thus its inner surface becomes the seat of adhesive inflammation, whenever the blood is prevented by a ligature from passing along it, or the opposite sides of the vessel are gently held in contact for a certain period. In elderly persons it is also noted for its singular tendency to ossify. Bichat calculated, that, in every ten individuals past their sixtieth year, the arteries of at least seven have earthy incrustations on them. These ossifications, which never affect the middle coat, always begin upon the external surface of the inner coat, being lined by a thin pellicle, which intervenes between them and the circulating blood, and is plainly the internal coat itself. These calcareous depositions in the arteries are not regulated by the laws of common ossification, the cartilaginous state rarely preceding them. The earthy matter is always deposited in detached plates, or scales, and the whole artery is seldom converted into one continued solid tube. Thus the portions of the internal coat, between the scales, were considered by Bichat as so many articular bands; the arteries thus ossified being composed of numerous pieces, moveable upon each other, and capable, in a certain degree, of yielding to the impulse of the circulation. While these earthy plates continue thin, the inside of the artery retains its natural smoothness; but, when they acquire thickness, they project into the cavity of the vessel; the thin pellicle breaks at their circumference; and they then adhere merely to the fibrous coat.

The *middle coat*, which is the thickest, consists of several layers of firm, compact fibres, considered by Hunter, Jones, and many other physiologists, as *fleshy* or *muscular*. It is sometimes called the *fibrous coat*, and often the *muscular*. Bichat names it the *proper membrane of an artery*, and observes, that it is very apparent in the large arteries, but less perceptible in their ramifications, where it is gradually lost.*

* *Anat. Génér.*, tom. i., p. 270. Yet, according to Hunter's experiments, the smaller the arteries are, the more contractile and muscular they become in relation to their size; while, compara-

Its fibres have a circular direction; being, however, rather obliquely connected, and interlaced with each other, than complete circles. According to Jones, they are of a peculiar nature, well supplied with nerves, and in form and disposition like muscular fibres, but different from them in possessing a remarkable degree of elasticity. They also differ from muscular fibres in being of a yellowish dun colour; in not having the same taste when boiled (*Rudolph's Elem.*, vol. i., p. 80; *J. J. Berzelius, Animal Chym.*, p. 25); and in having no fibrine as one of their constituent parts. With respect to the colour of muscular fibres, a red colour is peculiar only to those of vertebrated animals, and, even in amphibia, they appear very pale, and, in numerous fishes, still paler. Many of the lower animals, as, for instance, the actine, possess a manifest power of contraction; yet, as Dr. Bostock observes (*Physiol.*, vol. i., p. 399), their substance is quite as unlike that of the muscles of warm-blooded animals, as the transverse fibres of the arteries are alleged to be. The non-muscularity of the middle coat of an artery, therefore, must not be inferred from the mere circumstance of its not corresponding in colour to the muscles of the human body.

Such physiologists as consider the middle coat of the arteries to be muscular, among whom are Haller, Walther, Hunter, and Soemmerring, build their opinions upon various grounds, some of the firmest of which were explored by Mr. Hunter. It is also argued, that the fibres become soft and grayish in the small arteries, and assume much of the appearance of those in the intestines; that, notwithstanding the dryness, resistance, elasticity, and fragility of the arterial fibres, not more difference really exists between them and the muscular fibres, than between those of different muscles; and that the muscularity of arteries is proved by their functions. With such statements Bécclard joins another, which disagrees with the researches of Berzelius; namely, that he has detected a proportion of fibrine in the middle coat of the arteries.*

Dr. Jones represents the elasticity of an artery as so particularly inherent in the middle coat, that, if this coat were separated from the two others, it would retain its cylindrical form, while they would collapse. This statement is certainly not applicable to the largest arteries, the outer coat of which possesses very considerable elasticity, and perhaps even a greater degree of it than the middle one.

tively speaking, the proportion of elastic matter is most abundant in the great arteries.—Ed.

* Bécclard, *Additions à l'Anat. Gén.*, p. 78. According to Cuvier, the middle coat of the arteries, which is fibrous in man and the horse, is decidedly muscular in the elephant. Dr. Wedemeyer, summing up all the objections made to the doctrine of the muscularity of the arteries, states, that, whereas the true muscular fibre is reddish, soft, extensible during life, and very brittle after death, the fibrous coat of the arteries is, on the contrary, yellowish, firm, hard, and very elastic even after death; that its *vasa vasorum* do not

The *external coat* of the arteries is often described as condensed cellular membrane. Its texture towards the middle coat is close and smooth, but, more externally, it is open and rough, in consequence of the cellular substance by which it is connected to an additional covering named the arterial sheath. The external coat is remarkable for its density, whiteness, and great elasticity. If an artery be surrounded with a tight ligature, the middle and internal coats will be completely divided, while the external coat will remain entire. Hence, the strength of an artery must depend in a great measure upon this coat, and its importance may be conceived from the fact, that it encloses and transmits the *vasa vasorum*, by which the artery itself is nourished.

The sheath of arteries is merely the laminated cellular substance that forms around them a sort of canal. On one side it is connected to their external coat by numerous filaments of cellular membrane; while, on the other, it is continuous with the common cellular substance. It does not exist where arteries are covered by serous membranes. Other arteries are likewise destitute of it, apparently in consequence of there being no cellular membrane in their vicinity, as in the brain. In the limbs, it is generally very compact; but, in some other situations, it is quite lax, as around the spermatic arteries.—(*Bécclard*, op. cit., p. 79.)

According to Bichat, although the cellular tissue forms the external coat of the arteries, and serves for the insertion of the arterial fibres, it is not continued into their interstices; a peculiarity, he says, in which the arterial tissue differs from that of muscles, veins, &c. This absence of cellular tissue he also remarked between the middle and internal coats; though the observation disagrees with the statements of Haller, Soemmerring, and others. It is to the want of cellular substance in the proper arterial tissue, that Bichat refers a great deal of the fragility by which it is characterized; the difficulty of arterial dilatations; the freedom of arteries from fat, anasarca, hydatids, cysts, and various tumours, to which the cellular membrane is liable.—(*Anal. Gén.*, tom. i., pp. 285–287.)

Arteries are furnished with minute arteries and veins of their own, technically named *vasa vasorum*, and without the agency of which the nutrition, growth, and morbid states of the arterial system would defy all rational explanation. These small nutrient arteries originate from the neighbouring ramifications, and not from the artery itself, to which they are distributed. One

distribute themselves as in the muscular fibre; that it does not contain any fibrine; that it is not excited to contract by galvanism, or any other irritant; and that, in its extreme liability to the deposition of calcareous matter between itself and the inner serous coat, it shows its resemblance to white fibrous tissue in other parts of the body, as well as its difference from true muscular tissue, between which and serous membranes calcareous matter is rarely secreted.—See *Untersuchungen über den Kreislauf des Bluts*, &c., Hannover, 1828.—Ed.

exception to this arrangement is pointed out by Bichat: the aorta, at its commencement, gives off the coronary arteries, which, besides supplying the heart, ramify on that great vessel.

Absorbent vessels are very manifest around the large arteries, for instance, the crural. The enlargement of the cavities of arteries, as the body, limbs, and other parts increase in size, implies the continual performance of absorption in the arterial structure. Other powerful arguments in support of this inference may be drawn from various pathological facts, especially from the liability of arteries to ulceration.

According to Soemmerring (*De Corp. Hum. Fab.*, tom. v., p. 59), all the arteries have nerves, which also appear to him to be smaller and fewer in the large trunks, than in the branches of middling diameter. Hence he concludes, that the more minute arteries are, the greater is their proportion of nerve in relation to their size. He states, that the vertebral artery, and the large mesenteric branches in thin subjects, can be seen without any difficult preparation, surrounded by a beautiful network of nerves. Lucae asserts that he has followed the nerves even into the substance of arteries. The late Mr. Wilson also succeeded in tracing filaments of nerves into the arterial coats. "I can have no doubt," he remarks (*On the Vascular System*, p. 155), "of nervous filaments communicating with the packets of muscular fibres, as there is sufficient proof, in the action of blushing, that these fibres are much influenced by emotions of the mind." The heart and larger arteries receive but few nerves directly from the cerebro-spinal portion of the nervous system, their nerves being principally supplied by the ganglionic system of the great sympathetic, which appears to have the organic or nutritive functions of life more especially under its influence. The two divisions of the nervous system are, however, intimately connected by the numerous branches which the great sympathetic receives from the spinal marrow, and by a few smaller branches coming from the brain. In an experiment made by Sir Everard Home, the great sympathetic nerve was irritated in the necks of dogs and rabbits, and a temporary increase of pulsation is said to have been thereby produced in the carotid arteries.—(*Phil. Trans.*, 1814.) In experiments of this kind, the physiologist should be careful not to confound the general disturbance of the circulation from the pain and agitation, with a local augmentation of the pulse of a particular artery from the effect of the irritation of the nerve or nerves, by which it is supposed to be influenced.

The veins are membranous tubes, like the arteries, but differ from these vessels in having a thinner and less fibrous texture, and in being often furnished with valves, which, in the arterial system, are nowhere found, except at the roots of the aorta and pulmonary artery. The veins are nearly destitute of that texture which is seen in the middle coat of the arteries, and are consequently to be regarded as little more than simply elastic tubes. As Soemmerring remarks, it is only in the large trunks of the

veins that any fibrous appearance can be traced.

—(Op. cit., vol. v., p. 328.) Their office is to return the blood to the heart, after it has served the purposes for which it was sent from the two ventricles of that organ. Their action is, therefore, entirely mechanical, and the blood is transmitted by them (as far, at least, as they themselves are concerned) upon hydraulic principles.—(*Bostock's Physiol.*, vol. ii., p. 403.) That the large veins have longitudinal fibres is generally admitted; but the transvers or circular* ones ascribed to them by Marx (*Diatribæ de Structura atque Vita Venarum*, Carlsr., 1819) seem to Rudolphi to be nothing more than cellular membrane. He has never seen distinct circular fibres in the veins of the human subject, nor even a single one in the vena cava of a horse.—(*Elem. of Physiol.*, vol. i., p. 90.) The force with which the veins resist any power tending to tear them is much greater than might be expected from their apparent tenuity. Their area is much larger in proportion to their sides than that of the arteries; and, according to the experiments and calculations of Wintringham, the proportion which the thickness of the arterial coats bears to that of the venous tunics, is in the largest trunks as fifteen to one. The veins also bear greater distention than the arteries without bursting. In Wintringham's experiments, the vena cava inferior sustained a column of water weighing 176 lbs., while the aorta, in the same situation, was burst by a column of 158 lbs. 11 oz. The iliac vein was to the artery in this respect as 1034 to 1000. But in the vessels of the viscera, the arteries exceeded the veins, and, in an old dog, the aorta was stronger than the vena cava. In the living subject, however, the veins are found more liable to dilatation and rupture than the arteries. They yield more readily, and admit of greater dilatation. The inner coat or lining of veins is thinner, more dilatable, and less brittle than that of arteries. Ossification never takes place in it; and as all what Bichat calls the *common* membrane of the black blood is of the same nature, the tricuspidal valve, with the semilunar or sigmoid valve of the pulmonary artery, and the lining of that vessel, never exhibit bony deposits, which are so common in the corresponding parts of the system of red blood.

The valves of the veins are produced by folds of the internal coat. In the larger trunks they are generally arranged in pairs, as at the entrance of the internal jugular into the subclavian in the large veins of the leg and arm, and the vena azygos. Three valves situated together are sometimes observed, but not frequently. Solitary valves are frequently seen in the smaller veins. The size of the valves is proportioned to that of the vessel, but they are not always large enough to close it completely. The valves are chiefly found in veins which have a perpendicular position, as in the limbs, penis, testicle, and the vena azygos. They are particularly

* "We have ascertained, by very minute dissections, that the veins have no circular fibres."—See Doane's Meckel, vol. i., p. 127.

numerous in the limbs and cutaneous veins, and very scarce in the viscera. There are no valves from the right auricle down to the iliac veins; none in the hepatic, venal, uterine, cerebral, or coronary veins, excepting the single one at the mouth of the coronary in the auricle itself. According to Haller, there are none in the small veins generally, the diameter of which is less than one line. The valves begin in the iliac veins, where, however, they are not numerous; and they are found in such branches of the hypogastric veins as do not come from the uterus and bladder. The effect of the valves in compelling the blood to run in one direction in the veins is manifest. They lie close to the side of the vessel, and make no resistance to the blood's natural course; but when that fluid is repelled in the vein, it lifts up the loose edge, and causes the margins of the two valves to form a partition in the cavity of the vessel. Hence the blood cannot retreat farther than the situation of the first pair of valves; consequently any portion of a venous trunk has to sustain only the quantity of blood contained between the two valves which bound it. Had it not been for this arrangement, the whole column of venous blood, when its return to the auricle was impeded, would have pressed on the minute veins with a degree of force which the coats of these vessels could not have resisted. The necessity of such a structure arises out of the comparatively slow motion of the venous blood, the absence of an impelling agent at the commencement of the venous circulation, and the degree in which it is influenced by the force of gravitation. In consequence of the valves, all pressure must have the effect of sending the blood on towards the heart. For the same reason, the swell of the muscles, when they act, must promote the venous circulation.

The coats of veins are furnished with minute arteries and veins, not essentially different from the nutrient vessels of the arteries. Their exhalants and absorbents are calculated to be few; and their supply of nerves much inferior to what the arteries possess.

The following are some of the considerations which led Mr. Hunter to believe the arteries muscular as well as elastic. When the inside of the arteries and veins of the alligator and turtle is inspected, he says, fasciculi of muscular fibres can be plainly seen.—(*On the Blood*, p. 118.) But in order to prove the point, he had recourse to experiments, in which he contrasted the action of the arteries with that of simple elastic substances. "Action in an elastic body," he observes, "can only be produced by a mechanical power; but muscles acting upon another principle can act quickly or slowly, much or little, according to the stimulus applied; though all muscles do not act alike in this respect. If an artery is cut through, or laid bare, it will be found that it contracts by degrees, till its whole cavity is closed; but if it be allowed to remain in this contracted state till after the death of the animal, and be then dilated beyond the state of rest of elastic substances, it will only contract to the degree of that state. This it

will do immediately; but *the contraction will not be equal to that of which it was capable while alive.*

"The posterior tibial artery of a dog being laid bare, and its size attended to, it was observed to be so much contracted in a short time, as almost to prevent the blood from passing through it, and, when divided, the blood only oozed from the orifice.

"On laying bare the carotid and crural arteries, and observing what took place in them, while the animal was allowed to bleed to death, these arteries very evidently became smaller and smaller.

"When the various uses of the arteries are considered; such as their forming different parts of the body from the blood; their performing the different secretions; their allowing at one time the blood to pass readily into the smaller branches, as in blushing, and at another preventing it altogether, as in paleness from fear; and if to these circumstances we add the power of producing a diseased increase of any or of every part of the body; we cannot but conclude that they are possessed of muscular powers."

Certain experiments to which Mr. Hunter had recourse, led him to infer, that the large arteries are most elastic, and the small ones most muscular. He injected the uterus of a cow, after it had been separated from the animal more than twenty-four hours, and he allowed it to stand another day, at the end of which the larger vessels had become much more turgid than they were when first injected; and the smaller arteries, he says, had contracted so as to force the injection back into the larger. He regarded this as a proof that the muscular power of the small arteries is superior to that of the large ones, and that they retain it longer after their detachment from the rest of the system. The latter character is one that Mr. Hunter particularly ascribed to all the involuntary muscles, to which class the arterial fibres belong.—(*Op. cit.*, p. 115.)

Nothing can differ more widely than the relative spissitude and power ascribed to the elastic and muscular arterial coats, compared with each other in different parts of the circulating course. As the heart is the salient point of the circulation, and pours forth about two ounces of blood at every jet, the greatest force is exerted against the arteries that immediately issue from the heart. Here, therefore, we find the greatest resisting power; for, in the aorta and pulmonary artery, the elastic tunic is stronger than the muscular, by which contrivance these vessels are never too much dilated by the action of the heart in its contraction, or, as the Greeks call it, systole. In like manner, this tunic becomes stronger at the bending of the joints, and continues so through the whole length of the curve; and the same provision takes place at the sharp angles made by a trunk and its branch, or at an angle formed by the division of one trunk into two. As the arteries, however, recede from the heart, the blood, resisted at every step by the elastic tunic of the canal it flows through, progressively loses its impetus, and a less elastic power becomes necessary, and is actually pro-

vided. At a considerable distance, therefore, from the heart, in whatever direction the arteries ramify, their muscular tunic soon balances their elastic, and gradually becomes superior; till at length, in the capillary arteries, it is nearly, if not altogether, the only tunic of which the canal consists: whence the ease with which these vessels collapse on some occasions, as from loss of blood, or the exercise of terror, or any other depressing passion; and the equal facility with which they open in other cases, as in the sudden blush of shame or modesty.

[Many of the phenomena which Mr. Hunter and other distinguished physiologists refer to the muscularity of the arterial system, Bichat ascribes to a property which he terms contractility of tissue, that is to say, a property depending upon organization, and not upon life. He takes a view of such contractility as operating in the transverse and longitudinal directions. In the former it is much more strongly marked than extensibility. He observes, that as soon as an artery ceases to be distended with blood, it evidently shrinks. Hence:—1. The conversion of the umbilical artery and ductus arteriosus, after birth, into ligamentous impervious substances. 2. The obliteration of an artery all the way from the place of a ligature to the point at which the first collateral branch goes off. 3. The diminution of the calibre of an artery between two ligatures, as soon as the blood between them is discharged by a puncture. 4. In experiments upon dogs, into which blood was transfused, with the view of causing an artificial plethora, Bichat found that the diameter of the arteries was nearly double what it was in dogs of the same size, after profuse hemorrhage. The same difference, he says, may be noticed in two animals of equal size, when one has been killed by hemorrhage and the other by asphyxia. 5. These experiments left no doubt in Bichat's mind of the fulness and smallness of the pulse, an artery being really more or less bulky according to the quantity of blood which it contains.—(See also *Hunter*, op. cit., p. 124.) There is a limit, however, beyond which the vessel cannot be extended; but, from a deficiency of blood, it may contract to such a degree as to represent as it were but a thread.

Mr. Hunter calculated the degree of contraction that takes place in the different arteries of an animal bled to death. He subjected to very careful admeasurement the arteries of a horse killed in this manner, and whose muscles had all been allowed to contract equally, whence “we might reasonably presume that the vessels, at least such of them as were furnished with muscles, would also be contracted, the stimulus of death acting equally upon muscles in every form and every situation.” He removed from the carcass sections of the aorta, iliac, axillary, carotid, crural, humeral, and radial arteries, with the precaution of not altering in the least their texture, or state of contraction. He measured them when slit open, so as to learn their greatest degree of contraction. He then stretched them transversely, and measured them

when elongated as much as possible. Lastly, he measured them a third time, in the state to which they recovered by their own powers. He found that the power of recovering was greatest near the heart, and gradually diminished towards the extremities of the body. This was owing, as Mr. Hunter supposed, to the extension having entirely destroyed the power of muscular contraction, which is comparatively greatest in the small arteries, while the degree of contraction which actually took place after such extension, proceeded from elasticity, which is most abundant in the larger trunks.

Here what Mr. Hunter imputes partly to muscularity and partly to elasticity, Bichat would refer to contractility of tissue. The latter is of opinion, that most physiologists have confounded this kind of contractility in the arteries with irritability, the difference of which is shown by its always ceasing a few hours after death, whereas the contractility, spoken of by Bichat, takes place after death, though in a less marked degree.

Mr. Hunter, who, as we have seen, refers all contractility of the arteries to muscularity and elasticity, relates some experiments, the tendency of which is to prove that they have no muscular power of contraction in the longitudinal direction. In the first experiment, a longitudinal section of the aorta ascendens, measuring two inches, after having been stretched and allowed to contract again, measured the same length. The same thing was observed in portions of the carotid and humeral arteries. “These experiments,” Mr. Hunter says, “appear to be decisive, and prove, that the muscular power acts chiefly in the transverse direction; yet, it is to be observed, that the elastic power of arteries is greater in the longitudinal than the transverse direction. This appears to be intended to counteract the lengthening effect of the heart, as well as that arising from the action of the muscular coat; for the transverse contraction of that coat lengthens the artery, and therefore stretches the elastic, which again contracts upon the diastole of the artery.”—(Loc. cit., p. 128.)

Many of Mr. Hunter's observations embrace the subjects of the vital properties of the arteries; as, for instance, whenever he reasons about the disputed question of their muscularity. Bichat, after considering the elasticity, extensibility, and contractility of tissue, or the properties which he believed to depend on the structure or organization of arteries, offers some interesting reflections on their *vital properties*. First, he inquires, whether *animal sensibility* exists in them? The application of a ligature to an artery, he says, sometimes produces pain; but more frequently not. The latter statement the editor deems incorrect, or, at least, repugnant to what he has noticed in the practice of surgery. Nor can Bichat's observation be reconciled with what he presently says about the great sensibility of the inner coat of the arteries. However, as he admits that they sometimes give pain when tied, this affirmative proof of their sensibility is all that can be required.

He states, that, in whatever manner the carotid of a dog be irritated, whether with a scalpel, acids, alkalis, &c., the animal never betrays signs of pain. With regard to the inner coat, however, he found, that, although the injection of a mild fluid, like water, at the temperature of the animal, caused no uneasiness, the injection of a stimulating fluid like ink, diluted acids, wine, &c., excites very acute pain.—(*Anal. Gén.*, tom. i., p. 295.)

Animal contractility, as Bichat terms it, or (as it might be expressed) contractility under the influence of the brain, and resembling that of the voluntary muscles, is stated by this author not to belong to the arteries. Such contractility, he asserts, could only depend upon a connexion between these vessels and the brain; yet irritation of this organ, producing convulsions of parts subject to the will, has no effect upon the arteries; and opium, which, in a certain dose, paralyzes those parts, leaves the vessels unaffected. Another assertion made by Bichat is, that, if the spinal marrow be exposed, irritated, and compressed, the action of the arteries is neither increased nor diminished, even though the voluntary muscles be at the same time convulsed or paralyzed from it. On the other hand, the experiments of Dr. Philip contradict Bichat on this interesting point, and show that the motion of the blood in the capillaries is influenced by stimulants, applied to the central parts of the nervous system; which circumstance, if established as a fact, must depend upon the contractile power of those vessels.—(*Exp. Inquiries*, &c., p. 291, 292, 2d edit.) In direct opposition to the result of Sir Everard Home's experiment, already mentioned, Bichat found the arteries to be quite unaffected, either by irritation of the cerebral nerves, which accompany them, or by that of the ganglionic nerves, which are irregularly and abundantly distributed upon their external surface. He even tried galvanism without any effect.

The same physiologist represents the arterial system as destitute of what he calls *organic sensible contractility*, or that kind of contractility which, in his system, is classed as one of the properties of organic life, and illustrated in the action of the heart, intestines, &c. In whatever manner an artery be irritated in the living body, he asserts that it constantly remains motionless. Even when the arterial coats are stripped off layer by layer, either in a living animal, or one recently killed, none of that trembling and palpitation is perceived, which occur in the fibres of organic muscles under similar circumstances. The conclusion to which Bichat's experiments lead him is, that during life the arteries have no contraction that is under the vital influence, and he refers all the circumstances usually brought forward to prove the contrary, to contractility of tissue. Thus, he observes, when an artery is tied at two points, and opened in the interspace, it empties itself of the blood contained in it, as well as of any other fluid accidentally placed in it. The same thing also occurs, when only one ligature is so applied, that it intercepts the influence of the

heart. The dependance of these circumstances upon contractility of tissue, he argues, is so much the fact, that, as long as the artery is free from putridity, they take place in the dead subject. If an artery be filled, and then opened, it empties itself by contracting. The contraction produced by defect of extension, is what Bichat regarded as a test of contractility of tissue; irritability, or organic sensible contractility, always implies the operation of a stimulus.

Bichat describes *organic sensible contractility*, or *tonicity*, as plainly existing in arteries. In those which pulsate, he says, it is restricted to the purposes of nutrition; but, as soon as the influence of the heart on the motion of the blood ceases, which (according to his theory) is probably at the beginning of the capillary system, then the organic insensible contractility begins to have effect, not only upon the nutrition of the coats of the vessels, but also upon the circulation within them. Indeed, in this physiologist's views, the circulation in the small vessels is altogether maintained by their tonic power, the heart having absolutely no concern with it.

Bichat represents the arteries as endued with *organic sensibility*, which he says is never separated from the organic insensible contractility. In the large trunks, however, where it is only necessary for their nutrition, it prevails in a very obscure degree. It is by the organic insensible contractility, and the organic sensibility, that Bichat would solve many of the difficulties attending the comprehension of the process of secretion. What Mr. Hunter and numerous modern physiologists would ascribe to the action of vessels, Bichat refers to those two rather imaginary properties of the minute arteries. The difference seems, after all, to consist rather in words than meaning.

The following is a summary of the principal arguments, respecting the muscularity of arteries:

1. When arteries are stimulated in living animals with a sharp instrument (*Verschuur, De Arter. et Venarum Vi Irritabili*, p. 17), strong acids,* or electricity (*Birker, De Nat. Hum.*, p. 45, Lugd. Bat.), the portion of the vessels so stimulated is declared by the subjoined experimenters to contract. On the other hand, the contraction of an artery on its being pricked, variously stimulated, or even galvanized, is positively denied by Bichat,† who ascribes the

* Zimmermann, *De Irritabilitate*, p. 24. Larry, in *Vandermonde's Journ.*, tom. vi., p. 7. *Verschuur*, op. cit., p. 19.

† Wedemeyer's experiments support the doctrine of Haller and Bichat, that the greater arteries do not possess irritability, or vital contractility. With a battery of fifty pairs of plates, Wedemeyer galvanized the carotid artery, and the thoracic and abdominal aorta, sometimes during life, sometimes immediately after death, caused in various modes, and the artery was sometimes left in connexion with the heart, and sometimes removed from the body; but its result was always the same: he never could remark any contraction. Neither could he excite any contraction with mechanical stimulants. Wedemeyer could not perceive that galvanism produced any contraction of the arteries of the umbilical cord and placenta, as asserted by

change produced by acids to a kind of crispation, attended with chymical injury of structure, whereby the vessel is for ever prevented from resuming its pristine diameter, which it would do, if the contraction depended on mere stimulation. But in opposition to him, we have again the galvanic experiments of Giulio and Rossi, and that of Sir E. Home, who, as we have noticed, produced violent throbbing in the carotid by applying alkali to the great sympathetic nerve.*

2. Arteries are said to be capable of a peristaltic motion. The editor is not acquainted with the facts on which Soemmerring (*De Corp. Hum. Fabricâ*, tom. v., p. 66), founds this statement; unless it refer to Dr. Whytt's exploded hypothesis of an oscillation in the minute vessels.

3. The doctrine of the contractile power of the capillaries has received important corroboration from the experiments of Drs. Wilson Philip, Thomson, and Hastings. These gentlemen placed the web of a frog's foot in the microscope, and distinctly saw the capillaries contract upon the application of such stimulants as cause the contraction of the muscular fibre. Dr. Hastings found, also, the large arterial trunks, and even the veins, contract, as Verschuur and others had previously noticed. Dr. Thomson has seen the arteries contract in such a degree, on the application of ammonia, that their cavity appeared to be quite effaced. On the contrary, the muriate of soda always caused a dilatation of them.

4. Arteries are alleged to pulsate very differently in different parts. With reference to strength and fulness of the vessels, the editor's own observations enable him to corroborate this fact; but he has never known an artery of one part of the body beat more slowly or quickly than the rest of the arterial system. The occurrence, however, is mentioned by writers as a fact. An increased flow of blood to any particular organ, whether in health or disease, is

Osiander. The apparent contraction of the aorta under electricity, he says, is nothing else than increased pulsation, arising from the action of the electric fluid on the heart, which is excited to increased action. Oesterreicher has observed in fishes alternate contraction and dilatation of the bronchial artery. Wedemeyer has made the same observation; but says that this may easily be accounted for, because, near the origin of the vessel at the heart, distinct muscular fibres may be traced, not at all like the hard fibrous coat of the arteries in general. The same structure, he says, is particularly conspicuous in the torpedo. On the other hand, Cuvier's statement, that the fibrous coat of the arteries in the elephant is plainly muscular; and Bèclard's, that the same tissue in the arteries of the human subject actually contains fibrine; must not be forgotten in forming a judgment on this contested point.

* Oesterreicher explains this fact on a different principle: if a nerve, supplying any vessel, be divided, and then stimulated at the end farthest from the brain, the artery does not pulsate with greater force; and hence, if its pulsation is increased when the nerve is not previously divided, this arises from nothing else than the increased action of the heart, caused by the pain inflicted on the animal.—Ed.

inexplicable, unless some change in the diameter, or action of the vessels supplying it, be taken into the account.

5. In one case upon record, the pulse of the arteries of a paralytic arm was quite indistinguishable; while, in the other arm, it was full and strong.—(*Hoffmann von der Empfindlichkeit*, &c., § 842.) Here it is argued, that, if the pulse had depended upon the heart alone, it would have been as strong in the paralytic as in the healthy limb. Some highly instructive examples of the entire want of pulsation in the arteries of paralytic limbs are recorded by Dr. Storer,* by whom, however, this effect is described as exceedingly uncommon.

6. Another argument is derived from the operation of local stimulants in producing inflammation. The lachrymal gland, when the eyes are irritated, or when it is itself affected through the mind, pours fourth tears. The saliva is more copiously secreted from the effect of stimulating medicines, or of the sight and smell of victuals.

7. It is argued also, that, as the nerves of arteries are quite evident and abundant, these vessels must be connected with the brain, and be influenced by affections of the nervous system. Putting out of the present consideration the results of experiments, in which the effect of stimulating the nerves of arteries was examined, and about which the flattest contradictions prevail, let us only recollect the quick action of blushing; the instantaneous paleness of fear; the influence of the mind over the secretions; and the sudden distention of the corpora cavernosa from mental causes; and we can scarcely fail to conclude, that the arteries are under the influence of the nervous system.

8. One important argument in favour of the contractile power of the arteries, is derived from cases in which the circulation was carried on, although the heart was either wanting, defective in its structure, or more or less ossified. Examples of the first kind are recorded by Hewson (*Exp. Inq.*, vol. ii., p. 15) and Brodie (*Phil. Trans.*, 1809, p. 161), and of the latter by A. Burns, and other writers. According to Mr. A. Burns, the left ventricle of the heart may be so ossified, that it can have no share in propelling

* Trans. for Improvement of Med. Knowl., vol. iii., p. 448. Such cases seem to affect very much the doctrines maintained by Wedemeyer and others, that all the phenomena of the arterial pulse may be imitated exactly, when life has been for many hours extinct, by impelling water into the vessels by successive jets from a syringe; that the pulse is owing entirely to the impulse communicated by the heart, in consequence of which the artery is partly dilated, and partly made to shift its place; that all the phenomena of the circulation may be referred to the elastic contractility of the arterial coats, and that the greater arteries, therefore, contribute to move the blood forward only by restoring, through their elastic reaction, the force expended in dilating them. The power of arteries to contract beyond the point to which their elastic materials will bring them, as demonstrated by Hunter, is here also to be remembered, as not admitting of explanation without reference to a vital contractility.—Ed.

the blood into the arteries. Yet the circulation is continued through all parts of the body. And, from what happens in cases of ossified arteries, he infers, no doubt with considerable exaggeration, that the circulation can be much better conducted without the action of the ventricles, than without the reaction of the arteries. The cases of ossified heart reported by Mr. A. Burns are highly interesting.—(*On Diseases of the Heart*, p. 129, &c.)

Drs. W. Philip and Hastings (*Treatise on the Mucous Membrane*, *Introd.*, p. 51), in their experiments, saw the circulation in the small vessels continue for some time after the heart had been removed from the body; a circumstance hardly explicable without the admission of an action in the vessels themselves.

9. It is decidedly proved, that, during life, an artery can contract below its middling diameter, or that width to which its mere elasticity would reduce it. How can this be effected, but by muscularity?

10. Arteries, empty at the moment of death, and even contracted below their middling diameter, recover their ordinary size as soon as the vital influence is completely exhausted. Their muscular power is then annihilated, and their elasticity predominates.—(*See Experiments in Hunter on the Blood*, p. 116, &c.)

From the tenour of all that has been said, the existence of a power of contraction in the minute vessels can hardly be doubted, whatever may be the opinion espoused respecting the muscularity of the arterial trunks. Some physiologists, not exactly agreeing with Mr. Hunter, may yet be disposed to consider the latter simply in the light of a mechanical or hydraulic system, and the capillaries as the physiological or vital organs.*

The wisdom with which the structure of the body is contrived, is most convincingly exemplified in the vascular system. We have instances of it in the universal situation of the arterial trunks in the direction of the flexion of the joints, whereby they are hindered from being overstretched, and are protected from external injury; in their occasional tortuosities, by which they are enabled to adapt themselves to the continually changing positions of organs, without suffering from extension; and in their anas-

tomoses, or frequent communications with one another, by which the necessary supply of blood to parts is rendered secure, when any particular trunk is temporarily obstructed by pressure, or permanently obliterated by this and other causes.

After having divided, and ramified to a considerable extent, and in a manner generally resembling the branching of a tree, the arteries, both of the greater and lesser circulations, terminate in the general capillary system. The exact point at which the arteries end and the capillaries begin, cannot be demonstrated. According to Bichat, it is where the blood ceases to be at all under the influence of the heart, and the circulation is first maintained altogether by a contractile power of the minute vessels, to which he allots the mysterious term of insensible organic contractility. But this imaginary limit would not satisfy many physiologists, particularly those who argue that the action of the heart always extends its effect to the capillaries, as well as the arteries in general. Anatomists commonly describe the arteries as terminating in excretory tubes, exhalants, veins, &c.; but, in reality, the capillary system constantly intervenes between those vessels and the arteries. The microscopic investigations of Dr. Marshall Hall into the action of the capillary vessels tend to show, that they are a network of pellucid vessels, differing from the small arteries in the circumstance of their subdividing without becoming smaller; and freely anastomosing with each other, like nervous plexuses, forming thus, as Bichat always inculcated, an intermediate system of vessels between the arterial and venous system.* As already observed, while the large arteries are regarded by some physiologists as merely mechanical tubes, the minute ones, or capillaries, are known to be the part of the vascular system, in which all the important objects of the circulation are mainly prepared and accomplished, as nutrition, secretion, the oxydation of the blood, its decarbonization, &c.†]

* On the Circulation of the Blood, by Marshall Hall, M. D. Wedemeyer's account of the structure and disposition of the minute vessels is contained in his "Untersuchungen über den Kreislauf des Bluts," 1828; or in the 100th No. of the *Edinb. Med. Journ.*, July, 1829.

† With regard to exhalant pores, Dr. Wedemeyer objects to the notion that they are visible and organic, or, as he explains the term, endowed with a species of contractility, by means of which they retain certain substances, and discharge others. He maintains, that if any such pores existed, they would be perceptible with the aid of the microscope; and he considers that all the phenomena of exhalation may be produced through invisible pores, or the interstices between the ultimate particles which form the organic tissues, and may be explained by the phenomena of capillary attraction, as modified by the action of the nervous system on textures. In these views, as has been correctly noticed (*Edinb. Med. and Surg. Journ.* for July, 1829, p. 87), he approaches closely to the theory which M. Dutrochet has founded on his discovery of endosmose and exosmose. (See *op. cit.*, No. 99.) Magendie's experiments tend to establish the fact, that the exhalants do not terminate in open orifices, but that exhalation and

* See Bostock's *Physiology*, vol. i., p. 403. Dr. Marshall Hall inclines to the opinion, that the capillaries are rather passive than active canals, through which the blood is circulated by the impulse of the arteries, the absorbing action of the veins, and also by capillary attraction. He fully admits, however, the contractility of the small arteries.—(*On the Circulation*, &c.) Galvanism would appear, from the investigations of Dr. Reuss, of Moscow, and those of M. Dutrochet, Mr. Faust, Dr. Mitchell, and Dr. Stevens, to exercise a locomotive influence on the circulating fluids. For information on this curious question, see *Nouvelles Recherches sur l'Endosmose et l'Exosmose* &c., par M. Dutrochet, 1828; Faust's *Experiments*, &c., on the Endosmose and Exosmose of Gases, and the Relation of these Phenomena with Respiration; *Amer. Journ. of Med. Science*, vol. vii., Nov., 1830; Stevens on the Healthy and Diseased Properties of the Blood, &c.—*Ed.*

I have observed, that the force with which the blood is at first projected from the heart, is progressively diminished by the resistance it encounters in the thick and powerfully elastic tunica of the trunks or large arteries into which it is immediately propelled. There are two other causes which co-operate in producing a progressively diminishing force. The first is the short angles against which the blood has to strike at the origin of all the different branches; and the next, and most important, is the larger diameter of the general mass of the arteries, compared with that of the heart, or the arteries from which they immediately proceed; the range of the diameter augmenting in proportion to the increase of the ramifications. From experiments, indeed, made by Mr. John Hunter on the carotids of camels and swans (*On Blood, Inflammation, &c.*, part i., sect. viii., p. 170), the very same arteries appear gradually to widen from the end nearest the heart to that most remote from it. From all which he concludes, that the aggregate diameter of the arterial system forms a cone, whose apex is at the heart. And he concludes also, and most correctly, that this conic proportion is most obvious, increases most rapidly, and spreads with its broadest base in infants, or rather in the fœtus; for here the main trunks of the arteries are extremely short, while the capillaries are very large, and from the obliteration of many vessels in subsequent life, more numerous than at any other period. It is highly probable, indeed, that while the aorta in childhood is not a fourth part of the size of the same vessel in an adult, the aggregate of the capillaries of the former possesses a diameter more than four times as large as the aorta in the latter.

We may hence, in some degree, account for the difference in the quickness of the pulse at different periods of life. In early infancy it beats as much as 140 strokes in a minute; towards the end of the second year it is reduced to 100; at puberty it is only 80; about virility 75; and after sixty years of age seldom more than 60 in a minute. For reasons connected with the preceding, it is more frequent in persons of short stature, those of strong passions of mind, those of great muscular exertion, and in females. From the increasing diameter of the bloodvessels as they diverge from the heart, the blood has a greater space for moving forward, and is able to move with more freedom; and hence one reason for the empty state in which the arteries are found immediately after death: a second reason is, that the tunics of the veins, possessing little or no elasticity, readily dilate to the distensive power of the blood as it moves forward: a third, and indeed the principal reason, as sufficiently proved by Dr. Carson, is the natural elasticity or resilience of the lungs, which, by keeping them after death in a state of dilatation, allows the blood to accumulate here as in the vacuum. And hence, again, the reason of the accumulation of blood,

secretion take place through the thin coats of the vessels.—ED.

which is usually found in the chest after death, as well as the empty state of the vessels.

This vacuity of the arteries after death was one of the objections urged very forcibly by the ancients against the circulation of the blood, or even its following at all the course of the arteries; and which Dr. Harvey very unsatisfactorily replied to, by asserting, contrary, indeed, to fact, that the heart continues to contract for some time after death, and even after it has received blood; for it is generally found loaded with blood.—(Carson "*On the Vacuity of the Arteries after Death*;" *Med. Chir. Trans.*, vol. xi., part i.)

The pulmonary artery, which receives from the heart the blood returned into it from the veins, bears a very close proportion to the diameter of the aorta (Hunter, p. 133), which sends the blood from the heart over the whole of the larger circulation. The aorta possesses more strength, but their elasticity is nearly equal, and the measure of each, on being slit, is about $3\frac{1}{2}$ inches: and hence there can be little doubt, that the quantity of blood sent back to the heart is on an exact balance with that which flows from it. It is not, however, at any time the identical blood, which is thus returned to the heart; for every organ takes from the general current, as it visits it, such parts and such principles as it stands in need of to support the wear and tear of its own action; while another considerable portion is thrown off, as we have already observed, in the form of secretions or exhalations, from various emunctories that open externally or into internal cavities. But the drain which is hereby produced on the arterial blood, is compensated by the various fluids collected from every part by the absorbent vessels, and by the flow of the chyle from the digestive organs; both which are poured into the thoracic duct, and finally intermixed with the returning current of venous blood a short time before it reaches the heart; and, in this manner, the balance of arterial and venous blood is maintained.

With respect to the actual quantity of blood contained in the entire system, our means of determination are so inexact, and consequently the calculations, or rather the conjectures, that have been offered upon the subject, are so strikingly discrepant, that it is not easy to reach a satisfactory conclusion. It is only necessary to state a few of the different opinions that have been offered, to show the absurdity of several of them. Muller and Abeildgaard estimate the weight, even in an adult, at very little more than eight pounds (*Blumenb. Elem. Phys.*, p. iv., sect. 6); Borelli at twenty; Planch at twenty-eight; Haller at thirty; Dr. Young at forty (*Phil. Trans.*, 1809, p. 5.); Hamberger at eighty; and Keil at one hundred. Blumenbach states the proportion in an adult healthy man to be as 1 to 5 of the entire weight of the body. Yet, little reliance can be placed on this last mode of determination, on account of the great diversity, in point of bulk and weight, of adults, whose aggregate quantity of blood is in all probability nearly alike. The mean numbers, as those of Baron Haller and Dr. Young,

making the amount from 30lb. to 40lb., appear most reasonable; and, perhaps, fall not far short of the sum intended by Blumenbach. The subject requires further examination, and a nicer estimate.

II. There is another question, which has also, in all ages, greatly occupied the attention of physiologists, but upon which we still remain in a very considerable degree of indecision; and that is, the **MOVING POWERS** employed in the circulation; or, in other words, the projectile force by which the blood is sent forward.*

[Harvey, Haller, Spallanzani, Legallois, Pary, and Magendie maintain, that the sole moving power of the blood is the action of the heart. Pecquet, Bartholine, Bohn, Senac, Verschuir, Zimmermann, John Hunter, Blumenbach, Scemmering, Langenbeck, Tiedemann, Béclard, Sir E. Home, Dr. Hastings, and Dr. W. Philip infer from their researches, that the circulation does not depend on the heart alone, but is also supported by muscular contraction of the arteries. Darwin, Bichat, Richerand, and probably Meckel, deny that the greater arteries possess vital contractility, or contribute to the propulsion of the blood, but assign to the smaller

arteries and capillary vessels a *vital contractility, through means of which the blood is first attracted, and then propelled, and ascribe to the circulation in them a nearly complete independence of the influence of the heart.* Others, as Carus, Treviranus, Döllinger, and Oesterrheicher, are led by their inquiries to believe, that neither the larger arteries, nor the capillary vessels, contribute by their contractions to the progress of the blood; but, that *the blood moves chiefly through means of its vitality, or an inherent power of motion, and that its movement, as thus effected, is materially supported by the action of the heart alone.*]*

The heart forms the salient point of motion, and with its systole or contraction the circulation commences. But what is it that excites the heart to contract! One of the most common answers to this question, in the writings of physiologists, is, the flow of the blood into the ventricles. But this is merely to argue in a circle; for the question still returns, what is it that makes the blood flow into the ventricles! Others have referred the cause to an immediate impulse from the brain. Now, in contractions of the voluntary muscles, there is no doubt of the existence of such an impulse, for we are conscious of it, and assent to it; but we are neither conscious of, nor assent to, any thing of the kind in respect to the contraction of the heart; and are perfectly sure that no such power of the will takes place during sleep. It is a mere assumption; and an assumption which can only apply to a part of the great animal kingdom, even during wakefulness; for, as it is only in mammals and birds that the nerves can be thus influenced in their passage to the heart, the postulate does not account for the contraction or dilatation of the heart in other classes of animals.

Mr. John Hunter ascribes this action of the heart, or rather the whole career of the circulation, of which he regards the action of the heart as a single and ordinary link in the general chain, to what he calls a stimulus of necessity; by which he seems to mean, an instinctive power, dependant on the general sympathy of the system, which in every part is craving or demanding such an alteration; or, in other terms, is uneasy without it. His words are as follow:—"The alternate contraction and relaxation of the heart constitutes a part of the circulation; and the whole takes place in consequence of the necessity, the constitution demanding it, and becoming the stimulus. It is rather, therefore, the want of repletion, which makes a negative impression on the constitu-

* In the Am. Journal of Med. Sciences, No. 22, p. 348, Dr. Robinson, of Petersburg, Va., has recorded an interesting case of malformation, which may throw additional light on the action of the heart. In a newborn and full-grown infant, the two clavicles, the sternum, and the costal cartilages were deficient; and the cavity of the thorax was exposed to view. The pericardium was absent, and the motions of the heart were observed for fifteen or twenty minutes; this organ was then removed from its attachments, opened, and thrown into a basin of cold water. It however still continued to beat, with less force, but with perfect regularity. The conclusions drawn by Dr. R., from seeing and touching the heart, are as follow:—"Systole and diastole are the natural muscular actions of the heart. The force of the diastole is equal to, if not greater than, the force of the systole. There is no pause between auricle and ventricle, either in diastole or systole: the action passing from base to apex with great velocity; perhaps accelerated, certainly not retarded. There is not only no pause between the diastole and systole, but the latter almost seems to appear before the former vanishes: thus presenting the appearance of one compound action, in which all the parts concerned co-operate perfectly. The diastole always precedes the systole in the natural order of action. Similar actions in similar parts of the different sides are always synchronous. The time of action, including systole and diastole, is less than the time of the pause. The pause succeeds the systole of the organ. The impulse of the apex against the side of the thorax is caused by the diastole of the auricles, especially the left; for, as the distance of the axis of the heart from the diaphragm must be increased by the increase of its transverse diameter in diastole, and as it is firmly tied down at its base, this increase of distance of the axis can be effected only by its turning on the distended auricle—as each action of the heart is performed by a convulsive jerk, the force of the impulse is naturally accounted for. There is in the heart a vis insita, or vis propria: this is demonstrated by its perseverance in action so long, after its entire separation from all influence of the brain, nerves, and ganglions."—D.

* See Wedemeyer's Untersuchungen über den Kreislauf des Bluts, &c., Hanover, 1828; and Edinb. Med. and Surgical Journ., No. c., July, 1829, in which a detail of the contents of Wedemeyer's treatise will be found; the first part of which treats of the part performed by the greater arteries in the circulation; the second, of the movement of the blood in the minute arteries and capillaries; the third, of the movement of the blood independently of mechanical actions; and the fourth, of the phenomena of capillary attraction in the animal system.—ED.

tion, which becomes the stimulus, than the immediate impression of something applied to the heart. This we see to be the case, wherever a constant supply, or some kind of aid, is wanted in consequence of some action. We have as regularly the stimulus for respiration, the moment one is finished an immediate demand taking place; and if prevented, as this action is under the influence of the will, the stimulus of want is increased. We have the stimulus of want of food, which takes place regularly in health, and so it is with the circulation. The heart, we find, can rest one stroke, but the constitution feels it; even the mind and heart are thereby stimulated to action. The constant want in the constitution of this action in the heart, is as much as the constant action of the spring of a clock is to its pendulum, all hanging or depending on each other.”—(*On Blood*, p. 149.)

Mr. Hunter’s “Treatise on the Blood” is a work of such sterling merit, so rich in its facts, and so valuable in its remarks, that, notwithstanding a few nice-spun and chimerical speculations that occasionally bewilder it, there is no book on physiology which a student ought to study more assiduously. Yet I am much afraid, that the language now read has no great deal of meaning in it; and that it does little more than tell us, that the heart contracts because it contracts, or, rather, that the circulation takes place because it takes place.

Few physiologists indeed seem to have adopted this opinion: and hence a far more plausible and intelligible hypothesis has been since offered. This consists in supposing the heart to be stimulated by the oxygen of the blood introduced into it in the lungs by the process of respiration. Such was the favourite opinion of Dr. Darwin; and such appears to have been the opinion of Blumenbach, who was so fully persuaded of the oxygenized state of the blood when first received by the heart and poured into the arteries, that he expresses a desire of changing the terms *arterial* and *venous* blood for *oxygenized* and *carbonized*.

That oxygen, if introduced into the blood, would stimulate the heart, there can be no doubt, from numerous experiments which prove that a very small quantity of any foreign body whatever, even an ounce or two of solution of gumarabic, infused into the blood by opening a vein, will not only stimulate the heart, but the stomach, intestinal canal, and other organs, with which the heart readily sympathizes.—(*De Chirurgiâ Infusoriâ renovendâ*. Aut. J. M. Regnaudot, Svo., Lugd. Bat., 1779.) [Whether the gumarabic thus injected into the veins would stimulate the preceding viscera, requires proof; but various experiments of M. Magendie show, that it would produce death on another principle; namely, that of obstructing the capillary circulation in the lungs. The hypothesis of Darwin is refuted by the fact, that it would at all events only account for the contraction of the left cavities of the heart; since those of the right side, which perform their contractile functions perfectly well, receive blood that

has not undergone the oxygenating change of respiration. Mr. Brodie found in his experiments on rabbits, that the heart continued unaltered for at least two minutes after that viscous and the great bloodvessels were empty of blood; and hence he concluded, that its action does not depend upon the presence of the blood in its cavities.—(See *Cook on Nervous Diseases*, *Introd.*, p. 61.) It should also be recollected, that if the contact of the blood were necessarily followed by the contraction of the heart, this organ would never be relaxed, because, though the quantity of that fluid undoubtedly varies at different moments in the auricles and ventricles, it is difficult to suppose that they are ever free from it. Senac’s doctrine, that the contraction of the heart is caused by the stimulus of the distention of the blood, is also one that cannot now be retained.]

But passing by, till this question is settled, the doctrine of the primum mobile, or first moving power of the blood from the heart—by what means is the motion, thus mysteriously commenced, maintained afterward through the whole circulatory course? Harvey replied to this question by asserting, that it is maintained by the action of the heart alone, which propels the blood equally through the entire length of the arteries and veins, both which he regarded as tubes alike inert, and in no respect contributing to the propulsive energy.

This dictum was at first received with universal assent; and the mechanical physiologists immediately set to work, in order to calculate the force with which the heart acts at every contraction, in the same manner as they had endeavoured to calculate the force of the stomach in the process of digestion. It is not necessary to enter into the detail of these estimates. It is sufficient to observe, that, from Michelot to Sauvages, or Cheselden, they all differed from each other as widely as in calculating the quantity of blood in the system; and that, while Keil estimated the projectile power of the heart at five ounces, and Hales at fifty-one pounds and a half, Borelli fixed it at no less than one hundred and eighty thousand pounds.*

There are various facts, however (and several have been already mentioned in the course of this proem), which sufficiently prove, that the heart cannot be the sole propulsive power through the entire range of the circulation. The two following are also much insisted upon: Firstly, that the pulse, if the systole of the heart were the only projectile force, must take place, not SYNCHRONOUSLY all over the system, as it is well known to do, except in a few morbid cases in which local causes interfere, but SUBSEQUENTLY to the contraction of the heart, and SUCCESSIVELY through the whole line of the arterial tubes, in proportion as they lie more

* For some valuable matter on this point, see the *Researches* of J. L. M. Poiseuille on the Force of the Aortal, or Left Side of the Heart, in *Breschet’s Répertoire Gén. d’Anat.*, &c., 3me trimestre de 1828; or, the translation in *Edinb. Med. and Surg. Journ.*, No. for July, 1829, p. 28.—ED.

remote from the salient point.* And, secondly, that whatever may be the projectile power of the heart, it must altogether cease with the arteries, and cannot reach the veins.

And hence arose another hypothesis, which ascribed the propulsive power to a progressive *vis a tergo*, or a force communicated from the ventricles of the heart to the commencement of the arteries, producing a vibration or alternate dilatation and contraction of their tunics through their whole length to the veins; and thus acting in conjunction with the projectile force of the heart itself.

In proof of this auxiliary power afforded by the coats of the arteries, the phenomenon of pulsation was triumphantly appealed to; which, it was maintained, gave a direct and incontrovertible evidence, that an alternate dilatation and contraction, or enlargement and diminution in the diameter of the arteries, is constantly taking place. This, by Bichat, is attributed solely to the locomotion of the arterial tubes, propagated to their terminal ramifications, and thence continued to the veins; but, by most modern physiologists, to a joint power, compounded of the action of the heart and the arteries.

Bichat's doctrine has of late been incontrovertibly refuted by one or two very simple experiments of M. Magendie.—(*Physiologie*, tom. ii., p. 320.) Besides which, however, it is now a well-ascertained fact, and one that has been thoroughly elucidated by Dr. Parry of Bath (*Exp. Inq. into the Nature, Cause, and Varieties of the Arterial Pulse*, &c., Bath, 1816), that no increase of size, or indeed change of bulk of any kind, takes place in arteries during either the systole or diastole of the heart's ventricles in a state of health. The arteries of animals, to ascertain this point, have been exposed in different parts, and to considerable lengths, without evincing the least apparent increase of size. And hence it is the pressure of the finger, or of some other substance against the side of an artery that alone occasions pulsation, in consequence of the resistance hereby made to the regular flow of the blood; the alternating beat being produced by the greater momentum with which the current strikes against the finger or other cause of obstruction during the systole, than during the diastole of the heart.

Döllinger confirmed Parry's experiments by laying bare the carotid of a dog before his pupils, which gave to the eye no proof of altered form or motion, though a pulse was distinctly felt by the finger. And, in like manner, a pulsatory motion is always felt by the fingers when applied to a leaden water-pipe while a pump is at work upon it at one end, and alternately giving a fresh pressure to the column of water it contains by forcing in a fresh supply: yet the pipe is all this time incompressible.

[Sir David Barry plunged his arm into a horse's chest, and found the aorta constantly

full, without any variation of its distention for an instant, though he took hold of it for five minutes, and repeated the experiment. On the other hand, the vena cava was so little distended that it felt like a thin flaccid membrane. (*Dissert. sur le Passage du Sang à travers le Cœur*, p. 78, Paris, 1827.)]

In inflammation, the pulse of the inflamed part in consequence of local excitement is much more frequent than that of the heart or of any other organ. Thus, in a whitlow, the radial artery may give to the finger a hundred pulsations in a minute, while not more than seventy strokes may be exhibited in any other part of the system. The rapidity of the pulse is in this case usually in proportion to the degree of the inflammatory action (*Exp. of the Prin. of Pathology*, &c., by Daniel Pring, M. D., p. 119, 8vo., 1823): and hence, if the system should labour at the same time under ten different inflammations in different parts or organs of a different structure, as glands, muscles, and membranes, it is possible that it may have so many different seats of pulsation taking place at such different parts at one and the same time, while all of them are at variance with the pulsation of the heart. Even where there is no inflammation, such discrepancies in the pulse are occasionally to be met with, insomuch that Riel gives a case in which the heart, the carotids, and the radial arteries all pulsated differently (*Memorabilia Clinica*, vol. ii., fascic. 1-6, Hall., 1792); and we can hence readily perceive why they should be more frequent and striking under the increased action produced by inflammation, and often, in a debilitated organ, more disposed to irregular action, and particularly irregular contractile action, in its capillaries.

[Respecting the correctness of the statement, that the pulsations of inflamed parts are often more numerous and frequent than those of the rest of the system, the editor has never seen a case in confirmation of it; and were not the thing asserted by so many men of eminence, he should be inclined to set it down as erroneous. In whitlows, and other cases, the arteries leading to the part affected throb with increased force; but never, as far as the editor's observations reach, with a quickness exceeding that of the action of the heart. However, if the statement made by writers be accurate, physiologists need no longer doubt and dispute about the muscularity of arteries, and even of those which cannot be regarded as capillaries, to which all physiologists impute a contractile power under some name or another.]

We are let a little into the mystery of the above-mentioned phenomenon by the curious fact, that some of the arteries possess a higher degree of contractile power than others, and that the capillaries possess the highest measure allotted to any of them. "Indeed, every fact," observes Dr. Bostock (*Physiology*, vol. i., p. 402), "with which we are acquainted, respecting the mechanism and functions of the sanguiferous system, leads us to the same conclusion, that the large arteries are to be regarded as canals transmitting the blood from the heart,

* This is still maintained to be the fact by M. Poiseuille, as will be presently noticed.—Ed.

where it receives its great impulse, into the smaller branches; and that it is chiefly in these smaller branches that it exercises its various functions." We may hence see why the capillaries are, in many cases, so much sooner excited than the larger canals, and exhibit so much more violence of action: a distinction of high importance in explaining the doctrine of inflammation, though it has been less attended to by pathologists than it deserves.

The hypothesis, therefore, of a *vis à tergo*, whether dependant upon the heart alone, upon the arteries alone, or upon a combination of the two, has by no means proved sufficiently satisfactory, or been sufficiently supported by evidence in respect to the entire circulation. Under no modification does it account for the flow of the blood through the veins. And in regard to the whole of the views which have been thus far examined, Mr. John Hunter, as I have already observed, was so extremely discontented, that he placed no more stress upon one part or organ of the sanguiferous system than upon another; upon the heart than upon the arteries; or upon the arteries than upon the veins; regarding the whole economy as the result of a sort of instinct, to which, as just noticed, he gave the name of a stimulus of necessity; and which opinion he supported by making an appeal to insects which had no proper heart; to worms, most of which have no heart whatever; and to monsters which have been born without a heart; while at the same time he contended that veins, at least the larger, exhibit, under certain circumstances, an expansile and contractile power as well as arteries. "I think it probable," says he (p. 187), "that where there is a universal action of the vascular system, the action of the arteries and veins is alternate: that where the arteries contract, as in many fevers, the veins rather dilate, more especially the larger." And it is hence again highly probable, that in this "universal action of the vascular system," the secretions, or extreme arteries, take an important part; and not impossible, though the thing needs proof that they operate, as has been suggested by Dr. Pring,* by a kind of suction, which may be regarded as a *vis à fronte*.

* Ubi *suprà*, p. 132, 165. With respect to Bichat's doctrine, that the impulsive power of the heart is almost nugatory in relation to the blood in the capillaries, Dr. Wedemeyer does not admit its correctness, observing, that the transmission of the heart's impulse, even to the extreme capillaries, may be inferred from the slight force required to impel water, a solution of indigo, or fresh drawn blood, through them with a syringe, even from a large artery; a force certainly inferior to that with which the blood in the same artery flows through it under the action of the heart during life. This statement, as an able critic has remarked, receives corroboration from the late discovery of M. Poiseuille, of Paris, that each molecule of blood retains the force it received from the heart, even after it has passed through a long course, and through many subdivisions of the arterial system.—(Edinb. Med. Journ., No. c., p. 88.) That the impulse of the heart extends even to the capillaries is further shown by the effects of deple-

Upon the whole, we may conclude with Haller, that the heart exerts a very considerable degree of force in the general economy of the circulation, although it is impossible to estimate its power with mathematical precision. And we may reasonably refer the first or arterial half of the general circuit of the blood to this force, if not alone, in conjunction with the aid contributed by the elastic and contractile tunics of the arteries themselves, whether pulsation be a result of these powers alternately exercised, or of mere local pressure.*

It yet remains, however, to account for the second half, or that which consists in the passage of the blood through the veins; and upon this subject, there is one most important and elucidating fact, which, till of late, has never been in any degree brought forward in the course of the inquiry. It is this: that when the heart, by the contraction of its ventricles, has exhausted itself of the blood contained within it, a comparative vacuum must follow, and the blood from the *venæ cavæ*, or venous system at large, be sucked up into the right auricle.† This ingenious remark seems first to have been thrown out by Dr. Wilson Philip (*Inquiry*, &c., p. 9, &c.): and Dr. Carson, of Liverpool, taking advantage of it, has constructed a simple and beautiful theory of the projectile powers employed in the circulation, the general principle of which may be expressed in a few words. The heart is supposed to act at one and the same time in a twofold capacity. By the contraction of the ventricles, it propels the blood

tion, or of fainting, on sanguinolent secretions, on redundant secretions, and on hemorrhage.—Ed.

* It would appear from Dr. Poiseuille's experiments, that the force with which a molecule of blood moves in the carotid or in the aorta, is precisely the same with the force of its movements in the smallest arterial branches: or, in other terms, that a molecule of blood moves with the same force throughout the whole arterial system; "a fact," says this author, "which I was far from anticipating. It is not easy to account for the uniformity here unfolded. When the heart contracts, a wave of blood is pushed into the arterial system, already full of blood. The phenomena that ensue are dilatation of the arteries, and a kind of locomotion of the arterial system, by which its curvatures tend to straighten themselves. These changes cannot take place except at the expense of the force with which the wave is propelled from the heart. But hardly has the arterial system become dilated, and scarcely have its curvatures yielded to the action of the heart, when the arteries, through the elasticity of their coats, contract again, and restore to the force of the blood all the loss it had sustained. In this way, perhaps, we may explain how the intensity of the force communicated to the blood by the heart, is preserved (as the experiments referred to show), even to the last arterial ramifications."—See Edinb. Med. and Surg. Journ. for July, 1829, or Breschet's *Répertoire Gén. d'Anat.*, &c., 1828.

† Bichat and Dr. Bostock deny the existence of this suction-power, which, however, has Wedemeyer in its favour, who conceives that the heart has the power of promoting the capillary circulation, though only in a feeble degree, by the suction-power of its *auricular cavities*, or the blood in the veins.—Ed.

through the arteries; and by the dilatation of the auricles, it draws it up from the veins. It is at once, therefore, a forcing and a suction pump. The contraction of the heart, and consequently its comparative vacuum, are supposed to be considerably assisted by the elasticity of the lungs, and the play of the diaphragm, which we had occasion to notice at some length in our physiological proem to the preceding class, and the great resistance which they jointly afford to the atmospheric pressure; while this very pressure, applied on every part of the exterior of the animal frame, contributes in an equal degree to the ascent of the blood in the veins; for as the column of venous blood is perpetually girt on all sides, and cannot fall back because of the numerous valves with which the veins are furnished, it must necessarily take an opposite or ascending direction.

A suction power, however, as existing in any part of the heart, has been positively denied by Sir David Barry; whose hypothesis transferred it from the ventricles of this organ to the cavity of the thorax, or rather to the great veins contained within such cavity. The grand cause of the venous part of the circulation is, with him, "atmospheric pressure, diminished, or entirely taken off, around the cardiac ends of the venous tubes, during the expansion of the chest, but unaltered and entire around every other part of their surface, opposed only by the gravity of the fluid acted upon." He has, indeed, sufficiently shown, by a multitude of experiments, that the suction operation of the great veins is precisely coincident with the instant, in which the animal experimented upon endeavours to form a vacuum in the chest: that the black blood passes through the veins only during the act and time of inspiration; and that this venous movement is always placed under the influence of atmospheric pressure. There can hence be no doubt that the action of the atmosphere upon the cavity of the chest during the alternating process of inspiration and expiration, exercises a much more powerful effect upon the circulating system than has hitherto been taken into the account. But as the pulsation of the heart and arteries may be made to continue with regularity, even in mammalian animals, by a forced quiescence of the lungs, for sixty or eighty strokes in succession, in divers for half an hour, and in syncope for a much longer period of time; and as a like circle of action is found to prevail in animals below this rank, as in fishes and reptiles, whose mode of respiration is different, and does not allow of the same thoracic suction power, Sir David Barry seems to have overrated the assistance which the venous circulation derives from this quarter, in concluding, that of all the contributing forces, "the pressure of the atmosphere is by far the most intense in its degree, the most constant in its influence, and the most unvarying in its amount: that, without which, the circulation could not be maintained beyond a few moments."—(*Experimental Researches*, &c., p. 53, 8vo.) It is well observed by Dr. Bostock, that in the healthy state of the system, we respire, upon the aver-

age, about twenty times in a minute, while the average velocity of the pulse may be estimated at eighty, so that the heart contracts *four times during each act of respiration*; and must consequently receive the blood during all the various states of distention to which the lungs are subject; yet we do not perceive that the pulse exhibits any corresponding variations, either in its strength or its velocity. And further, we shall find it very difficult to produce any effect upon the pulse by the most powerful voluntary efforts of inspiration or expiration; yet, in such cases, the capacity of the thorax will certainly undergo a much greater change than it can possibly experience in its ordinary action.*

There are, nevertheless, numerous difficulties that yet remain to be explained; such as the proportion of projectile power furnished by the conducting pipes themselves; by what means the want of a diaphragm is compensated in birds and reptiles which have no such organ; what constitutes the projectile power in animals that have no heart, and consequently no double pump to work with; † [the mode of contraction

* *Elementary System of Physiology*, vol. ii., p. 56, 8vo., 1826.—The above observations on Sir David Barry's theory were lately found among Dr. Good's papers, and would have been inserted in the last edition of this work, had they been put into the editor's hands early enough for the purpose. Wedemeyer infers from an experiment made on a horse, the particulars of which are given in the *Edinb. Med. Journ.*, No. c., p. 89, that, in the natural state of the breathing, the suction-power must be very insignificant, which, according to Sir David Barry's researches, is exerted upon the venous blood by inspiration. Wedemeyer objects to that author's statements, 1. That the tendency to a vacuum in the chest during inspiration must be completely overcome by the entrance of the air, an elastic mobile fluid, before any material suction-power can be exerted on a heavy inelastic liquid, such as the blood. 2. That the afflux of blood in a tube towards the jugular vein of the horse, was observed by Sir David Barry to correspond with inspiration only when the animal was lying, and consequently breathing with unnatural force with one side only of the chest; and that, in the erect posture, no such correspondence is to be observed, unless the animal be excited to violent respiration. 3. That the tendency to a vacuum in the chest cannot account for the movement of the blood in the pulmonary veins, which are subjected outwardly to the same power which is supposed to act on the blood within them. 4. That the venous circulation may be kept up in the mammalia by artificial breathing, for twenty-five minutes or longer after decapitation, although, in such circumstances, the chest internally is constantly subjected to pressure; and that in frogs and other cold-blooded animals, the venous circulation will continue for hours, after the breathing has been annihilated by laying open the chest. 5. That the venous circulation goes on in the fœtus, and in many of the lower animals, without any respiratory movements whatsoever. These objections, along with what has been advanced by Dr. Arnott on the subject, seem to an able critic to render the supposed discovery of Sir David Barry exceedingly doubtful. *Vid. Edinb. Med. Journ.*, No. cc.; and Wedemeyer's *Untersuchungen über den Kreislauf des Bluts*, 1828.—Ed.

† *Diatribe Anatomico-Physiologica de Structurâ*

in the vessels; since, as there are no valves in the arteries, if the contraction be supposed to take place simultaneously in their whole course, it may appear to some physiologists as likely to have a tendency to propel the blood backwards or forwards. Indeed, Bichat avails himself of the fact, that the arteries have no valves, to strengthen his position, that these tubes cannot be muscular.]

There is also another curious fact, which physiology has pointed out, but has never hitherto been able to explain; and that is, a direct communication between remote or unconnected organs, apparently, by some other channel than the circulation of the blood. Something of this kind seems to exist between the spleen and the stomach, the former of which has been proved by Sir Everard Home to receive fluids from the cardiac portion of the latter, though we can trace no intercourse of vessels: but the most extraordinary example of this kind which at present we seem to possess, is, the communication which exists between the stomach and the bladder. For the experiments of Sir Everard Home, (*Phil. Trans.*, 1811, p. 163), and the still more decisive ones of Dr. Wollaston and Dr. Marcet, (*Ibid.*, p. 96), seem to have established beyond a controversy, that certain substances introduced into the stomach, as rhubarb, or prussiate of potash, may pass into the bladder without taking the course of the bloodvessels, and consequently by some other channel; a channel, indeed, of which we know nothing.* This is a subject well worth studying: for if two organs, so remotely situated as the stomach and the bladder, be thus capable of maintaining a peculiar intercourse, so other organs may possess a like intercommunication; and, by such means, lay a foundation for those numerous sympathies between distant parts which so often strike and astonish us. M. Magendie's hypothesis, that veins are absorbents, may explain the facts in Sir Everard Home's experiments, but has no bearing upon that of Dr. Wollaston and Dr. Marcet.

The discovery of the circulation of the blood has given a great importance to the DOCTRINE OF PULSATION; for by the strength or weakness, the slowness or frequency, the hardness or softness, the freedom or oppression, the regularity or irregularity of the beat of the artery against the pressure of the finger, we are now able to determine many momentous facts, relative, not merely to the state of the heart, but of the general system; and, in many cases, to prognosticate upon grounds which were altogether unknown to the earlier cultivators of medicine.

atque Vitâ Venarum: à Medicorum ordine Heidelburgensi præmio proposito ornata.—Auctore Henrico Marx, 8vo., Carlsruhe, 1822.

* In some particulars of a remarkable and perhaps quite unique case of *tæniæ*, voided from the meatus urinarius, it is stated by Mr. Law, of Penrith, who attended the patient, that the turpentine which she took by the mouth found its way into the bladder in twenty seconds. The letter mentioning this curious fact, was shown to the editor by his friend, Mr. Docker, late of Canterbury.—ED.

And on this account it is, that the Greek physicians took but little notice of the pulse, which, even in the days of Celsus, was regarded as a *res fallacissima*.

The pulse is influenced indirectly by the general state of the body, but directly by that of the heart, or of the arteries, or of both, or of the quantity of blood which the vessels have to contain.

In an adult male of good health, and not too corpulent, the common standard of the pulse may be fixed at seventy strokes in a minute; but it varies in different individuals from sixty to eighty, being greatly affected by the temperament, and partly by the habit of life. In the man of a high sanguine character it rarely sinks below eighty, and is often at ninety; and in the melancholic, it seldom rises above sixty, and sometimes sinks to forty. In some idiosyncrasies the discrepancy is so considerable, and complicated with other changes than those of frequency and tardiness, that there is no reducing them to any rule. Sir John Floyer, who has numerous bright openings in the midst of a generally obscure horizon, set down the standard number of pulses in health at seventy-five, and affirms that they cease altogether at forty, and are followed by a loss of all sense and motion.—(*The Physician's Pulse-Watch*, &c., 2 vols., 8vo., Lond., 1707.)

Lizarri tells us, however, of a person whose pulse was not more than ten beats in a minute.—(*Raccolta d' Opusculi Scientifici*, p. 265.) Dr. Heberden says, he once saw a person whose pulse, as he was told, did not number in the beginning of his illness above twelve or sixteen in a minute; though he suspects, in this and all other instances, where it is below forty, that the artery beats oftener than it can be felt; because such low pulses are usually unequal in their strength, and some of the beats are so faint as but just to be perceived; so that others, probably still fainter, are too weak to make a sensible impression on the finger. He had attended two patients, who, in the best health, had always very unequal pulses, as well in their strength as in the spaces between them, but which constantly became regular as the patient grew ill, and gave a never failing sign of recovery in their once more returning to a state of irregularity.—(*Med. Trans.*, vol. ii., art. ii., p. 29.) In women the pulse is, generally speaking, six or eight strokes in a minute quicker than in men, and hence, many women, of firm health and a lively disposition, have a standard pulse of eighty-five.

In a weakly frame, the pulse is usually rapid; for debility is almost always accompanied with irritability, and the heart partakes of the general infirmity. In this case, also, from the feebleness with which the heart contracts, the ventricle is but imperfectly emptied, and consequently sooner filled again, and sooner stimulated to contraction. Hence, in infancy, the pulse is peculiarly quick, and gradually becomes slower as the child increases in strength. Dr. Heberden, who paid particular attention to this subject, estimates the pulse on the day of his

birth, and while asleep, from a hundred and thirty to a hundred and forty; and fixes it at little less than the same rate, or that of a hundred and twenty strokes, for the first month. During the first year he calculates it at from a hundred and twenty to a hundred and eight; during the second, at from a hundred to ninety; during the third, from a hundred and eight to eighty, at which it continues for the three ensuing years. In the seventh year it is frequently reduced to seventy-two; and in the twelfth, to seventy.—(*Med. Trans.*, vol. ii., art. ii., p. 29.) In advanced age, the pulse sinks often considerably below sixty strokes in a minute. "I knew one," says Dr. Heberden, "whose chief distemper was the age of fourscore, in whom, for the last two years of his life, I only once counted so many as forty-two pulsations; but they were seldom above thirty, and sometimes not more than twenty-six. And though he seemed heavy and torpid, yet he could go out in a carriage, and walk about his garden, receive company, and eat with a tolerable appetite."

I have at this moment under my care a case of still greater anomaly, in which the pulse is never more than thirty, and more commonly, even after walking, not more than twenty-seven strokes in a minute. Mr. Alexander, the patient I refer to, is sixty-five years of age. About six years ago, from the bursting of a pipe for the conveyance of coal-gas, he fell down in a fit of asphyxy, from which he revived with great difficulty. The reducing plan was carried too far, and, though he has recovered from the accident, and his head is uniformly clear, he is dyspeptic, and subject to palpitations of the heart. [In September, 1828, a gentleman, named Paine, was confined in the Fleet prison, whose pulse was sometimes as low as thirty, and hardly ever above forty: he suffered a good deal from asthma.]

The pulse may be counted with great accuracy up to a hundred and forty or a hundred and fifty in a minute; and if the stroke be equal, and the wrist slender, so that we can take in more than half the artery by the pressure of two fingers, we can reach a hundred and eighty; Professor Frank gives an instance of two hundred (*De Cur. Hom. Morb. Epit.*, tom. ii., p. 175, 8vo., Manheim, 1792), in a case of complicated carditis; but, beyond this, there is great confusion and uncertainty; and it is difficult, therefore, to understand by what nice mode of measurement Dr. Wendt could distinguish, as he tells us he has done, a pulse of two hundred and forty-three strokes in a minute.—(*De Mutatione quâdam Pulsûs insigni*, Erlang., 1778; V. Bald. Syll. v.) Sir John Floyer (*Op. cit.*) sets down a hundred and forty as the amount of "as many pulses as can be counted."

The pulse is quickened by very slight excitements, both external and internal. The stimulus of the air, of the light, and of sounds, is sufficient to make that of an infant awake fifteen or twenty strokes more frequent than when it is asleep, and beyond their control. The pulse of an adult is usually quickened eight or ten strokes during the digestion of a meal; and running, or any sudden and rapturous emotion of the mind,

will double the ordinary scale. The depressing passions, on the contrary, check it, and have sometimes put a total stop to the heart's motion, with a deadly shock, and killed the patient in a moment. There are many drugs that have a like tendency, of which all the simple narcotic poisons afford examples. The digitalis and hyoscyamus are expressly used on account of this property: the prussic acid, and the plants that contain it, as bitter almonds and the leaves of the *prunus laurocerasus*, when given in free doses, destroy the irritability, and extinguish the pulse instantly; and this so effectually that the heart, when immediately examined, has been insensible, not only to puncture, but to concentrated acids.

As the excitement of the stomach during the natural process of digestion is capable of accelerating the pulse eight or ten strokes in a minute, there can be no difficulty in conceiving, that it may be still more accelerated by a morbid excitement of any other large organ, and particularly where the primary seat of excitement is in the sanguiferous system itself. And as, generally speaking, the frequency of the beat is in proportion to the degree of excitement, the pulse becomes a sort of nosometer, or measurer of the violence and danger of the disease: and it measures it equally, whether the return of the beat be below the standard of health or above it.

How far, in either case, the pulse may vary from its natural number without great danger, depends upon a multitude of collateral circumstances, as the age of the patient, his idiosyncrasy, the peculiar disease he is labouring under, and the strength or weakness of the system. And hence, in addition to the number of the pulse, we should also attend to its degree of fulness, softness, firmness, freedom, and regularity; a critical knowledge of which can only be learned by experience and a nice discrimination.

It has been highly injurious, however, to the study of medicine, that this subject has been often too finely elaborated, and the variations of the pulse been ramified into so many divisions and subdivisions, and nice unnecessary distinctions, as to puzzle the young and be of no use to the old. And hence, some of the best pathologists of modern times have been too much disposed to shake off nearly the whole of the encumbrance, and pay no attention whatever to the pulse except in regard to its frequency. Among this number was Dr. Heberden:—"Such minute distinctions of the several pulses," says he (*Med. Trans.*, vol. ii., p. 20), "exist chiefly in the imagination of the makers, or, at least, have little place in the knowledge and cure of diseases. Time, indeed, has so fully set them aside, that most of these names of pulses are now as unheard of in practice as if they had never been given." And in forming, therefore, his prognostic of a disease, while he appeals to the pulse merely in respect to its number, he draws his other grounds of decision from the nature of the malady, and the violence of its specific signs.

But this is to limit the subject to too strict a

boundary ; and to exclude ourselves from what, in many instances, are clear and even leading diagnostics. There are some practitioners, and of very high merit too, whose fingers are no more capable of catching the finer distinctions of the pulse, than the ears of other persons are the niceties of musical sounds. I suspect this was the case with Dr. Heberden, as it was also with the late Dr. Hunter ; of whom Mr. John Hunter observes, that, "though he was extremely accurate in most things, he could never feel that nice distinction in the pulse that many others did, and was ready to suspect more nicety of discrimination than can really be found. Frequency of pulsation in a given time is measurable by instruments ; smartness or quickness in the stroke, with a pause, is measurable by the touch, but the nicer peculiarities in the pulse are only sensations in the mind. I think," continues this distinguished physiologist, "I have been certain of the pulse having a disagreeable jar in it when others did not perceive it, when they were only sensible of its frequency and strength : and it is, perhaps, this jar that is the specific distinction between constitutional disease or irritation and health. Frequency of pulsation may often arise from stimulus, but the stroke will then be soft ; yet softness is not to be depended on as a mark of health ; it is often a sign of dissolution ; but then there must be other attending symptoms."—(*On Blood*, part ii., ch. iii., p. 318.)

Dr. Fordyce's table of the pulse is, perhaps, unnecessarily complicated ; but the strength or weakness, fullness or smallness, hardness or softness, regularity or irregularity of the pulse, are indications nearly as clear as its frequency or slowness, and, in many cases, quite as diagnostic of the general nature of the disease. Frequency and slowness of the pulse, taken by themselves, indicate little more than the degree of irritability of the heart, or the force of the stimulus that is operating upon it. The strength and regularity, or weakness and irregularity of the pulse, are as palpable to the finger as the preceding sign, and show, in characters nearly as decisive, the degree of vigour or debility of the heart ; and, hereby, except where this organ is labouring under some local affection, the vigour or debility of the system, which a mere variation in the state of the frequency of the pulse will not tell us. A full and a small pulse may be distinguished with almost as much ease as any other property it possesses ; this Mr. John Hunter ascribes to the state of the arteries : but, if I mistake not, it gives us rather a measure of the quantity of blood circulating through the system, than of the muscular strength of the arteries, or of the heart itself ; which is often a very important indication, and especially when combined with the preceding signs ; as it will then be our best guide in cases where we have determined upon emptying the vessels as far as we can do it without danger. Hardness and softness of the pulse, together with that vibratory thrill which has been called wiriness, are not quite so easily learned as its ful-

ness and smallness, but a nice finger will readily discriminate them, and practice will point out the difference to every one.* These characters Dr. Fordyce makes dependant, and, I think, with great reason, on the state of the arteries, rather than on that of the heart, or on the quantity of the circulating fluid ; and Mr. John Hunter concurs in the same view. They measure the degree of vascular tone, or power of resistance ; and when the same effect, whether above or below the natural standard, takes place in the capillary arteries, it produces that change in the pulse which he distinguished by the names of obstruction and freedom, but which it is not always easy to discriminate from several of the preceding qualities ; nor is it of great importance, as we have in such cases other symptoms that more strikingly manifest the same fact.†

Thus far, perhaps, the doctrine of pulsation may be studied to advantage : but when, beyond this, we come to a distinction between the free and dilated pulse, as proposed also by Dr. Fordyce ; the quick and the frequent, as proposed by Stahl (*De Differentiâ Pulsûs celeris et frequentis*) ; and the dicrotic, coturnising, and inciduous, proposed by Solano,‡ as mere subvarieties of the rebounding, or redoubling, itself a variety of the irregular pulse, we perplex pathology with a labyrinth in which the student is lost, and the master wanders to no purpose.

* If a pulse be exceeding *hard*, and at the same time small, then it has been called a *wiry* pulse ; if a pulse be both *hard* and *large*, it is a *strong* pulse also ; if a pulse be *small* and *soft* together, then it must be considered as *weak*.—See Elliotson's Lectures, delivered at the London University, pub. in Med. Gaz. for 1831–2, p. 141.

† The following useful and practical distinctions of the pulse are from the pen of Dr. Miner. "That pulse is said to be *frequent*, in which there is a great number of attractions and dilatations of the artery in a given time ; and *infrequent* when there are but few. The pulse is *quick*, when each contraction and dilatation occupies but a short time, whether there are many or few in a minute ; and it is *slow*, when the individual contractions and dilatations occupy a comparatively long time, whether they are numerous or few in a minute. The pulse is *strong*, when every dilatation of the artery gives great resistance to pressure ; and *weak*, when it gives but little resistance. The pulse is considered as *full*, when a large quantity of blood passes along at every dilatation of the artery ; and it is *small*, when the quantity that passes at each dilatation is considerable. The pulse is *hard*, when the artery may be felt like a wire or tense cord, both in its contraction and dilatation ; and it is *soft*, when it is felt only in its dilatation, and easily becomes imperceptible on pressure. A *regular* pulse is equal and uniform in frequency, quickness, strength, fullness, and hardness ; under the term *irregularity* may be included all those varieties of pulse which do not fall unequivocally under some one of the preceding heads."—See Essays on Fevers and other medical subjects by Miner and Tully, Middletown, 1823. See also The Principles of Medicine, &c., by Samuel Jackson, M. D., Philadelphia, 1832, p. 488.—D.

‡ *Novæ Observationes circa Crisium Prædictiones et Pulsus*. Wetsch, Medicinæ ex pulsû Vind., 1770 ; Vienn., 1773.

"Infida," says Professor Frank, "arbitraria et æquivoca est multorum de pulsibus criticis doctrina."—(*De Curand. Hom. Morbis Epit.*, tom. i., p. 30.)

De Bordeu acquired great reputation in the middle of the last century, for applying the doctrine of pulsation as an index to the diseases of every distinct organ of the body; whence he not only adopted most of the subdivisions of Solano, but added others, and subdivided them still further. He started it as a new hypothesis, which he endeavoured to support by facts and arguments, that every separate organ possesses a principle of life in some measure peculiar to itself, and independent of the rest of the frame; that each is endowed with a proper function, and susceptible of proper sensations and movements; and that, by the agreement and co-operation of all these distinctive powers, the life and health of the entire system are built up and maintained. These principles are developed and defended in his thesis, "*De Sensû genericè considerato*," published at Montpellier in 1742. Though arrogating the merit of originality, they are, however, little more than a revival of the ancient doctrine of harmony invented by Aristoxenus, and at one time very popular in Greece, as we learn from Lucretius:—

"— Multa quidem sapientum turba putarunt
Sensum animi certâ non esse in parte locatum;
Verùm habitum quemdam vitalem corporis esse,
'ÆPMONIAN' Graiæ quam dicunt."*

M. de Bordeu, in adopting this hypothesis, supposed, further, that an affection of any particular organ will occasion a peculiar variation in the pulse from its natural state; and, by a careful attention to these changes, he conceived himself capable of ascertaining the seat of the disease, and the channel through which nature was aiming at a crisis. He describes, in consequence, an overwhelming multiplicity of *organic pulses*: but his general division is into superior and inferior pulses; and this he founds on an observation that the actions of the parts seated above the diaphragm, and of those below, excite very different impressions on the circulatory system. These views are chiefly given in the most famous of all his publications, entitled "*Recherches sur le Pouls, par rapport aux Crises*."—Paris, 1756, 8vo. This hypothesis became extremely popular in France and Germany, and excited a considerable degree of attention at Edinburgh. It is now, however, little heard of, and is by no means worth reviving.

In effect, a voluminous and complicated classification of pulses is rather a proof of an active fancy than of a sound judgment: and though Dr. Heberden and Dr. Hunter may have thought too lightly of this branch of pathognomy, it is better to adopt their simplicity than the puerile conceits of many more elaborate pulse-makers. The Chinese have a more operose system of pulsations than any that have appeared in Eu-

rope: but nothing can be more whimsical than their divisions, though Floyer fell in love with them, and thought them models of wisdom and accuracy. Avicenna treated of the pulse musically; and Hoffenueffer, pursuing his principles, drew up, in 1641, a musical scale of the pulse, dividing it into musical time, and marking the different beats by semibreves, minims, and crotchets, semiquavers, and demisemiquavers; thus reducing his patient to a harpsichord, and his profession to a chapter on thorough-base.

III. [Blood, when first drawn from the vessels, is an adhesive fluid, of a homogeneous consistence, of the specific gravity of about 1.050, of a red colour in man and the higher animals, and of the temperature of about 98° in the human subject. Soon after its discharge from the vessels, if it be suffered to remain at rest,* it begins to coagulate, and, as the process advances, it separates into two distinct parts, namely, a red mass floating in a yellowish fluid. The red part is called the clot, or crassamentum, and the fluid part the serum. The average time, requisite for the coagulation of venous blood, is said to be seven minutes; and the crassamentum has been estimated to amount to about one third of the weight of the serum.—(*Bostock's Physiology*, vol. i., p. 434.) In the act of coagulation, it is generally believed that an evolution of heat takes place, though the point is yet a contested one; Dr. J. Davy's investigations (*Edin. Med. Journ.*, No. 95) disagreeing with those on which the preceding doctrine is founded, and corroborating the view adopted by Mr. Hunter.

The coagulum, or clot, may be deprived of its red colour by repeated ablution in water; thus showing, as Dr. Bostock observes, that the colouring matter is only mechanically mixed with the substance left behind, called fibrin, and not chymically combined with it.

Many causes of sudden death have the curious effect of impeding the coagulation of the blood. This is exemplified in persons rapidly killed by lightning and electricity; a blow on the stomach, or injury of the brain; by the bite of a rattlesnake, and other venomous animals; by acrid vegetable poisons, like laurel-water; excessive fatigue; and even violent agitation of the mind. In the same cases, Mr. Hunter found a singular coincidence between the want of coagulability in the fibrin of the blood and the loss of contractility in the muscles after death. The body is also disposed to putrefy with unusual quickness. Hence there appears some analogy, if not identity, between muscular contraction, and the coagulation of the fibrin of the blood; an opinion strengthened, as Dr. Bostock has observed, by the fact that the chymical composition of fibrin is similar to that of muscle. From the relation between the coagulation of the blood and the contractility of mus-

* De Rer. Nat., lib. iii., 98. See the author's examination of this hypothesis, and its resemblance to others of later date, in the notes to his Translation of Lucretius, book v., 100, and 101.

* Rest, however, is not essentially necessary to the coagulation of the blood; for if this fluid be shaken in a vial it will still coagulate. Prof. Physic has ascertained by experiment that blood will coagulate also without the contact of air.—See Prof. Horner's Anatomy, vol. ii., p. 162.—D.

cles, Mr. Hunter appears to have deduced his celebrated hypothesis of the life of the blood; a doctrine which embraces the principle that a fluid is capable of organization, and may be endowed with functions either identical with, or very similar to, those which are the most characteristic of the living animal solid.—(*Bostock*, vol. cit., p. 443.)

At the temperature of 160°, the serum itself coagulates, from which a fluid, termed the serosity, may yet be obtained by pressure. The coagulated part is albumen, which principle exists also in the serosity, but is suspended by the presence of an alkali.

The coagulation of the blood is a circumstance, not only interesting to the physiologists, but a source of useful information to the medical practitioner; for certain appearances of the blood, after its coagulation, are a general indication of inflammation, or other disturbance in the system. Thus, when the upper stratum of the coagulum has a yellow buffy look, in consequence of the red globules having subsided from it; when its surface is more or less concave, and the quantity of serum in the basin copious; the blood is said to be *sizy*, and to exhibit the *buffy coat*, or *inflammatory crust*. As, however, the buffy coat frequently occurs, when no inflammation nor inflammatory fever exists, the state of the pulse and other symptoms should always be duly considered, and the decision for the further use of the lancet never be founded merely on the look of the blood, without reference to other circumstances in the case.]

To speak minutely of the CONSTITUENT PRINCIPLES OF THE BLOOD, would carry us too far into the regions of animal chymistry; and I shall hence limit myself to a very brief analysis of those that are fixed or confinable, having already paid some attention to the gases in the physiological proem to the preceding class.

For the first judicious account of these principles, we are indebted to an elaborate memoir of MM. Parmentier and Deyeux, who arranged them under the following heads:—1. A peculiar aroma, or odour, of which every one must be sensible who has been present at a slaughterhouse, on cutting up the fresh bodies of oxen. 2. Fibrin, or fibrous matter, frequently also called coagulable lymph, and gluten. 3. Gelatin. 4. Albumen. 5. Red colouring matter. 6. Iron. 7. Sulphur. 8. Soda. 9. Water.

Still minuter and more exact experiments have since been made upon particular portions of the whole of the blood, especially by Dr. Marcet (*Trans. Medico-Chirurg. Soc.*, vol. ii., p. 370), Dr. Bostock (*Id.*, vol. i.), and Berzelius (*Id.*, vol. iii.), which confirm the greater part of the preceding results, but have detected a few errors, which it is necessary to notice.

Neither the blood of man nor of quadrupeds, so far as it has been examined, contains any gelatin. "The mistake," says M. Berzelius, "arises from the gelatinous appearance of the albumen: I have never been able to detect a particle of gelatin in blood, and, as far as my researches extend, I have found gelatin to be a substance altogether unknown to the economy

of the living body, and to be produced by the action of boiling water on cartilage, skin, and cellular membrane; substances which are totally distinct from fibrin and albumen." It follows, therefore, that wherever gelatin is found in the animal frame, it is produced by a decomposition and recombination of the particles of the blood by the action of the secretions. But, instead of the gelatin, Dr. Bostock has since discovered in the serosity, or that part which remains when the lymph or serum has parted with its albumen by heat, a distinct substance, which he has denominated, from its quality, uncoagulable matter (*Elementary System of Physiology*, vol. i., p. 476, 8vo., 1824), and which Dr. Marcet has called muco-extractive matter. Berzelius has affirmed it to be impure lactate of soda.

The sulphur, detected in the blood by Parmentier and Deyeux, does not exist in a free state, but is a component part of its albumen, as are also its carbon and hydrogen, which, in consequence, have as strong a claim to be considered as constituent principles as sulphur. It is by means of its constituent sulphur, that the albumen of blood, or of an egg, becomes capable of blackening a silver instrument employed to stir it.

The iron traced in the blood is, in like manner, a constituent principle of the red colouring matter, and exists in so intimate a union with it, that it cannot be detected by the best reagents we possess, till the composition of the colouring matter is totally destroyed by heat, or some other means.

With these explanations, we are now able to proceed to a clear comprehension of the following brief analysis of the blood, as corrected by the later experiments of Berzelius, supported by those I have just adverted to of Dr. Marcet and Dr. Bostock.

Blood is composed of two parts: one, homogeneous and liquid; and one, only suspended in the liquor, and spontaneously separating from it when at rest.

The homogeneous and liquid part consists of much albumen and a little fibrin, both combined with soda, and all dissolved in water. It also contains a small portion of a few other saline and animal substances.*

* Dr. Stevens has endeavoured to prove, that the fibrin partly owes its fluidity within the body to its being held in solution by the saline substances contained in the serum; but, if this hypothesis were true, the fibrin, one would expect, ought not to be totally insoluble in solutions of neutral salts. It seems to be nearly contradicted, indeed, by one of Dr. Stevens's own experiments. "If, at a certain period after coagulation has commenced, we add muriate of soda, or a saline solution, to the coagulating blood, the moment that the fibrin feels the stimulus of the salt, the whole of it becomes suddenly solid; and," he adds, "I have seen the fibrin of inflammatory blood, which had been drawn during the hot stages of the marsh fever, contract, on the application of salt, with almost as much rapidity as the muscles, when we apply the same stimulus to the fibres in the living body."—Stevens on the Blood, p. 183.

The suspended part consists of the colouring matter. It differs from albumen chiefly in its serum. Iron enters as a constituent ingredient into this material, in the proportion specified in the foot-note. It seems to be the colouring principle; but cannot be separated from it as long as it continues to be colouring matter. This separation can only be effected by combustion, or by the concentrated acids, both of which agents entirely decompose the substance with which the metal is combined. The iron exists in the form of oxyde, with a small proportion of subphosphate of the same. But the colouring matter cannot be artificially produced by uniting albumen with red subphosphate of iron.*

Fibrin, albumen, and colouring matter, have sometimes been considered as modifications of one and the same substance. Each of these three substances *yields*, when decomposed, but does not *contain*, earthy phosphates and carbonate of lime; for the entire blood holds in solution no earthy phosphate, except, perhaps, in too small a quantity to be detected.

From these earths, it is clear, that the bones derive their earthy supply; which, however, it is also clear they can only do, as in the case of the formation of gelatin, in consequence of a decomposition of the blood as it arrives at the secretments of the bones.

Vauquelin endeavoured to separate the colouring matter from the blood by means of sulphuric acid; but this does not very well answer the purpose. A method, proposed by Berzelius, is much simpler, as well as more effective.—(*Ann. de Chim. et de Phys.*, tom. v., p. 42.) It consists in placing the clot or coagulum of blood upon blotting paper, to get rid of the serum as completely as possible. The clot is then to be put into water, in which the colouring matter dissolves, while the fibrin remains unaffected; when, the water being evaporated, the colouring matter is obtained in a separate state. On reducing this matter to ashes, about 1.200 of iron can always be separated.

It is difficult to determine by what means the iron or the sulphur, or the elementary principles of calcareous earth, obtain an existence, or the means of existence, in the blood. If these materials were equally diffused throughout the surface of the earth, we might easily conceive that they are introduced through the medium of food. But as this is not the case, some regions, like New South Wales, at least, on this side the Blue Mountains, containing no limestone whatever, and others no iron or sulphur, while all these are capable of being obtained apparently as freely from the blood of the inhabitants of such regions, as from that of those who live in quarters where such materials enter

largely into the natural products of the soil,—it is perhaps most reasonable to conclude, that they are generated in the laboratory of the animal system itself, by the all-controlling influence of the living principle.

What may be the aggregate quantity of any of these minerals in the mass of blood belonging to an adult, has not been determined with accuracy. The amount of the iron has been calculated by Parmentier and Deyeux, upon grounds furnished them by Menghini, at seventy scruples, or very nearly three ounces, estimating the average of blood in the vessels of an adult at twenty-four pounds, which is most probably something short of the mark.

Whether iron exists in any other part of the animal frame than the colouring matter of the blood, is in some degree doubtful. Vauquelin seems to have traced it in egg-shells and oyster-shells; and Mr. Brande thinks he has done the same in the chyle and in the serum, and this as largely as in the colouring matter of the blood, which, after all, he thinks contains only a very minute quantity.* But these experiments are too indefinite, and by no means coincide with those of Berzelius, since confirmed by other chymists. If the experiments of Menghini may be relied upon, human blood contains a larger proportion of iron than that of quadrupeds; quadrupeds have more than fishes; and fishes more than birds.

But, though there can be no longer any question of the existence of iron as a constituent principle in the blood, we are in total ignorance of the part it is intended to perform. It is, perhaps, the colouring material, though, as I have already observed in the physiological proem to the preceding class, even here we are still very much in the dark, and are overwhelmed with contending hypotheses.† It is probable

* Phil. Trans., 1812, p. 112. For additional information, see Turner's Elements of Chymistry, and Lecanu's Exp. in Ann. de Chim. et de Phys., vii., 49.

† The theory of Dr. Stevens is, that the colouring matter of the blood is a peculiar animal substance, which has the property of striking a bright red die with salt; and, as salt exists in the serum, that it is the cause of the red colour of arterial blood. The reader will find in the Med. Gazette for 1832-3, p. 881, some valuable observations and experiments on the causes of the colour of arterial and venous blood, by Mr. G. H. Hoffman. If these experiments can be depended upon they prove, 1. That carbonic acid gas will blacken red colouring matter of blood, suspended in the serum. 2. That atmospheric air and oxygen will restore its red colour. 3. That carbonic acid gas does exist in venous blood. 4. That the air-pump is not competent to extract the whole of the gases with which the blood is impregnated. 5. That air or oxygen, without salt, will not redden black blood. 6. That salt, without air, will. 7. That blood, without salt, is black. 8. That blood, with excess of salt, and impregnated with carbonic acid gas, is also black, and that its red colour cannot be restored by air, oxygen, or a further addition of salt. 9. That pure oxygen gas will heighten the red colour of hematosine suspended in serum, and impregnated with atmospheric air. 10. That nitrogen gas does not possess a positive power to blacken red blood. 11.

* According to M. Lecanu, blood contains per-oxide of iron in the proportion of 2.100 in 1000.000. See Ann. de Chim. et de Phys., xlviii., p. 308. The colouring principle is termed *hematosine*, 100 parts of which, burnt in the open air, leaves 1.25 of ashes, containing 0.625 of oxyde of iron, and 0.625 of carbonate and phosphate of lime, phosphate of magnesia, and subphosphate of iron, blended together.—Berzelius.

that the red particles of the blood contribute to the strength of animals to whom they are *natural*, as conjectured by Mr. J. Hunter, and that the strength of such animals is in proportion, or nearly so, to their number. Yet such particles are never found in the blood of several classes of animals, as insects and worms; and in those in which they are found, they have often no existence in the commencement of life; for they are not discoverable in the egg of the chick, when the heart first begins to pulsate; nor are they, in any animals, pushed into the extreme arteries, where we must suppose the serum reaches. And hence, whatever their value, they cannot be regarded as the most important part of the blood, or as chiefly contributing to the growth and repair of the system.—(*On Blood*, pp. 46, 48.)

Various attempts have at different times been made to determine the form and measure the diameter of the corpuscles of the blood; but they do not seem to have been accompanied with very great success. Della Torre, by applying his microscope, detected the red particles, as he thought, to be flat circles or rings, with a perforation in the centre; and Mr. Hewson ascribed to them the same shape, but represented them as hollow or vesicular, with a dot of red colouring matter in the centre instead of a perforation; so that, if his description could have been substantiated, they might literally have been regarded as the wheels of life moving on iron axles. Mr. Hewson's hypothesis, however, extended much farther; for, by a variety of plausible experiments, he persuaded himself, and many others also, that it is the office of the thymus and lymphatic glands to secrete and elaborate these vesicles, which are then carried by the lymphatics and thoracic duct to the arteries, and from the arteries to the spleen, which furnishes them with their coloured axles. Some of these physiological and microscopic *divertissements*, however, have been long overturned; while the general shape of the corpuscles has been gravely shown by other exquisite analyses to be globular: the diameter of which, as measured by the microscopical experiments of M. Bauer, is 1-2000 part of an inch; a dimension, however, which has since been reduced by Captain Kater to 1-5000 part of an inch.* M. Bauer has also ascertained,

That carbonic acid and hydrogen gases do. 12. That on macerating the crassamentum in water for an hour and a half, salt is extracted from a stratum of the coagulum equal in thickness to that which may, while moistened with serum, be red-dened for the same length of time by exposure to the air. Mr. Hoffman considers it highly probable, also, from the results of his investigations, that free oxygen gas does exist in arterial blood. These results tend, in the main, to support Dr. Stevens's theory of respiration; although it is admitted, that some links in the chain of evidence, necessary to establish it, are wanting.—*En.*

* Phil. Trans., 1818, pp. 173, 187. Dr. Hodgkin, who has carefully examined the red particles of the blood with a microscope, denies that they are globular; and his description of them is different from that given of them by other experimenters.—See Catalogue of Anatomical Museum of Guy's Hospital, Obs. on sect. xi.—*En.*

as he thinks, that it is not the centre of the globule that is dotted, but its outline that is surrounded with colouring matter; so that, instead of being annular wheels with iron axles, they are spherular wheels with iron tires. It is somewhat singular that, in the revolution of science, M. Bauer's views are now sinking below the horizon, while those of Mr. Hewson are again ascending into notice; for the later experiments of M. Prevost have restored to the red corpuscles of the blood their flat circles and points; and divested them of a globular form. MM. Prevost and Dumas believe the colouring matter to be a membrane, by which these corpuscles are surrounded. They pursued a dextrous method of drying the red particles as soon as separated, and found that, when divested of this red matter and rendered colourless, they are of the same size in every animal they examined; being 1-7600 part of an inch,* but that, with the colouring matter, the size differs in different animals; being 1-3100 of an inch in man, the dog, rabbit, pig, guinea-pig, and hedgehog; in the ass, 1-4200; the cat and man, 1-4300; the sheep, horse, mule, and cow, 1-500; and the goat, 1-700. These particles have a peculiar tendency to form themselves into lines, as observed by Sir E. Home; the lines resembling in every respect the muscular fibre. Fibrin they found also to be a collection of colourless corpuscles of the same kind as the above: the same corpuscles may be also traced in the white of the egg. Those of a chick, six days after incubation, they found larger than those of a hen; as also, that those, which in some young animals are circular, afterwards become elliptical. Even this last was also observed by Hewson; and the remarks may lead to some facts connected with inflammation, by which they may be influenced; as they may be likewise, by the temperature of hot climates.

According to a later set of experiments by M. Bauer, the fluid of the blood has a tendency to run into globules from the first and simplest stage of its formation; while, as it becomes more elaborated, the globules assume a larger and apparently a firmer form, till they at length become tinged with the red colouring matter. We have hence three distinct orders of globules; the first and minutest of which show themselves in the mesenteric glands, and perhaps in the lacteals, white in colour, and floating in a clear, perfectly colourless fluid. The second and middle orders consist of globules, void of colour, found floating in the serum, and which Sir Everard Home has called lymph-globules, and conceives to be the material chiefly thrown out in the process of inflammation. The third and

* Prof. Wagner, of Erlangen, has repeatedly measured the globules of the blood, and always with the same results. He thinks that they vary in size, being from the three hundredth to the four hundredth of a line in diameter, and that the contradictory estimates of authors depend partly on the imperfection of the micrometers employed, and in the want of accuracy in the observations.—See North American Archives of Med. and Surg. Science, No. 2, p. 153.—*D.*

largest order is that of the red globules, the colouring matter of which he supposes to be derived from the changes that take place in the act of respiration. But, though the great mass of the globules, found in the lacteal glands, are of the extreme minuteness just described, he observed that many of them were much larger; that about eight tenths varied from the smallest speck to the size of the lymph-globules; that about one tenth were of the size of red globules deprived of the colouring matter; and about one twentieth of the size of the red globules with the colouring matter incasing them. And he is hence inclined to think, that the lacteal glands are the cradle, in which the whole receive their form and structure, however elaborated by other combinations afterward.

The subject, however, even upon these points, calls for much further attention;* and we have also still much to learn, not merely in respect to the real difference between human blood and that of quadrupeds, but the real difference between that of any one species of animal and any other. M. Berzelius observes, that "the great agreement in the composition of human and ox blood is remarkable, and explains to us the possibility of the phenomena observed in the experiments in transfusion." But we have a clear proof, that the blood of one species of animals differs so much from that of another, either in its principles or their modification, that no benefit can result from transfusion, unless from like kinds to like kinds. Thus, according to several interesting experiments of Dr. Blundell, a dog, asphyxiated by hemorrhage, may easily be recovered by a transfusion of blood from another dog, but is little or not at all relieved, if the blood be taken from man (*Transac. Medico-Chir. Soc.*, vol. ix., p. 86); and the experiments of MM. Prevost and Dumas precisely coincide with this doctrine.

[In the operation of transfusion, which seems to have been invented, or, at least, perfected by Lower about 1660, the artery of one animal is connected by a tube with the vein of another animal, under which circumstances the first is gradually deprived of its blood, and the second rendered plethoric. If an opening be made in the veins of the latter, its original blood will escape, and be replaced by that of the other animal. At the time when these experiments were made, diseases were supposed to depend upon morbid qualities in the blood; and as transfusion held out the prospect of exchanging this fluid at pleasure, it was hailed as a most important means of restoring the health, and some individuals actually submitted to have the blood of lambs or calves transmitted into their vessels, for the purpose of being cured of certain diseases, or of having their vigour renovated.—(*Bostock's Physiology*, vol. i., p. 348.) The first experiments performed on the human subject ended fatally; and in France the con-

tinuance of the practice was prohibited by law. Dr. Blundell, however, has established the important fact, that the blood of an animal of the same species may be safely transfused; but, that if the blood of a different kind of animal be employed, great disorder of the functions is occasioned, and death generally ensues. With strict attention to this principle, the experiment has now been tried upon the human subject in several instances, and occasionally with decided success.]*

Upon the whole, we cannot but regard the blood as, in many respects, the most important fluid of the animal machine: from it all the solids are derived and nourished, and all the other fluids are secreted; and it is hence the basis or common pabulum of every part. And, as it is the source of general health, so it is also of general disease. In inflammation, it takes a considerable share, and evinces a peculiar appearance. The miasms of fevers and exanthems are harmless to every other part of the system, and only become mischievous when they reach the blood; and emetic tartar, when introduced into the jugular vein, will vomit in one or two minutes, although it might require, perhaps, half an hour if thrown into the stomach, and, in fact, does not vomit till it has reached the circulation. And the same is true of opium, jalap, and most of the poisons, animal, mineral, and vegetable. If imperfectly elaborated, or with a disproportion of some of its constituent principles to the rest, the whole system partakes of the evil, and a diathesis or morbid habit is the certain consequence; whence tabes, atrophy, scurvy, and various species of gangrene. And if it become once impregnated with a peculiar taint, it is wonderful to remark the tenacity with which it retains it, though often in a state of dormancy or inactivity, for years or even entire generations. For, as every germe and fibre of every other part is formed and regenerated from the blood, there is no other part of the system that we can so well look to as the seat of such taints, or the predisposing cause of the disorders I am now alluding to; often corporeal, as gout, struma, phthisis; sometimes mental, as madness; and occasionally both, as cretinism.

[Whether the blood be primarily affected in certain diseases, or chiefly concerned in the transmission of what have been considered hereditary disorders, as the author has conjectured, are questions very difficult to solve; and the doctrine, if carried too far, would be at variance with some well-established facts, and approved theories, which ascribe the first origin of many complaints rather to an affection of the blood-vessels, absorbents, or nerves, than to a change of the blood itself. It must not be inferred, however, that, in disease, this fluid is not sub-

* These accounts of M. Bauer's investigations were found among Dr. Good's MSS. subsequently to the publication of the third edition of this work, with the place for their intended insertion in it marked by the author himself.—Ed.

* It is proved, by recent experiments, that foreign substances may sometimes be introduced into the sanguineous system with great benefit. There are several cases recorded in different American journals, where patients, when moribund from cholera, have been immediately benefited, by injecting into the veins a weak solution of the carbonate and muriate of soda.—See note on p. 164.—D.

ject to alteration, a fact, of which the valuable observations of Dr. Armstrong furnish convincing evidence;* nor even that it may not be sometimes the primary vehicle of disease into the constitution. Passing over the variations which occur in its quantity, velocity, and distribution, subjects on which this able physician has offered many judicious and practical reflections, let us attend to what his experience has taught him respecting the altered qualities of the blood in cases of disease. It differs, he says, in different persons, and even in the same person under different circumstances. In general, plethora takes place either in strong individuals of firm fibre, or in plump, lax persons. In both cases, there is a superabundance of the red portion of the blood, but the crassamentum is much firmer in the former subjects than the latter. On the contrary, when local plethora affects the mucous textures of pale, thin men, relaxed by sedentary habits and a spare, slop diet, the red particles are often deficient, and the quantity of fibrin and albumen lessened. A similar effect is well-known to result from copious and repeated blood-letting, the blood becoming thinner and thinner, and the skin paler and more flabby than natural. Indeed, says Dr. Armstrong, the blood is brought into a like condition by protracted disorder, especially where the digestive processes are disturbed, as in cases of chlorosis, in some of which he has known the blood flow from the punctured vein like so much thin claret, or very pale red ink. Nor are the red particles alone affected; for, when rich blood shows the buffy coat on coagulating, it is firm, opaque, and striated generally on the surface; whereas, in poor blood, it is loose and semi-opaque, like so much ill-strained jelly; appearances unequivocally revealing that the fibrin itself is more or less altered. In several cases where the circulation was much increased in force and frequency, Dr. Armstrong has seen the blood gush from an opened vein with the bright vermilion colour of arterial blood; while, on other occasions, where its course had been impeded or retarded in the small arteries, it exhibited a dark venous character. In some examples of fully developed typhus, where the tongue was glazed, dry, and brown, and the lips and cheeks of a dusky or purple hue, he has seen the blood from the temporal artery present a venous colour. The circulation of such blood within the arteries, seems to Dr. Armstrong to be connected with many of the most conspicuous phenomena of the advanced stage of genuine typhus, and dependant upon a specific bronchitis, in which the mucous texture of the bronchial tubes is loaded with dark blood, and smeared with a copious and tenacious secretion. The contagions of smallpox, measles, and scarlatina, he says, first operate on the blood, after which the solids are specifically

affected, especially the skin and mucous membrane of the air-passages. In specific fevers, where the venous blood is not duly converted into arterial from the presence of bronchitis, that fluid emits an unpleasant odour, not unlike the smell of bugs. The blood of those who live on animal food has more azote in it than the blood of persons who live on vegetables. A diet of salted meat likewise produces a change in the blood, as illustrated in cases of sea-scurvy. The circulation of extraneous substances in the blood appears to Dr. Armstrong to be a frequent cause of fever, as he has ascertained to be the fact in relation to mercury. Mental derangement he also conceives may sometimes be connected with a morbid state of the same fluid.—(See *Armstrong's Mor. Anat. of Bowels, &c.*, p. 6, 4to., Lond., 1828.) From a case reported in the *Lancet*, No. cccxxviii., p. 909, it would appear that, in diseases of the spleen and liver, the blood may even acquire an acid quality.]

As already noticed, the blood has been supposed to be alive; a belief of very high antiquity, and which has been warmly embraced by Dr. Harvey and many others of the first physiologists of modern times.* It was a favourite opinion of Mr. John Hunter, and runs through the whole of his doctrines. "That the blood," says he, "has life, is an opinion I have started above thirty years, and have taught it for near twenty of that time in my lectures. It does not, therefore, come out at present as a new doctrine; but has had time to meet with considerable opposition, and acquire its advocates. To conceive that blood is endowed with life while circulating, is, perhaps, carrying the imagination as far as it will can go; but the difficulty arises merely from its being a fluid, the mind not being accustomed to the idea of a living fluid."—(*On Blood*, p. 77.)

The experiments and train of reasoning he urges in favour of this opinion, are highly ingenious and peculiarly strong. And, though they may not be demonstrative of a vital and energetic essence separate from the blood itself, but inherent in its substance, and controlling its motions, they seem very clearly to show, that the blood is endowed with peculiar powers; and that, as matter at large is subject to the laws of gravitation, so the matter of the blood is subject to the laws of instinct. We may here add, in favour of Mr. Hunter's opinion, the following two corollaries of Dr. Philip, deduced from a large field of experiments. "The power of the bloodvessels, like that of the heart, is independent of the nervous system.—The bloodvessels can support the motion of the blood after the heart is removed."—(*Phil. Trans.*, 1815, p. 445.)

Admitting these deductions to be established, the power here referred to, and capable of influencing the blood or the bloodvessels, separately from that of the heart and of the nervous sys-

* This will doubtless be admitted by those who have examined this fluid, as taken from patients affected with cholera; the analyses of eminent chymists prove, that in this disease the quantity of albumen in the blood is somewhat lessened; the colouring matter is remarkably increased; while the fibrin is excessively diminished.—D.

* The opinion that the blood possesses vital powers is ably sustained by Dr. Caldwell, of Philadelphia, in his *Experimental Inquiry on the Vitality of the Blood*. See also a *Dissertation on the Pathology of the Human Fluids*, by Jacob Dyckman, M. D., New-York, 1814; a work of great merit.—D.

tem, must be the power of symple life, or of instinct, which is simple life operating by the exercise of its own laws.

This view of the subject has of late, however, been carried by Dr. Pring to an extent far beyond what Mr. Hunter at any time contemplated. For Dr. Pring not only supposes the blood to be alive, and to communicate life to the sentient and

healthful parts of the system, but to its insentient and diseased elements as well; and that the matter of animal poisons, derived from the blood, are themselves also living bodies, acting specifically by the vital but discrepant properties they are endowed with. And he thinks that hereby "a distinction may be furnished between the contagious and infectious diseases."^{*}

CLASS III.

HÆMATICA.

ORDER I. PYRECTICA. FEVERS.

HEAT AND NUMBER OF THE PULSE PRETERNATURALLY AUGMENTED: USUALLY PRECEDED BY RIGOUR, AND FOLLOWED BY PERSPIRATION: DURING THE RIGOUR, PAINS FIXED OR WANDERING: LASSITUDE: DEBILITY OF MIND AND VOLUNTARY MUSCLES.

No complaint is so common as fever; none in which mankind, whether professional or laical, are so little likely to be mistaken, and yet none so difficult to be defined. In reality, no writer seems to have been fully satisfied with his own definition; and it is not extraordinary, therefore, that he should seldom have given satisfaction to others. The difficulty proceeds from the complexity of the symptoms that enter into the character of a fever: the contrariety of many of them to each other in different stages of it; and the occasional absence of some that, in other instances, appear to constitute its leading features. "Febris," says Professor Frank, "*certorum potius morborum UMBRA, quam ipse morbus est.*"[†]

The nosologist has also two other difficulties of considerable magnitude to contend with in laying down a clear and perspicuous survey of fevers; and that is, their division or collocation, and their generic names. But, as I have already pointed out these difficulties, and the means by which they are attempted to be remedied under the present arrangement and nomenclature, in the running commentary to the Order before us in the volume of Nosology, I shall beg to refer the reader to the observations there laid down, and shall subjoin only one or two additional remarks upon the same subject.

Although the number of the pulse, as well as the heat, is preternaturally augmented in almost every case of fever, an extraordinary instance is

sometimes to be met with, that opposes the general law, for the most part dependant, I believe, on a great and sudden oppression of the brain; an explanation which withdraws the anomaly, and accounts for the ordinary increase of pulsation as soon as such oppression is removed. Thus, in the yellow fever of Antigua, in 1816, the pulse, as Dr. Musgrave informs us, was, in one instance, under forty-four. "We almost fancied," says he, "this unusual softness might be constitutional: but, on opening a vein, it greatly increased in frequency; and, after the loss of a considerable quantity of blood, it numbered eighty, with nearly complete relief from every uneasy sensation."[—](*Trans. Med. Chir. Soc.*, vol. ix., p. 133.)

In such cases, the heat of the system usually exhibits as little febrile augmentation as the pulse: for, as the former is the result of increased action, till such increased action takes place, the heat, as in the first stage of the paroxysm, may continue even below the natural standard. Ordinarily, however, the heat is considerably heightened, inasmuch as in some instances to reach 108° Fahrenheit, which, however, is the utmost point it has ever been known to attain in fever.

There is a still more curious variation from the general law, which is sometimes, though very rarely, found to take place, of which Schenck gives a single example that occurred in his own practice; I mean a reversed order of the symptoms of the febrile paroxysm, and an appearance of the sweating stage before the shivering and hot fit.—(*Lib. vi.*, obs. 34.)

To provide for these extraordinary and anomalous incidents by any definition whatever, is beyond the power of language. They must be left to themselves, and will rather confirm than disturb the definition now offered, agreeably to the maxim of the schools—*exceptio probat regulam*.

In dividing fevers into distinct genera, I have taken the line of demarcation from the character of their duration, as limited to a single paroxysm; as composed of numerous paroxysms, with intervals of intermission or perfect apyrexia; as composed of numerous exacerbations, with intervals of remission, or imperfect apyrexia; and as composed of a single series of increase and decrease, with a mere tendency to intervals of remission, without perfect apyrexia at any

^{*} Principles of Pathology and Therapeutics, &c. By Daniel Pring, M. D., 8vo., 1823.

[†] De Curand. Hoin. Morb., Epit. i., p. 2, tom. iv., 8vo., Mannh., 1792. "The word *fever*, derived from the Latin term *febris* (a derivative of the verb *ferveo*, signifying, to be hot), is applied to a class of diseases, characterized by morbid heat of the skin, frequency of pulse, and disturbance in the various functions."[—]Dr. Tweedie, in Cyclop. of Pract. Med., art. FEVER.

time. Other nosologists have drawn their generic distinctions from other circumstances; as their disposition or indisposition to putridity; their inclination to a sporadic or an epidemic character; the vigour and violence, or weakness and debility, of their action; or, in the language of Dr. Darwin, the nature of their influence on the sensitive or irritative fibres of the animal frame. The most obvious mark, however, and that which has been most generally approved, is the character of duration assumed in the arrangement before us. To all the rest, there are greater or less objections, which, as I have already examined them in the comment just referred to, need not be repeated in the present place.

Regulated, therefore, by the principle before us, fever admits of the four following genera:—

I. Ephemera.	Diary Fever.
II. Anetus.	Intermittent Fever.
III. Epanetus.	Remittent Fever.
IV. Enecia.	Continued Fever.

To each of these belong several species, and to most of the species several varieties, as will be noticed in their respective order.

Some slight deviation from the ordinary nomenclature may be observed in the generic names above: but the reader can have no difficulty upon this head, as he will find the changes that have hereby been occasioned are in every instance founded upon a principle of correctness and simplification; and consequently calculated to disentangle rather than to add to his encumbrances, and to facilitate his progress in the labyrinth before him. The term *Ephemera*, is, indeed, well known to every one. *Anetus* and *Epanetus* are Greek terms, importing intermittent and remittent, from ἀντήμι and ἐπανήμι. *Enecia*, from the same tongue, denotes continued action, and is a derivation from ἡνέκεις.

Before, however, we enter upon the practical part of this subject, it appears necessary to make a few remarks upon one or two other questions that have very largely occupied the attention of many pathologists, and especially concerning the proximate and remote causes of fever; and the tendency, which fever has been supposed to evince, of terminating suddenly, either favourably or unfavourably, at fixed periods of its progress.

Proximate and remote causes are rather terms of recent, than of ancient writers. In early times, the causes of diseases chiefly contemplated were *PROGUMENAL*, or predisponent, and *PROCATARTIC*, or occasional. Thus, an hereditary taint, or habitual indulgence in high living, may be regarded as a *progumenal* cause of gout; and catching cold, or an unusual exertion of muscular exercise, may form its *procatartic* cause: both of which are absolutely necessary; for, it is clear, that the latter without the former would not produce the malady; and it is just as clear, that the former might remain harmless in the constitution for years, were it not to meet with the co-operation of the latter, which is often, on this account, denominated an exciting cause. Generally speaking, the

first was regarded as an internal, and the second as an external cause; and, in the instance selected, they are so; but they are not so always.

To be acquainted with causes of these kinds is always useful; and, in guarding against the approach of diseases, it is often of the utmost importance: but they give us very little information upon the real nature of diseases, and the mode of managing them when present. And hence another set of causes have been adverted to, and have of late been chiefly studied, and particularly in the case of fever. "That only," says Gaubius, "deserves the name of a physical cause, which so constitutes the disease, that, when present, the disease exists; while it continues, the disease continues; when changed or removed, the disease is altered or destroyed." It is this which constitutes the *PROXIMATE* cause, and is, in fact, the essence of the disease, the actual source of all its effects. The *REMOTE* cause is that which directly produces the proximate; as a specific virus in syphilis, or a specific miasm in influenza, or epidemic catarrh.

In fever we can often trace the remote causes, though we are still too little acquainted with the nature of several of them to be able to restrict them to a specific mode of action: of the proximate cause, we know but very little at present, and it will probably be long before we shall know much more.

Let us, however, begin with the *PROXIMATE* cause, as that which has most excited the attention of physicians in all ages. Upon this subject, indeed, a great deal of learned dust has been raised, and a great deal of valuable time consumed. Ancient speculations, for they are not entitled to the name of theories, have been overthrown; and modern speculations, in vast abundance, erected upon their ruins; which, in rapid succession, have also had their day and expired. It is an inquiry, therefore, not likely to prove very productive; yet, as forming a part of medical science, of which no student should be altogether ignorant, it seems necessary to take a brief survey of the most popular doctrines which have been advanced upon the subject in different ages.

Fevers, then, in respect to their proximate cause, have been conjectured to originate from a morbid change, either in the composition of the blood, or in the tone or power of the living fibre. The first view has given rise to various hypotheses, that rank under the common division of the *HUMORAL PATHOLOGY*. The second has given rise to other hypotheses, appertaining to the common division of the *FIBROUS* or *NERVOUS PATHOLOGY*.

The hypotheses, derived from the one or the other of these sources, that are chiefly entitled to attention, are the following; of which the first two belong to the former division, and the remainder to the latter.

I. That of the Greek schools, founded on the doctrine of a concoction and critical evacuation of morbid matter.

II. That of Boerhaave, founded on the doc-

trine of a peculiar viscosity, or lentor of the blood.

III. That of Stahl, Hoffmann, and Cullen, founded on the doctrine of a spasm in the extremities of the solidum vivum, or living fibre.

IV. That of Brown and Darwin, founded on the doctrine of accumulated and exhausted excitability, or sensorial power.

V. To which we may add, that fevers have, by some physiologists, as Dr. Clutterbuck, M. Broussais, and Professor Marcus, been identified with inflammation; and their proximate cause been ascribed to increased action in some particular organ.

I. It was the opinion of Hippocrates, that fever is an effort of nature to expel something hurtful from the body, either ingenerated, or introduced from without. Beholding a violent commotion in the system, followed by an evacuation from the skin and kidneys, with which the paroxysm terminated, he ascribed the commotion to a fermentation, concoction, or ebullition, by which the noxious matter was separated from the sound humours; and the evacuation to a despumation or scum which such separation produces, or rather to the discharge of this morbid scum from the emunctories that open externally. Galen supported this view with all the medical learning of his day; and it is the only explanation of fever to be met with in medical writings, through the long course of three thousand years; in fact, till the time of Sydenham, who still adhered to it, and whose pages are full of the language to which it naturally gave birth.

It blended itself almost immediately with the dialect of the chymists of the day, notwithstanding the professed hatred of Paracelsus and Van Helmont towards the whole range of Galenic doctrines, and the solemn pomp with which the former had condemned and burnt the entire works of Hippocrates and Galen. And hence, under the influence of chymistry, at this time assuming a soberer aspect, the supposed animal despumation was contemplated as possessed, according to different circumstances, of different chymical qualities and characters; and particularly as being acid, alkaline, effervescent, or charged with some other acrimonious principle, too highly exalted, or in too great a proportion.

This doctrine, considered merely hypothetically, is not only innocent, but highly ingenious and plausible. It is in unison with several of the phenomena of pyretic diseases, and derives a strong collateral support from the general history of exanthems, or eruptive fevers, in which we actually see a peccant matter, producing general commotion, multiplying itself as a ferment, and, at length, separated and thrown off at the surface by a direct depuration of the system.

There is no writer, perhaps, in our own day, who has carried this view of the subject farther, or even so far, as Professor Frank, who regards typhus, plague, petechial, and all pestilential fevers, and, indeed, nervous fevers of every kind, whether continued or remittent, not only as

proceeding from specific contagions in the same inanner as exanthems, but from contagions producing a like leaven in the system, and matured and thrown off through the various outlets of the body, by the same process of depuration; and hence, after describing all the varieties of malignant nervous fevers under the character of pestilential, he tells us “non aliter hæc methodus in ipsâ PESTE tum in PESTILENTIALI, sic vocatâ, febre, profuisse visa est: ubi, *maturo satis tempore*, CONTAGII PER CUTEM EXPULSIO sollicitè à medentibus absolvetur.”—(*De Cur. Hom. Morb. Epit.*, tom. i., p. 130, compare with the § p. 127.)

So far, however, as relates to exanthems, the opinion is sufficiently correct. But the moment it is brought forward as the proximate cause of fever, properly so called, in which there is no specific eruption, it completely fails.

For, first, no explanation is here given as to the means by which any such concoction or fermentation, or multiplication of morbid matter in any way, takes place. Next, there are many fevers produced evidently by cold, fear, and other excitements, as well mental as corporeal, in which most certainly there is no morbid matter introduced, and wherein we have no reason to conceive there is any generated internally; while the disease, limited, perhaps, to a single paroxysm, closes, nevertheless, with an evacuation from the skin or the kidneys. And, thirdly, we sometimes behold fevers suddenly cured, as Dr. Cullen has observed, by a hemorrhage so moderate, as, for example, a few drops of blood from the nose, as to be incapable of carrying out any considerable portion of a matter diffused over the whole mass of the blood; while we are equally incapable of conceiving how such diffused morbid matter could collect itself at a focal point, or pass off at a single outlet, or of tracing in the discharge, after the minutest examination, any properties different from those of blood in a state of full health.

I have observed that this hypothesis is, however, harmless enough when merely brought forward as a speculation. But it has not always been limited to this point; for it has occasionally been advanced as a practical and efficient principle; and the febrile commotion, and particularly the hot fit, has, in treating the disease, been purposely increased, with a view of assisting nature in her curious but unknown process of expelling the peccant material, and the most dangerous consequences have followed.

II. The acute and penetrating mind of Boerhaave, who was born in 1668, was sufficiently sensible of this danger; and the discoveries which were now taking place in chymistry and physiology, led him progressively to the construction of a new theory, which in a few years became so popular as to obtain a complete triumph over that of the Greek schools.

Leeuwenhoeck, by a delicate and indefatigable application of the microscope to animals of a transparent skin, had endeavoured to establish it as a fact that the constituent principles of the

blood consist of globular corpuscles; but, that these corpuscles differ in size in a regular descending series, according to the constituent principles themselves; and that each set of principles has its peculiar bloodvessels, possessing a diameter just large enough to admit the globules that belong to it, and consequently incapable, without force, of allowing an entrance to those of a larger magnitude; and hence, that the bloodvessels possess a descending series as well as the particles of the blood.

It was upon this supposed fact that Boerhaave built his hypothesis. He conceived that almost all diseases may be resolved into an introduction of any given series of particles of blood into a series of vessels to which they do not properly belong, and he distinguished such introduction by the name of *error loci*. He conceived, still further, that this heterogeneous admixture is very frequently taking place; and that its chief cause consists in a disproportion of one or more sets of the sanguineous principles to the rest, by which their globular form is occasionally broken down or agglutinated; and hence rendered too thin and serous, or too gross and viscid. The viscosity of the blood he distinguished by the name of *LENTOR*; and to a prevalence of this lentor, or viscosity, he ascribed the existence of fever; maintaining, that the general disturbance which constitutes fever proceeds from an *ERROR LOCI* of the viscid blood, whose grosser corpuscles, from their undue momentum as well as superabundance, press forcibly into improper series of vessels, and stagnate in the extremities of the capillaries, whence the origin of the cold stage, and consequently of the stages that succeed it, to which the cold stage gives rise (Aph. 756, *Comment. Van Swiet.*, tom ii., p. 528, edit. Lugd. Bat., 4to., 1745); and hence those medicines which were supposed capable of, dissolving that tenacity, or breaking down the coalescence of such a state of the blood, were denominated *DILUENTS*, *HUMECTANTS*, and *ATTENUANTS*, while those of an opposite character were called *INSPISSANTS*: terms which have descended to our own day, and are still retained, even by those who pay little attention to the hypothesis that gave them birth.

The system of Boerhaave, therefore, consisted of an elegant and artful combination of both the earlier and later doctrines of corpuscular physiology. Without deserting the humoral temperaments of Galen, or the constituent elements and elective attractions of the alchemists, he availed himself of the favourite notions of the corpuscular pathologists, their points or stimuli, their frictions, angles, and spicules, derived from the Cartesian philosophy, which was now exercising as triumphant a sway over the animal as over the material system, and interwove the whole into an eclectic scheme, so plausible and conciliatory, that all parties insensibly felt themselves at home upon it, and adopted it with ready assent. In the emphatic language of M. Quesnay, it was "LA MÉDECINE COLLECTIVE."

The most triumphant fact in favour of the

Boerhaavian hypothesis is, that the crust in the blood in inflammations, and cauma or inflammatory fever, is often found peculiarly dense. But, as fevers (and certainly the greater number) are found without any crust; and, as a similar crust, though, perhaps, not quite so dense, exists under other and very different states of body, as in pregnancy and scurvy (porphyra), even this leading appeal has long lost its power of conviction: while the abruptness with which fevers make their assault, from sudden occasional causes, and in constitutions of every diversity, forbid the supposition that, in such cases, a lentor or sizy crisis of the blood, and especially a *glutinosum spontaneum*, can have time to be produced, however it may exist occasionally, and be, perhaps, the source of other disorders. The subject, however, has of late been again taken up by Dr. Storker of Dublin, with a view of reviving the humoral pathology in its more important doctrines, and of extending the arguments which have hitherto been urged in its favour.*

III. To the period of Boerhaave, in the production of fever, and, indeed, of all other diseases, the human body was regarded as almost entirely passive, a mere organic machine, operated, indeed, upon by some *AUTOCRATEIA*, as *NATURE*, or a *VIS MEDICATRIX*, but in the same manner as other machines, and mostly by similar laws. Its muscles were contemplated as mechanical levers, and its vessels as hydraulic tubes, whose powers were calculated upon the common principles of mechanics and hydrodynamics, and were only supposed to be interfered with by the internal changes perpetually taking place in the fluids they had to convey. A new era, however, at length began to dawn upon the world; a more comprehensive spirit to pervade medical study: the animal frame was allowed to exhibit pretensions superior to the inanimate, and not only to be governed by powers of its own, but by powers which are continually and systematically, from a given point,

* Pathological Obs., &c., Dublin, 8vo., 1823. See also Armstrong's Morbid Anatomy of the Bowels, &c., p. 6, et seq. 4to., Lond., 1828; and Dr. Clanny's Lect. on Typhus Fever. According to Dr. Stevens's investigations, when the bodies of persons who died of yellow fever were opened, the heart was found to contain, instead of blood, a dissolved fluid nearly as thin as water, and as black as ink. In both sides of the heart the fluid was equally black, and throughout the vascular system all distinction between venous and arterial blood was completely lost. Dr. Stevens thinks that the blood first loses its solid parts, and becomes thin; that it then becomes deprived of its saline principles, and turns black and viscid; and lastly, that it loses its vitality, so as to become incapable of supporting life. He regards this diseased state of the blood as the first link in the chain of morbid phenomena which constitute fever, and believes that the aërial poisons, from which all pestilential diseases arise, are attracted with the atmospheric air into the circulation, mix directly with the blood in the pulmonary system, and this poisoned or diseased state of the circulating blood is the cause of the subsequent morbid action in the solids.—Ed.

operating to a preservation of health where it exists, and to a restoration of health where it has been lost or injured. Stahl, who was contemporary with Boerhaave, and in the university of Halle, in 1694, first started this loftier and more luminous idea—more luminous, though the light was still struggling with darkness—made the mind the controlling principle, and the *solidum vivum*, or nervous system, the means by which it acted. Fever, on his hypothesis, consisted in a constrictive or *tonic spasm*; in his own language, *spasmus tonicus*, produced by a torpor or inertness of the brain, at the extremity of the nerves, and counteracted by the remedial exertions of the mind, the *vires medicatrices* of his hypothesis, labouring to throw off the assailing power; whence the general struggle and commotion by which the febrile paroxysm is characterized. Hoffmann, who was a colleague of Stahl, took advantage of this new view, followed up the crude and primary ideas of Stahl with much patient and laborious investigation, and soon presented to the world a more correct system, in a more attractive style; but, apparently, with a disingenuous concealment of the source from which he had borrowed his first hints. He omitted the metaphysical part of the Stahlian hypothesis, took from the mind the conservative and remedial power over the different organs, with which Stahl had so absurdly endowed it; seated this power as a law of life in the general organization; separated the nervous from the muscular fibres, the latter of which were regarded as only the extremities of the former by Stahl; allowed a wider range and longer term to the constrictive spasm of fever, and changed its name from *spasmus tonicus* to *spasmus periphericus*;* giving also to the moving power of the muscular or irritable fibres the name of *vis insita*, as that of the nervous fibre was called *vis nervæ*.

It is highly to the credit of Boerhaave that his mind, in the latter part of his life, was so fully open to the merits of this hypothesis that he admitted the agency of the nervous power, though a doctrine that struck at the root of his own system, of which we have a clear proof in the change which occurs in the fourth edition of his Aphorisms, and particularly aphorism 755, where he lays down the proximate cause of intermitting fevers. Hitherto it had run thus: "Unde post accuratum examen totius historię intermittentium causa proxima constituitur viscositas liquidi arteriosi." But to this, in the edition before us, is added the following: "forte et nervosi (liquidi) tam cerebri, quam cerebelli cordi, destinati, inertia."—(*De Motu Tonico. Theoria Medica vera*, Halle, 1734.)

It is also equally creditable to the learned Gausbuis, that, though strongly attached to the Boerhaavian school, in which he was educated, and a zealous contender for many of its doctrines, his understanding was alike open to the clearer and simpler views of the chymists of the day, upon

various points not yet generally adopted, and allowed him to become a more thorough convert to their philosophy. The reader may judge of this change in his mind by the following passage: "An et naturæ humanæ facultas inest, molecularis, acris detritas aut intropressas angulis, in sphæulas tornando, blanditium creandi? Non satis constat speciosam ideam æqualiter in fluidam solidamque acrimoniam quadrare.—Credibilis profectò mixtione chemica magis quam mechanica rotundatione, id opus perfici."—(*Pathol.*, § 298–300.) In effect, there not only was at this time, but had been for many years antecedently, a general feeling among the cultivators of medicine, that neither the laws of animal chymistry, nor of the living fibre, had been sufficiently studied for the purposes of a correct pathology: in proof of which it may be sufficient to refer to various articles on both subjects, inserted in the *Ephemerides Naturæ Curiosorum*, published at Frankfort, in 1684; and the writings of Baglivi (*Specimen de Fibrâ Motrici et Morbosa*) and Dr. Willis (*Pathologia Cerebri et Nervorum*), and still more particularly to Dr. Gilchrist's elaborate treatise on nervous fevers (*Edin. Med. Trans.*, vol. iv., art. xxiii.; and vol. v., part ii., art. xlviii.); who, following up the hint thrown out by Boerhaave in the aphorism just quoted, endeavours to show how well the two ideas of *lensor* and *spasm* are disposed to amalgamate in forming the proximate cause of fever; the spasm consisting of a universal muscular tension, and the *lensor* being united, according to the nature of the case, with inflammation, acrimony, or both; and hence often producing what he denominates an *alternate nismus* and *renismus*.

The materials, however, were now becoming too unwieldy; and the wheels of the machine were clogged by the very forces that were designed to increase its motion. Dr. Cullen was well aware of this, and boldly ventured upon a new attempt for the purpose of simplifying and facilitating its progress. For his basis he took the hypothesis of Stahl, as modified and improved by Hoffmann: and on this basis erected his stately and elaborate structure, so well known to the medical world, full of ingenuity and daring genius, and which, if it be at this moment crumbling into decay, certainly is not falling prostrate before any fabric of more substantial materials, or more elegant architecture. Dr. Cullen has been accused of the same want of ingenuousness towards Hoffmann, as Hoffmann is chargeable with towards Stahl; and of having introduced his system to the public with little or no acknowledgment of the sources from which he has drawn. But, surely, no one can bring forward such an accusation, who has read with any degree of attention the preface to his *Practice of Physic*, in which he gives a full account of Dr. Hoffmann's system in his own words, and pays complete homage to his merit.

According to the more elaborated principles of the Cullenian system, the human body is a congeries of organs, regulated by the laws not of inanimate matter, but of life, and superintended by a mobile and conservative power or energy,

* *Med. Nat. Systemat.*, tom. iii. § 1, cap. 4. Bochner, *Diss. de Spasmi Peripherici signo in Febribus continuentibus*, Hal., 1765.

seated in the brain, but distinct from the mind or soul; acting *wisely* but *necessarily*, for the general health; correcting deviations and supplying defects, not from a knowledge and choice of the means, but by a pre-established relation between the changes produced and the motions required for the restoration of health; and operating, therefore, through the medium of the moving fibres, upon whose healthy or unhealthy state depends the health or unhealthiness of the general frame: which fibres he regarded, with Stahl, as simple nerves, the muscular filaments being nothing more than their extremities, and by no means possessed of an independent vis insita.

The brain, therefore, upon this hypothesis, is the primum mobile; but it closely associates in its action with the heart, the stomach, and the extreme vessels. The force of the heart gives extension to the arteries, and the growth of the body depends upon such extension, in conjunction with the nutritious fluid furnished by the brain, and deposited by the nerves in the interstices of their own fibres; the matter of which fibres is a solid of a peculiar kind, whose parts are united by chymical attraction. All nervous power commences in the encephalon; it "consists in a motion beginning in the brain and propagated from thence into the moving fibres, in which a contraction is to be produced. The power by which this motion is propagated we name," says Dr. Cullen, "the ENERGY of the brain; and we therefore consider every modification of the motions produced, as modifications of that energy."—(*Mat. Med.*, part ii., chap. viii., p. 349.) He further lays it down as a law of the economy, that the energy of the brain is alternately excited and collapsed, since the very fibrous contraction is succeeded by a relaxation: whence spasms and convulsions are *motus abnormes*, and consist in an irregularity of such alternation. But we must distinguish in this system between the energy of the brain and the vital fluid it sends forth by the nerves: for, while the former rises and sinks alternately, the latter remains permanently the same. It is not a secretion, but an inherent principle, never exhausted, and that never needs renewal.—(*Mat. Med.*, part ii., chap. vi., p. 223.)

This hypothesis, in its various ramifications, influenced every part of his theory of medicine, and consequently laid a foundation for his doctrine of fever. The proximate cause of fever was, in his opinion, a collapse or declination of the energy of the brain, produced by the application of certain sedative powers, as contagion, miasm, cold, and fear, which constitute the remote causes. This diminished energy extends its influence over the whole system, and occasions a universal debility; but chiefly over the extreme vessels, on which it induces a spasm; and in this spasm the cold fit is supposed to consist.

"Such, however," to adopt the words of Dr. Cullen himself (*Prac. of Phys.*, § xlv.), "is the nature of the animal economy, that this debility proves an indirect stimulus to the sanguiferous system; whence, by the intervention of the cold stage, and spasms connected with it, the action of the heart and larger arteries is in-

creased, and continues so till it has had the effect of restoring the energy of the brain, of extending this energy to the extreme vessels, of restoring therefore their action, and thereby especially overcoming the spasm affecting them; upon the removing of which, the excretion of sweat, and other marks of the relaxation of the excretories take place."

This relaxed or perspiratory section of the paroxysm, however, is not regarded by Dr. Cullen as a part of the disease, but as the prelude to returning health. Yet the fit still consists of three stages: the first, of debility or diminished energy; the second, of spasm, and the third, of heat. And though Dr. Cullen had some doubts whether the remote cause of fever might not produce the spasm, as well as the atony of the nervous system, yet he inclined to ascribe the second stage to the operation of the first, as he did most decidedly the third to that of the second; and thus to regard the whole as a regular series of actions, employed by the vis medicatrix naturæ for the recovery of health.

That fever, in its commencement, or earliest stage, is characterized by debility of the living fibre, or, more closely in the words of Dr. Cullen, by diminished energy of the brain, extending directly or indirectly to the voluntary muscles and capillaries, and producing the *signa prodroma* of Professor Frank (*De Curand. Hom. Morb.*, tom. i., page 3, 8vo., Mannh., 1792), cannot for a moment be doubted by any one who accurately watches its phenomena. And thus far the Cullenian hypothesis is unquestionably correct; as it appears to be also in supposing the cold stage to be the foundation of the hot, and of the excretion of sweat, by which the hot stage is succeeded; the entire series forming Frank's *signa constitutiva*. But it fails in the two following important points, without noticing a few others of smaller consequence. The spasm on the minute vessels, produced by debility, takes the lead in the general assault; and, though it forms only a link in the remedial process, is the most formidable enemy to be subdued; and hence, all that follows in the paroxysm is an effort in the system to overcome this spasm. The effort at length proves successful, the debility yields to returning strength, the spasm is conquered, and the war should seem to be over. But this is not the fact: the war continues notwithstanding; there is nothing more than a hollow truce; debility and spasm take the field again, and other battles remain to be fought. There is nothing in this hypothesis to account for a return of debility and spasm after they have been subdued; nor to show why spasm should ever in the first instance be a result of debility. "In this system," says Dr. Parr, "the production of spasm by debility is an isolated fact without a support; and the introduction of the vires medicatrices naturæ is the interposition of a divinity in an epic, when no probable resource is at hand."

The next striking defect is, that debility is here made a cause of strength; the weakened action of the first stage giving rise to the increased action and re-excited energy that restore the

system to a balance of health : and here again we stand in need of the interposition of some present divinity, to accomplish such an effort by such means.

IV. It is not, therefore, to be wondered at, that this system, with all its ingenuity and masterly combination, should not have proved satisfactory to every one. In reality, it did not for many years prove satisfactory to every one in the celebrated school in which it was first propounded. And hence, under the plastic hands of Dr. Brown, arose another hypothesis, of which I shall proceed to give a very brief outline, together with the modification it received under the finishing strokes of Dr. Darwin.

Dr. Brown, who was at first a teacher of the classics at Edinburgh, and a translator of inaugural theses into Latin, commenced the study of medicine about the middle of life, by a permission to attend the medical schools gratuitously. He was at first strongly attached to Dr. Cullen and Dr. Cullen's system ; but an altercation ensued, and he felt an equal animosity towards both. A new and opposite system, if so it may be called, was in consequence manufactured and publicly propounded in a variety of ways. It had great simplicity of principle, and some plausibility of feature ; it attracted the curious by its novelty, the indolent by its facility, and every one by the boldness of its speculations. It circulated widely, and soon acquired popularity abroad as well as at home.

Man, according to Dr. Brown, is an organized machine, endowed with a principle of excitability, or predisposition to excitement, by means of a great variety of stimuli, both external and internal, some of which are perpetually acting upon the machine ; and hence the excitement, which constitutes the life of the machine, is maintained. Excitability, therefore, is the nervous energy of Dr. Cullen ; and, like that, is constantly varying in its accumulation and exhaustion : yet not, like the nervous energy of Dr. Cullen, under the direction and guidance of a *vis conservatrix et medicatrix naturæ*, distinct from the matter of the organization itself, but passively exposed to the effect of such stimuli as it may chance to meet with, and necessarily yielding to their influence.

Upon this hypothesis excitement is the vital flame, excitability the portion of fuel allotted to every man at his birth, and which, varying in every individual, is to serve him without any addition for the whole of his existence ; while the stimuli, by which we are surrounded, are the different kinds of blasts by which the flame is kept up. If the fuel, or excitability, be made the most of, by a due temperature or mean rate of blasts or stimuli, the flame or excitement may be maintained for sixty or seventy years. But its power of supporting a protracted flame may be weakened by having the blast either too high or too low. If too high, the fuel or excitability will, from the violence of the flame, be destroyed rapidly, and its power of prolonging the flame be weakened directly ; and, to this state of the machine Dr. Brown gave the

name of indirect debility, or exhausted excitability. If the blasts or stimuli be below the mean rate, the fuel, indeed, will be but little expended, but it will become drier and more inflammable ; and its power of prolonging the flame will be still more curtailed than in the former case ; for half the blast that would be required to excite rapid destruction antecedently, will be sufficient to excite the same effect now. This state of the machine, therefore, the author of the hypothesis contra-distinguished by the name of direct debility, or accumulated excitability.

Upon these principles he founded the character and mode of treatment of all diseases. They consist but of two families, to which he gave the name of sthenic and asthenic ; the forms produced by accumulated excitability, and marked by direct debility ; the latter occasioned by exhausted excitability, and marked by indirect debility. The remedial plan is as simple as the arrangement. Bleeding, low diet, and purging, cure the sthenic diseases ; and stimulants of various kinds and degrees, the asthenic.

Fevers, therefore, under this hypothesis, like other diseases, are either sthenic or asthenic ; they result from accumulated or exhausted excitability. Synocha, or inflammatory fever (causa under the present arrangement), belongs to the first division, and typhus to the second. Let us try the system by these examples.

The first symptoms of inflammatory fever, like those of all others, evince, as I have already observed, debility or languid action in every organ, let the debility be distinguished by whatever epithet it may. The vital flame is weak, and scarcely capable of being supported ; and yet the fuel is more inflammable than in a state of health ; the excitability is accumulated. This scheme, therefore, completely fails in accounting for the origin or first stage of inflammatory, or, in Dr. Brown's own language, sthenic fever.

Typhus pestilens, or jail-fever, is arranged by Dr. Brown as an asthenic disease ; and, as such, we have reason to expect debility, as characteristic of its entire progress. Yet, what is it that produces this debility ? The blast or stimulus is here contagion ; and the excitability is exhausted by the violence of this blast or stimulus ; but there is no means of its becoming exhausted without increasing the excitement : the fuel can only be lessened by augmenting the flame that consumes it. Yet in typhus, according to this hypothesis, the fuel is expended, not in proportion as the flame is active and violent, but in proportion as it is weak and inefficient. The excitability is exhausted, and the debility increases in proportion as the excitement forbears to draw upon it for a supply. The blast blows hard, but without raising the fire, and yet the fuel consumes rapidly. This scheme, therefore, completely fails in accounting for any stage of low or asthenic fevers of every description.

Dr. Brown, however, was not a man of much practice ; his writings show that he was but little versed in the symptoms of diseases ; his

descriptions are meager and confused : and hence, when he comes to assort diseases into the only two niches he allots for their reception, he makes sad work ; and maladies of the most opposite characters, and demanding the most opposite mode of treatment, are huddled together to be treated in the same manner, in many cases with no small risk of the patient. Thus, among the sthenic diseases are associated rheumatism, erysipelas, scarlet and inflammatory fever ; and, among the asthenic, gout, typhus, apoplexy, and dropsy.

The Brunonian hypothesis, nevertheless, offers one principle that is unquestionably founded on fact, and is peculiarly worthy of attention ; I mean, that of accumulated excitability from an absence or defect of stimuli ; in colloquial language, an increase of energy by rest. And it is this principle which forms the hinge on which turns the more finished system of Dr. Darwin.

Sensible of the objection that weighs equally against that part of the system of Dr. Cullen and Dr. Brown, which represents the energy or excitability of the living frame as capable of recruiting itself after collapse or exhaustion, without a recruiting material to feed on, he directly allows the existence of such a material ; regards it as a peculiar secretion, and the brain as the organ that elaborates and pours it forth. The brain, therefore, in the system of Dr. Darwin, is the common fountain from which every other organ is supplied with sensorial fluid, and is itself supplied from the blood, as the blood is from the food of the stomach.

All this is intelligible ; but when, beyond this, he endows his sensorial fluid with a mental as well as a corporeal faculty, makes it the vehicle of ideas as well as of sensation, and tells us, that ideas are the actual "contractions, or motions, or configurations, of the fibres which constitute the immediate organ of sense" (*Zoonom.*, vol. i., sect. ii., ii., 7), he wanders very unnecessarily from his subject, and clogs it with all the errors of materialism.

He supposes the sensorial power, thus secreted, to be capable of exhaustion in four different ways, or through four different faculties of which it is possessed : the faculty of IRRITABILITY, exhausted by external stimuli affecting simple irritable fibres : that of SENSIBILITY, exhausted by stimuli affecting the fibres of the organs of sense : that of VOLUNTARITY, exhausted by stimuli affecting the fibres of the voluntary organs, acting in obedience to the command of the will ; and that of ASSOCIABILITY, exhausted by stimuli affecting organs associated in their actions by sympathy or long habit. By all, or any of these means, the sensorial power becomes evacuated, as by food and rest it becomes replenished, often, indeed, with an accumulation or surplus stock of power.

In applying this doctrine to fever, he considers its occasional causes, whatever they may be, as inducing a quiescence or torpor of the extreme arteries, and the subsequent heat as an inordinate exertion of the sensorial power hereby accumulated to excess ; and, consequently,

the fever of Dr. Darwin commences a stage lower than that of Dr. Cullen, or in the cold fit, instead of in a collapse of the nervous energy lodged in the brain.

Now, allowing this explanation to account for the cold and hot stages of a single paroxysm of fever, like the spasm of Dr. Cullen, it will apply no farther. For, when the sensorium has exhausted itself of its accumulated irritability, the disease should cease. It may, perhaps, be said, that a second torpor will be produced by this very exhaustion, and a second paroxysm must necessarily ensue. Admitting this, however, for a moment, it must be obvious that the first or torpid stage only can ensue ; for the system being now quite exhausted, the quiescence that takes place during the torpor can only be supposed to recruit the common supply necessary for health ; we have no reason to conceive, nor is any held out to us, that this quantity can again rise to a surplus. Yet it must be farther remarked, that, in continued fevers, we have often no return of torpor or quietude whatever, and, consequently, no means of re-accumulating irritability ; but one continued train of preternatural action and exhaustion, till the system is completely worn out. And to this objection, the Darwinian hypothesis seems to be altogether without a reply.

A still later modification of the Brunonian system (for after all it is such, though the name of Brown is hereby openly despised), has been attempted in France by M. Broussais, and has acquired a very considerable degree of popularity, though a popularity that seems to have little chance of a longer duration than the two forms by which it has been preceded. Throwing out of the catalogue of vital properties the sensibility of Bichat, and indeed all other vital properties whatever but organic contractility, he maintains that this alone is the real source of all diseases whatever, and that no other exists or is wanted. This contractility is the excitability of Brown, and to the excitement that flows from it M. Broussais has given the name of irritation or excitation, upon a plus or minus degree of which all diseases, as in the hypothesis of Brown, are dependant. But he has this great advantage over Brown, that, instead of making the state of excitement or depression common to the entire system, M. Broussais limits both to particular organs, and contends, that when an organ is in a state of irritation, or *vital erection*, to adopt another quaint term from the technology he employs, such effect can only take place at the expense of some other part of the system, the contractility of which is proportionably diminished.—(*Exposition de la Nouvelle Doctrine Médicale*, &c., Par J. R. A. Gougel, Paris, 1824.) Diseases with him, therefore, proceed, for the most part, from an unequal distribution of excitation or irritation ; and as the doctrine of sympathy is carried to a considerable extent, and plays a very important part in the pathological drama, often, indeed, a very ingenious part, the author of the hypothesis obtains an easy and occasionally a correct mode of accounting for local diseases that originate in re-

more quarters; as, for example, when his favourite gastro-enteritis is the result of a cold, damp atmosphere applied to the skin, or a morbid condition of the lungs or of the head. So that gastritis or gastro-enteritis, primary or induced, is almost every thing with him: all fevers are local affections, and, under whatever shape they may appear, their real seat is the stomach, or alvine canal. Among many weak parts of the hypothesis, one of the weakest is its inability of accounting for the chymical changes that are so perpetually taking place in the system during the influence of disease. For as the only source of disease is in the quantity of the efflux of the vital fluids, without any change whatever in their quality, it leaves us entirely in the dark as to the origin of scrofula, cancer, all the exanthems, and, in few words, every other specific poison or morbid secretion whatever; the greater part of which, if not the whole, are still referred to a gastric origin, where we are expressly commanded to look as definitely for the real seat of plague, as for bilious fever, yellow fever, Indian cholera, or dysentery.*

It is not necessary to pursue this subject farther. Other conjectures, more or less discrepant from those now examined, have been offered: but they have not acquired sufficient notice, nor evinced sufficient ingenuity, to be worthy of examination.

V. Other pathologists have referred the proximate cause of fever to a morbid affection of some particular organ, or set of organs, associated in a common function. Thus, Baron Haller alludes to several in his day, who ascribed it to a diseased state of the vena cava (*Bibl. Med.*, Pr. i., p. 112); Bianchi pitched upon the liver (*Hist. Hepat.*, p. 112); Swalve on the pancreas (*Pancreas*, &c., p. 141), Rahn on the digestive organization generally.—(*Briefwechsel*, band. i., p. 150.) Professor Frank has divided the different kinds of fever between the digestive organs, the arteries, and the nerves, each in a particular state of diseased action; so that with him all fevers are nervous, inflammatory, or gastric.—(*De Cur. Morb. Hom. Epitome*, tom. v., 8vo., Mannh., 1792-4.) The Italian pathologists eagerly caught up this view, and modified it in various ways; and Broussais has of late given it another modification, by placing fever in the mucous membrane of any of the viscera, but chiefly in the mucous membrane of the digestive canal; and consequently gastric fever, with Broussais, takes the lead of all the rest, both in variety and vehemence of action: the particular character or intensity of the fever being resolvable into the temperament, idiosyncrasy, or other circumstances of the individual.—(*Examen*, &c., par F. J. V. Broussais, D. M., 8vo., 1821.) Dr. Clutterbuck has still more lately, in our own

country, and with far more reason and learning, brought forward the brain instead of the stomach; to an inflammation of which organ he ascribes fevers of every kind, regarding them merely as so many varieties of one specific disease, originating from this one common cause.—(*Treatise on Fever*, 8vo.) But this is to confound fever with local inflammation, the idiopathic with the symptomatic affection. In treating of inflammation under the ensuing Order, we shall have sufficient opportunities of seeing, that an inflamed state of almost any organ, and especially of membranous organs, or the membranous parts of organs, is sufficient to excite some degree of fever or other, and not unfrequently fever of the highest degree of danger from its duration or violence. And hence, the liver, the lungs, the stomach, the intestines, the peritonæum, and the brain, have an equal claim to be regarded as furnishing a proximate cause of fever when in a state of inflammation.

A very striking objection to Dr. Clutterbuck's hypothesis is, his limiting himself to a single organ as the cause of an effect, which is equally common to all of them. And on this ground it is, that Professor Marcus, of Bavaria, who has contended with similar strenuousness for the identity of fever and inflammation, has regarded all inflamed organs as equal causes; and is hereby enabled to account, which Dr. Clutterbuck's more restricted view does not so well allow of, for the different kinds of fever that are perpetually springing before us, one organ giving rise to one, and another to another. Thus inflammation of the brain, according to Dr. Marcus, is the proximate cause of typhus; inflammation of the lungs, of hectic fever; that of the peritonæum, of puerperal fever; and that of the mucous membrane of the trachea, of catarrhal fever: a view which has lately been adopted by several French writers of considerable intelligence, as an improvement upon the hypothesis of Broussais.*

The general answer, however, to pathologists of every description who thus confound or identify fever with inflammation, whether of a single organ or of all organs equally, is, that, though fever is commonly a symptom or sequel of inflammation, inflammation is not uncommonly a symptom or sequel of fevers. And hence, though post-obit examinations, in the case of those who have died of fever, should show inflammation in the brain, the liver, or any other organ, it is by no means a proof that the disease originated there, since the same appearance may take place equally as an effect, and as a cause: while a single example of fever terminating fatally, without a trace of inflammation in any organ whatever, and such examples are perpetually occurring, is sufficient to establish the existence of fever as an idiopathic malady, and to separate the febrile from the phlogistic divisions of diseases.†

* See M. Broussais' *Examen de la Doctrine Médicale généralement adoptée, et des Systèmes Modernes de Nosologie*, Paris, 1816. All the above observations by Dr. Good on the theory of Broussais, are new matter in the present edition, lately found among the author's MSS., and marked for insertion in this work.—Ed.

* M. Gaultier de Claubry, vide *Journ. Gén. de Médecine*, Avr., 1823, and M. Tacheron, *Recherches Anatomico-Pathologiques sur la Médecine Pratique*, &c., 8vo., 3 tomes, Paris, 1823.

† "It is too generally imagined, that the pri-

"A fever, therefore," to adopt the language of Dr. Fordyce, "is a disease that affects the whole system; it affects the head, the trunk of the body, and the extremities; it affects the circulation, the absorption, and the nervous system; it affects the skin, the muscular fibres, and the membranes; it affects the body, and affects likewise the mind. It is, therefore, a disease of the whole system, in every kind of sense. It does not, however, affect the various parts of the system uniformly and equally; but, on the contrary, sometimes one part is much affected in proportion to the affection of another part."*—(*On Fever*, Dissert. i., p. 23.)

many disease which induces fever is essentially local inflammation. The application of this doctrine to the early stage of fever, we hold to be not only at variance with facts, but dangerous as to the practical deductions to which it leads. We know that irritation, far short of inflammation, is sufficient to excite feverish indisposition, more particularly at those periods of life at which the vascular system is easily excited by apparently trivial, local, or sympathetic disturbance (for example, in infancy or childhood, by dentition, or intestinal irritation), and that this feverishness disappears when the cause is removed. The paroxysm of an intermittent is induced by the peculiar effect of a malarial poison; in this disease, the whole phenomena of fever are well marked; but certainly few will maintain, that the febrile disturbance is the consequence of local inflammation. There can be little doubt that the error alluded to may, in a great measure, be imputed to the attempts to discover the cause or nature of fever in the various local lesions which are observed in fatal cases. On the other hand, the important fact should ever be kept in view, that the primary disorder, whatever it may be, passes readily into inflammation, and that the lesions which arise in the progress of fever constitute the principal source of danger, and are in many instances the immediate cause of death."—Dr. Tweedie in *Cyclop. of Pract. Med.*, art. FEVER.

* It is singular that Dr. Good, who has stated, with much ability and clearness, the theories of medicine which have successively prevailed, should have entirely omitted even a cursory notice of our distinguished countryman Dr. Rush, who may be justly ranked among those who have successfully elucidated, at least in part, some of the soundest principles of medical practice. On the subject of Dr. Rush's merits as a systematic theorist, we avail ourselves of a supplementary note by Dr. J. W. Francis, in the American edition of Dr. Brewster's *Encyclopedia*, Vol. xii., p. 741 "Dr. Rush has been noticed as one of the class of modern eclectics, we think, improperly. No author of late times has probably laboured more perseveringly than Dr. Rush in favour of a particular system, and throughout his numerous medical writings traces of his peculiar theory are always apparent. His system may probably be considered a modification of the doctrines of Dr. Brown, but ushered into the world under circumstances more favourable to its successful reception. In the advantages of preliminary learning and general science, in experimental research and practical acumen, Brown can stand in no competition with Rush: while the greater elaboration of his doctrines by the latter early began and continued to an advanced age; his extraordinary eloquence as a public teacher, in the then only frequented university of the American republic; and

The result of the whole, as observed at the outset of this introduction, is, that we know little or nothing of the proximate cause of fever, or the means by which its phenomena are immediately produced. In the language of Lieutaud, applied to the subject before us, they are too often *atrâ caliginis mersæ*; nor have any of the systems hitherto invented to explain this recondite inquiry, however ingenious or elaborate, answered the purpose for which they were contrived.*

From the proximate cause of fever, let us next proceed to a few remarks upon its REMOTE causes.

Dr. Cullen, who has striven so strongly and so ingeniously to simplify the former, has made a similar attempt in respect to the latter. He first resolves all remote causes into debilitating or sedative powers, instead of being stimulant, as they were formerly very generally considered, and as they are still regarded by many pathologists, and especially by those who contemplate fever and inflammation as identical. Whether this position of Dr. Cullen be correct or not, it was necessary for him to lay it down and to maintain it, or he must have abandoned his system of fever altogether, which supposes it to commence in, and be primarily dependant upon, debility.

These sedative or debilitating causes he reduces to two,—MARSH and HUMAN effluvia; to the former of which he limits the term *miasmata*, and the power of producing intermittent fevers, which, with him, include remittent;

the popularity of his written productions, secured to him an ascendancy and duration which the principles of Brown, popular as they once were, never attained. Dr. Rush, however, seldom permitted mere theoretical views to mislead his practice; and his contemporaries will bear witness, that his prescriptions were as prudent and judicious, as his speculations were ardent and adventurous. At the present day, when the pretensions of several medical universities in the country present nearly equal claims, the medical practice in the United States is far too various to exhibit the liveries of any particular sect. More recently, the doctrines of sympathy, as they are termed, have been ably illustrated and defended, in the Philadelphia school, by Professor Chapman; while the principles of the humoral pathology, as modified by the late researches in physiology, and the results afforded by animal chymistry, are advocated by the professor of the practice of physic in the New-York University.—(See Dyckman's *Pathology of the Human Fluids*.) These two theories may be deemed those most current among American physicians."—D.

* The following observations by Dr. Tweedie agree with those of Andral (*Anat. Pathol.*, tom. ii., p. 211, &c., and *Clinique Méd.*). "In most cases of fever we can discover the existence of certain lesions, but these are too vague or indefinite to enable us uniformly to decide on the primary seat of the malady. It is more than probable, that, in what is usually called *idiopathic fever*, there is alteration either of the solids or fluids, although its precise locality cannot, in every case, be detected; but, without disease in either the one system or the other, we maintain that fever cannot exist."—*Cyclop. of Pract. Med.*, art. FEVER.

while, to the latter, he confines the term contagions, and the power of producing continued fevers. It is true, he has found himself compelled to take notice of a few other powers, as cold, fear, intemperance in venery or drinking; but these he is disposed to regard as little or nothing more than sub-agents, or co-agents, scarcely capable of producing fever by themselves.

"Whether fear or excess be alone," says he, "the remote cause of fever, or if they only operate either as concurring with the operation of marsh or human effluvia, or on giving an opportunity to the operation of cold, are questions not to be positively answered; they may possibly of themselves produce fever; but, most frequently, they operate as concurring in one or other of the ways above mentioned."—(*Pract. of Phys.*, book i., chap. iv., sect. xcvi.) To cold, however, he attributes a power of engendering fever more freely than to the rest; "yet even this," says he, "is commonly only an exciting cause, concurring with the operation of marsh or human effluvia."—(*Ibid.*, book i., chap. iv, sect. xcii.)

We shall find, as we proceed, that these elemental causes may admit of addition; as we shall also, that they more frequently exist as independent agents, than Dr. Cullen is disposed to allow. Yet, there can be little doubt, that the chief and most extensive causes of fever are human and marsh effluvia.

No great benefit, however, has resulted from endeavouring to draw a line of distinction between these two terms, and hence it is a distinction which has been very little attended to of late years. *Miasm* is a Greek word, importing pollution, corruption, or defilement generally; and *contagion* a Latin word, importing the application of such miasm or corruption to the body by the medium of touch.* Hence, there

is neither parallelism nor antagonism in their respective significations; there is nothing that necessarily connects them, either disjunctively or conjunctively. Both equally apply to the animal and the vegetable worlds—or to any source whatever of defilement and touch; and either may be predicated of the other; for, we may speak correctly of the miasm of contagion, or of contagion produced by miasm. Hence, the latter term is equally applied by Sauvages to both kinds of effluvia: "*Miasmata, tum sponte in sanguine enata, tum extus ex aëre, in massam sanguineam delata.*"—(*Nosol. Method.*, Cl. ii.; *Febr. Thcor.*, sect. 79.) And it is not a little singular, and confirms the force of this remark, that, since the publication of the first edition, in which the remark may be found as at present, M. Monfalcon, an ingenious and learned advocate of the Broussais hypothesis, has specifically applied, in direct contravention of Dr. Cullen's explanation, the terms miasm and miasmata to those morbid effluvia alone which are thrown off from the *living bodies* of men and animals in a state of disease, the influence or pathological action of which on the human frame he denominates *contagion*: while the effluvia from marshes, swamps, privies, cemeteries, and other sources of decomposing animal and vegetable materials, he simply but specifically distinguishes by the name of *marsh effluvia*, and their pathological action by that of *infection*.—(*Histoire des Malaria et des Maladies causées par les Emanations des Eaux Stagnantes*, &c., 8vo., Paris, 1824.)

In a work of practical information, it is hardly worth while to follow up the refinements of those writers who deny, and endeavour to disprove, the existence of contagion under any form or mode of origin.* Such speculations may be ingenious and very learned, and find amusement for a leisure hour in the closet; but they will rarely travel beyond its limits, and

* A distinction is sometimes made between a *contagious* and an *infectious disease*; the former being communicable only by contact with the patient, or with something that he has touched, or some palpable matter that has proceeded from him. Of this kind are itch, syphilis, cowpox, hydrophobia, elephantiasis, yaws, sibbens, the glanders, and, as is sometimes suspected, porrigo, and plague. *Infectious diseases* are those which a person may contract by merely being exposed to the patient's atmosphere. Some diseases are both *contagious* and *infectious*, being capable of propagation in both manners, as the smallpox, the chickenpox, scarlatina, and the measles. The earliest suggestion of the different modes in which contagious and infectious disorders are propagated, was made by M. Quesnay, in his *Mém. sur les Vices des Humeurs*.—(*Mém. de l'Acad. Royale de Chir.*) This author admits two species of contagion:—"The first consists in the communication of diseases, which extend from one body to another by their property of multiplying the cause that has excited them, and of multiplying themselves in other subjects by this augmentation of cause: smallpox is a manifest instance of this species of contagion." Quesnay's second form of contagion is characterized by "the communication of a spontaneous movement, that extends from one body to another susceptible of this movement." This he compares to the fermenting of

dough, or the extension of putrefaction through flesh. As Baron Dupuytren has explained, in a valuable document on contagious diseases, it appears that some of them are transmitted through the medium of the air; such are measles and scarlatina, after attaining a certain stage. Others are communicated by contact, as, for instance, the itch; some usually require contact and friction: such is the venereal disease. Others, like the cowpox and hydrophobia, need inoculation, or insertion. Some can be propagated only in one manner: such are measles, scarlatina, the itch, the cowpox, and hydrophobia. Others may be communicated in several ways, as syphilis and smallpox, the first of which may be transmitted with and without friction, and by inoculation; and the second by inoculation, contact, or the medium of the atmosphere. Dupuytren errs, however, in stating that measles cannot be communicated by inoculation.—See Rapport fait à l'Institut en 1825, sur un Mém. de M. Costa relatif à l'Epidémie qui ravagea Barcelonne en 1821.—En.

* Lassis, Recherches sur les véritables Causes des Maladies Epidémiques appelées Typhus, ou de la Non-contagion des Maladies Typhoides, &c., 8vo., Paris, 1813. Maclean's Results of an investigation respecting Epidemic and Pestilential Diseases, &c., 2 vols., 8vo., 1817-18.

should they ever be acted upon, would instantly destroy themselves.

It is a question of more importance, whether we have yet the means of realizing the distinction between human and marsh miasmata,* which Dr. Cullen has here laid down, and which has been generally adopted, from the weight of his authority. All specific miasmata may be regarded as morbid ferments, capable of suspension in the atmosphere, but varying very considerably in their degree of volatility, from that of the plague, which rarely quits the person except by immediate contact, to that of the spasmodic cholera of India, which works its way, if it be really from a specific poison, in the teeth of the most powerful monsoons, despising equally all temperatures of the atmosphere and all salubrities of district, and travelling with the rapidity of the fleetest epidemic. They are of various kinds, and appear to issue from various sources, but we can only discriminate them by their specific effects. These are most clearly exemplified in the order of exanthems; in which, for some thousands of years, they have proved themselves to be of a determinate character in all parts of the world where they have been the subject of observation, differing only in circumstances that may be imputed to season, climate, and other external causes, or to the peculiar constitutions of the individuals affected. Thus, the miasm of smallpox has uniformly continued true to smallpox, and that of measles, to measles; and neither of them has, in a single instance, run into the other disease, or produced any other malady than its own.

But, can we say the same of the supposed two distinct miasms of marsh and human effluvia? It is equally true, that the former has never produced any other than intermittent fever, or the latter any other than continued? And is it also equally true, that each of these maladies adheres as strictly to its own character in every age, and every part of the world, as smallpox and measles; and that they have uniformly shown as strong an indisposition to run into each other? Dr. Cullen's system is built upon an affirmative to these questions. For it, in fact, allows but two kinds of fever, each as distinctly proceeding from its own specific miasm as any of the exanthems.

But this is to suppose what is contradicted by the occurrences of every day: which compel us to confess, that, while we cannot draw a line of distinction between marsh and human effluvia from their specific effects, we have no other mode of distinguishing them.

Some writers, indeed, have denied that intermittents, or rather the intermittents of marsh-

lands, are produced by a miasm of any kind; for they deny that any kind of miasm is generated there; and contend, that the only cause of intermittents, in such situations, is air vitiated by being deprived of its proper proportion of oxygen in consequence of vegetable and animal putrefaction, combined with the debilitating heat of the autumnal day, and the sedative cold and damp of the autumnal night.—(*Currie, Trans. Amer. Phil. Soc.*) But this opinion is too loosely supported to be worthy of much attention. It is sufficiently disproved by the intermittent described by Sir George Baker, as existing in the more elevated situations of Lincolnshire, while the adjoining fens were quite free from it.—(*Medic. Trans.*, vol. iii., art. xiii.) And, in like manner, the severe and intractable intermittents, of whatever form or modification, that exercise their fearful sway from Cape Comorin to the banks of the Cavery, from the Ghauts to the coast of Coromandel, not unfrequently pass into a contagious type, and propagate themselves by contagion.—(*Report on the Epidemic Fever of Coimbatore, by Drs. Ainsly, Smith, and Christie.*) We have as much reason to suppose a febrile miasm in intermittents as in typhus; and, in some instances, they have been found as decidedly contagious. "That intermittent fevers," says Dr. Fordyce, "produce this matter, or, in other words, are infectious, the author (meaning himself) knows from his own observation, as well as from that of others."*

And, notwithstanding that it becomes us to speak with diffidence upon a subject, respecting which we are so much in want of information, I may venture to anticipate, that the evidence to be advanced in the ensuing pages upon the general nature and diversities of fever, will show that there is more reason for believing that the febrile principle, produced by marsh and human effluvia, is a common miasm, only varying in its effects by accidental modifications, and equally productive of contagion, than that it consists of two distinct poisons, giving rise to two distinct fevers, the one essentially contagious, as contended for by Dr. Cullen.†

* On Fever, Diss. i., p. 117. Notwithstanding Dr. Good's arguments, the Cullenian doctrine still prevails. "It appears quite certain," says Dr. Elliotson, "that intermittent and remittent fevers are not contagious." If a person catch a disease by going to see a patient who is labouring under it, this is no proof that the disorder is contagious; for the patient may be in the very spot where he contracted it from local circumstances; and the visitor goes to the spot, and exposes himself to the same causes. In order to prove that a disease is contagious, there should be a sufficient number of instances of persons going from the place where they contracted the disease to a healthy part, and there giving it to others. On this point the reader will find valuable rules of evidence laid down by Dr. Alison (On Epidemic Fever, in *Edinb. Med. and Surg. Journ.*, vol. xxvii.), and various judicious reflections by Professor Elliotson, in his Lectures delivered at the Lond. Univ., as published in *Med. Gaz.* 1831-2, p. 921.—Ed.

† Certain difficulties, in the adoption of this view of the subject, will be noticed when intermittent fever comes under consideration.—Ed.

* Johnson, *Influence of Tropical Climates, &c.*, pp. 20, 21, 3d edit., 1822. Miasm still denotes, in the common language of the profession, only the exhalations of decaying vegetable matter, which are the exciting causes of intermittent and remittent fevers. As Dr. Elliotson has very justly observed, however, *marsh-miasm* is an improper expression: it generally comes from a marsh; but it may arise without the presence of any marsh at all. Hence the term *malaria* is frequently preferred.—Ed.

In effect, we shall perceive, that this mysterious subject is capable of being, in some degree, more clearly elucidated and still farther simplified, than it has been by preceding pathologists.

In the decomposition of all organized matter, whether vegetable or animal, when suddenly effected by the aid of heat and moisture, an effluvia is thrown forth that is at all times highly injurious to the health; and, in a closely concentrated state, fatal to life itself. Thus, we are told by Fourcroy, that, in some of the burial grounds in France, whose graves are dug up sooner than they ought to be, the effluvia from an abdomen, suddenly opened by a stroke of the mattock, strikes so forcibly upon the grave-digger as to throw him into a state of asphyxy, if close at hand; and, if at a little distance, to oppress him with vertigo, fainting, nausea, loss of appetite, and tremors for many hours: while numbers of those, who live in the neighbourhood of such cemeteries, labour under dejected spirits, sallow countenances, and febrile emaciation.* This effluvia is from the decomposition of animal matter alone; but, the foul and noisome vapour that is perpetually blown off the coast of Batavia, and the stinking malaria that rushes from the southeast upon the Guinea coast, though loaded with vegetable exhalations alone, triumph in a still more rapid and wasteful destruction. The last peculiarly so, as being thoroughly impregnated with destructive miasm, while sweeping over the immense uninhabitable swamps and oozy mangrove thickets of the sultry regions of Benin, insomuch that Dr. Lind informs us, that the mortality produced by this

pestilential vapour in the year 1754 or 1755 was so general, that in several negro towns, the living were not sufficient to bury the dead; and that the gates of Cape Coast Castle were shut up for want of sentinels to perform duty; blacks and whites falling promiscuously before this fatal scourge.

In this case, as in the preceding, the vapour is always accompanied with an intolerable stench from the play of affinities between the different gases that are let loose by the putrefactive decomposition; and hence it is impossible to affirm, that the mortality thus produced is the result of any single or specific miasm operating to this effect. But it shows us, that the general effluvia from the decomposition of all dead organized matter, whether animal or vegetable, is equally deleterious to health and life. "Its presence," says the judicious Dr. Jackson, "is often connected with something offensive to the senses,—to the smell, and, perhaps, even to the taste. A certain degree of salivation, nausea, sickness, and headache, is often occasioned by the exhalations of a *swamp*, or the air of an *infected apartment*, but febrile action is not ordinarily the immediate consequence. To produce fever a space of time is required, different according to circumstances."—(*Outline of the History and Cure of Fever*, part i., ch. iii., p. 104.) How far the decomposition of dead vegetable matter, though its effluvia prove thus injurious to the health of man, may *alone* be capable of exciting fever of any kind, may, perhaps, admit of a doubt; for, in the bogs or peat-mosses of Scotland, and, still more, those of Ireland, the inhabitants are exempt from agues, though the ooze extends in immense tracts.*

The decomposition, however, to which on the present occasion we are chiefly to direct our attention, is of a mixed kind; for the marsh and oozy soil of countries that are closely or have been long inhabited, is necessarily a combination of animal and vegetable matter.

If this decomposition take place slowly, as in cold or dry weather, and more particularly in a breezy atmosphere, not the slightest evil is sustained during its entire process. And hence, in order to render it mischievous, and particularly in order to render it capable of producing fever of any kind, it is necessary that it should be assisted by the co-operation of certain

* *Elém. de Chimie*, Art. Putréfaction de Subst. Animal., tom. iv. These facts prove nothing more than either the asphyxiating nature, or the general unfavourable influence of such effluvia on the human constitution, and not the existence of any specific miasm or contagion, capable of bringing on either intermittent or continued fever. On this subject the following observations are curious and instructive:—"That it is vegetable and not animal matter which produces ague, is proved by this circumstance, that no person has that affection from being exposed to the most intense animal exhalations. Thousands of carcasses are annually employed in many manufactories, and yet no person is known to contract an ague from them; indeed, so far from it, that the most crowded places generally escape intermittent fevers. That part of Rome inhabited by the Jews, and called the *Judaicum*, is full of animal filth, but it escapes ague, while the elegant streets in the neighbourhood suffer from it very severely. Malaria not being the produce of dead animal matter, or effluvia arising from living bodies, the more men and animals are crowded together, the less access is there for the malaria; and, indeed, it is generally supposed, that the addition of smoke of every description has a great tendency to prevent it."—(Professor Elliotson's *Lect. at Lond. Univ.*, as published in *Med. Gaz.* for 1831-2, p. 895.) Further remarks on this point will be introduced when we come to intermittent fever, and here the editor will merely refer to the observations of M. Andouard, *Recherches sur la Fièvre Jaune*, and to various facts adduced by M. Brachet, of Lyons, in confirmation of the truth of the above view.—*Archives Gén. de Méd.*, tom. ix., pp. 380, 381.—Ed.

VOL. I.—Y

* The following is the explanation of this circumstance, given by Professor Elliotson:—"There is one description of bog which does not produce malaria; but then there is no putrefaction; decomposition has taken place in a peculiar manner. The vegetable matter becomes carbonized, and there is not sufficient heat for putrefaction to occur; but, it is said, that when peat-moss is in a certain latitude, and on a certain level, it can putrefy, and then, I believe, ague does prevail. That peat-bog does not putrefy is shown by a fact stated on good authority, viz., that animal matter thrown into it will not putrefy; but, it is said, that where peat-moss is placed in other situations, where it is warmer, and upon a proper level for moisture, it will putrefy and produce ague, just as other kinds of vegetable matter do."—*Lect. at Lond. Univ.*, *Med. Gaz.* 1831-2, p. 895.—Ed.

agents, many of which we do not seem to be acquainted with, but which, so far as we are capable of tracing them, appear to be auxiliary to the general process of putrefaction, as warmth, moisture, air, and rest or stagnation.

The simplest and slightest fever that is produced under the joint influence of these powers, is the intermittent: and we find these produced where their joint influence is but feeble, and where it exists, perhaps, in its lowest stage, as in the favourable climate of our own country; where we are not frequently overloaded with equinoctial rains, and have not often to complain of a sultry sky, or a stagnant atmosphere. Even here, however, we perceive a change in the character of the intermittent at different seasons: for while in the spring it usually exhibits a tertian type, in the autumn we find it assume a quartan. And as these can only be contemplated as varying branches of the same disease, we have thus far, at least, reason to regard it as produced by a common febrile miasm, modified in its operation by a variation in the relative proportion which its auxiliaries, known and unknown, bear to each other during the vernal and autumnal seasons: coupled, perhaps, with some degree of change, produced by the same seasons in the state of the human body.

If from our own country we throw our eyes over the globe, we shall find in every part of it where the same causes exist, that in proportion as they rise in potency, they produce a fever of a severer kind, more violent in its symptoms, and more curtailed in its intervals, till we gradually meet, first with no distinct intervals, and at length with no intervals whatever; and hence perceive the remittent progressively converted into intermittent and continued fevers. And that here we have still the same miasm, merely modified in its operation by the varied action of its auxiliary powers on the constitution of the individuals it attacks, is as clear as in the former case; because, in many attacks, we see different individuals, touched by the very same influence, exhibit all the varieties now alluded to, and intermittent, remittent, and continued fevers co-existing in every diversity of violence; commencing with either of these forms; keeping true to the form with which they commenced; or changing one form for another.* Such, as remarked by M. Devèze, was the course of the fever at Philadelphia in 1793 (*Traité de la Fièvre Jaune*, &c., 8vo., Paris, 1820); and such, according to M. Berthé, that of the southern

provinces in Spain, in 1800 (*Précis Historique de la Maladie, qui a régné dans l'Andalousie, en 1800*): and such was peculiarly the fact in the highly malignant yellow fever of Antigua, in 1816, as admirably described by Dr. Musgrave. —(*Medico-Chirurg. Trans.*, vol. ix., p. 92.)

This last disease first showed itself during sultry weather and a quiet atmosphere, in a swampy part of the island, among a ship's crew lately arrived, but from a healthy vessel, and themselves in good health on first landing. It soon spread widely, and at length indiscriminately in town and country, among all ranks, and conditions, and situations, blacks as well as whites, the oldest settlers as well as the newest comers. In some cases, the head was chiefly affected; in others, the stomach, the liver, or a still different organ. Hiccough and black vomit were common towards the close of the disease, though many died without it; and recovery was no exemption from a second attack.

Dr. Musgrave asserts further, that during the whole of this fatal epidemic, there was no instance of its being received by contagion. The argument, however, which he offers upon this subject is not quite convincing. Yet admitting the fact to be as he states it, we have an additional proof, if proof were wanting, firstly, that when the animal frame has been previously debilitated or relaxed, as in the case of a ship's crew that has been long voyaging in high latitudes, and living on salted provisions, it suffers sooner and more severely than where no such relaxation has taken place: and, secondly, that by a long and gradual exposure to the influence of febrile miasm, however produced, whether from the living human body or from dead organized matter, the animal frame becomes torpid to its action, as it does to the action of other irritants. Whence prisoners confined in jails with typhous miasm around them, as well as those who have long stood the climate in the West Indies, receive the contamination to which they are exposed far less rapidly than strangers, and are capable of communicating it from their clothes or persons to fresh men, without being in the least affected by it themselves; as appears to have been the case in various courts of justice, and particularly at the Black Assize at Oxford, in July, 1577; though Dr. Bancroft has endeavoured to explain this effect in another way.—(*Essay on the Disease called Yellow Fever*, &c., Lond., 1811.)

The argument, however, of Dr. Musgrave upon this point, we have said, is not quite satisfactory; because he admits that those who were about the patients, and paid no attention to personal cleanliness, did not wholly escape; but then, says he, they escaped *generally*, and were *not more frequently* affected, than those who never entered the doors of an infirmary. Now, as all ranks and conditions, blacks and whites, even far off in the country, were affected indiscriminately, we have no reason to expect that those whose habits had rendered them peculiarly torpid to the action of the febrile miasm should be more frequently affected than others. The very admission that

* See Sir Gilbert Blane's valuable article on Yellow Fever, in his *Select Dissertations*, &c., p. 284, 8vo., Lond., 1822. All these facts may be true without proving that malaria alone will give rise to continued fever, except in a secondary, indirect manner, when the change of the intermittent fever to this type may be explained by reference to morbid visceral alterations, sometimes brought on by intermittent fever, and possibly also in hospitals, by taking into the account the influence of the effluvia from patients congregated in such buildings. A similar mode of reasoning would account for the variation of continued fever to the intermittent or remittent type, when the patient is exposed to malaria.—*Ed.*

they were as much so, seems to imply that the febrile miasm was attacking them in some new mode against which they were not guarded by previous habit. Nor is it easy to conceive by what means the local disorder of the coast could be converted into so extensive an epidemic, unless through the medium of contagion.

I have dwelt the longer upon this subject, because it is desirable to reconcile as much as possible, the conflicting testimony of respectable writers, who, having adopted different theories, are insensibly led to support them by inaccordant descriptions of the same disease.

In direct opposition to Dr. Musgrave, Dr. Jackson, Dr. Bancroft, and a host of distinguished writers who think with them, we are told by Dr. Pym, that the Bulam fever, admitted by Dr. Musgrave to be the same as the above, not only is contagious, but is never introduced into any fresh region but by contagion :* while Dr. Rush, speaking of the yellow fever of Philadelphia of 1793, asserts that "there were, for several weeks, two sources of infection, viz., exhalation and contagion. The exhalation," says he, "infected at the distance of three and four hundred yards, while the contagion infected only across the streets. After the 12th of September, the atmosphere of every street in the city was loaded with contagion." He adds, that a few caught the disease who had it before : thus taking a middle course between Dr. Musgrave, who tells us, that recovery affords "no exemption from a second attack," and Dr. Pym, who affirms that the fever "attacks the human constitution but once." In the fever of Cadiz of the year 1800, Sir James Fellowes, who coincides in the view adopted by Dr. Pym, asserts, not only that it was contagious, and propagated only by contagion, but that the air, "from its stagnant state, became so vitiated, that its noxious qualities affected even animals : canary-birds died with blood issuing from their bills, and in all the neighbouring towns which were afterward infected, no sparrow ever appeared."†

I do not remember to have seen this last fact so directly affirmed by any modern writer ; but it is not contradicted in the course of the con-

troversy, and is in perfect coincidence with the state of the air during the plague in most places (*Diemerbr. de Peste*, cap. vi. ; *Van Swieten*, ex *prof. Sorbait*, in sect. 1407), and particularly at Athens, as described by Thucydides (*Hist.* xi., 52) : τεκμήριον δὲ τῶν μὲν τοιοῦτων ὀνείδευσιν σαφὲς ἐγένετο· καὶ οὐχ' ἰωρῶντο οὔτε ἄλλως, οὔτε περ τοιοῦτον οὐδέν. Οἱ δὲ κύνες μᾶλλον αἰσθῆσιν παρήγγον τοῦ ἀποβαίνοντος, διὰ τὸ ζυνδαιατῶσθαι. Whence Lucretius, who does but little more than translate Thucydides :

"Nec tamen omnino temere illis solibus ulla
Comparabat avis, neque noxia secla ferarum
Exibant sylvis ; languēbant pleraque morbo,
Et moriebantur ; cum primis fida canum vis
Strata animam ponebant in omnibus ægre :
Extorquebant enim vitam vis moribida membris.*

"Nor longer birds at noon, nor beasts at night
Their native woods deserted ; with the pest
Remote they languish'd and full frequent died.
But chief the dog his generous strength resign'd,
Tainting the highways, while the ruthless bane
Through every limb his sick'ning spirit drove."

There can be, or rather there ought to be, no question, therefore, that the fever before us was in some regions contagious, or produced from human effluvium ; as, in other regions, and under other circumstances, it was produced from marsh effluvium. And though from a prejudice of education that will presently be pointed out, the contrary is still contended for by names of considerable weight, they seem to be overbalanced in number as well as in authority by those who have enlisted themselves on the opposite side of the question ; of which last it may be sufficient to set down the names of Lind, Clarke, Belfour, Chisholm, Blane, McGrigor, and Johnson, from among our own countrymen ; and of Berthé, Bequene, Dahna, Bally, and Pugnet, among foreigners. The facts brought forward by Sir James McGrigor upon this subject are decisive, indeed, of themselves. And those who are more voracious of proofs may satisfy the most exorbitant appetite by the numerous and conclusive narratives collected by Dr. Chisholm, and especially the fever described by Dr. McCabe (*Edin. Med. and Surg. Journ.*, Oct., 1819), as prevailing among the Royal York Rangers, stationed at Trinidad. "The causes of this fever in its origin were, excessive heat, marsh effluvia from a marsh of immense extent in the immediate vicinity of Port of Spain, considerable labour, and fatigue. Its contagious character superadded to its marshy was produced by an influx of Spaniards from the Spanish Main, in a deplorable state of misery and wretchedness. It was among these unfortunate people that the contagious fever began."—(*Climate and Dis. of Trop. Countries*, p. 42, 8vo., 1822.)

It is probable that Sir James Fellowes and Dr. Pym might contend that, in this quarter, the fever was imported, and maintained by contagion alone, as they have contended was the case in the yellow fever of Cadiz in the year 1808 ; but, even in this last case, they have completely failed in establishing the question of its supposed

* Observations upon the Bulam Fever, which has of late years prevailed in the West Indies, on the coast of America, at Gibraltar, Cadiz, and other parts of Spain, &c., 8vo., 1815.

† Reports of the Pestilential Disorder of Andalusia, which appeared at Cadiz in the years 1800, 1809, 1810, 1813, &c., 8vo., 1815. But, on the other hand, the reader should recollect what has happened subsequently with reference to the present question. In 1821, the city of Barcelona was visited by the yellow fever in a severe and extensively fatal character. Now, if the report of the French medical commission, sent out to investigate the nature of this disorder, be considered, and the facts related be admitted, the contagious nature of the fever must be recognised. But if the reader afterward turn to the valuable documents collected by Dr. Chervin, he will be convinced that the facts which led the commissioners to infer that contagion had been at work, are by no means conclusive ; and he will be compelled to attribute the prevalence of the disease to local circumstances.—*Ed.*

* De Rer. Nat., lib. vi., 1117.

importation by a ship's crew from Spanish America; and, as there is no doubt in the mind of those who have not buckled on the armour of controversy, that this fever was the common fever of the Mediterranean coasts, so well described by Dr. Cleghorn, and which, under different names and with different degrees of violence, commits its ravages mostly about the autumnal equinox, from the swampy shores of the Nile to the oozy banks of the Tiber, and which is often found as destructive in the Campania as in the East or West Indies, there should be no longer any doubt of the operation of one and the same miasm or febrile principle in all these cases; sometimes issuing from the effluvia of the living body, and sometimes from that of dead organized matter: generated, to adopt the language of Professor Frank, "tam in ægotantium variorum corpore, quam in atmosphæra, plurimorum exhalationibus inquinata, favente anni constitutione" (*De Cur. Hom. Morb. Epit.*, tom. i., 8vo., March, 1792); and, consequently, that the whole of that part of Dr. Cullen's system is erroneous which supposes a different specific principle of fever to be generated in each; the one distinguished by being limited to the production of uncontagious intermittent fever, and the other to that of contagious continued fever. And it is of the more importance that the error of this doctrine should be pointed out, since it has proved the very groundwork of that alteration which has prevailed upon the subject before us. For the writers on both sides, having equally drunk from the Cullenian fountain, and being equally impressed with the truth of this doctrine, have only warred with each other in support of Dr. Cullen's distinction; and, hence, those who have so clearly witnessed the origin of the fever from marsh effluvia, that they have been compelled to acknowledge this as its source, have felt themselves compelled at the same time to deny that it is contagious; while those who have as clearly witnessed its contagious power, have as forcibly felt themselves compelled to deny that it has sprung from marshy miasm.

Dr. Jackson affords us one of the clearest proofs of the truth of this remark in his late, as well as in his earlier works. There is no writer who has more distinctly pointed out the close analogy between the symptoms of the marsh endemic of the West Indies, and contagious fever, as they very frequently show themselves, than he has done;—"The derangements," says he, "are exteriorly so much alike, that the discriminating characters cannot be delivered but with doubt and hesitation; the result of the whole appearances will often determine the judgment, but the symptoms, separately considered, lead to no certainty. The causes of endemic and of contagious fevers were equally connected, under certain conditions, with eruptions on the skin, ulcers of the extremities, diarrhœa, purging, dysentery, or flux, fever of an intermittent or remitting form, of a form continued, violent and rapid in course, moderate and of ordinary duration, or slow, lurking, and irregular, ceasing and returning at intervals,—changing

from general to local disease of various descriptions, and from local disease to general and formal fever. The general manner of attack, the course, changes, and duration of endemic and contagious fevers, have great similarity. Certain modes of action or combinations of action prevail more frequently in the one disease than the other, *but forms and modes do not constitute characteristic differences*; thus, affection of the stomach and biliary system, vomiting, and yellowness, are less frequent in contagious than in endemic fever; yet, they do occur in the former, and sometimes to considerable extent. Affection of the chest, alternating with delirium, or affection of the head, appears to be more common in contagious than in endemic fever; so likewise is a peculiar maniacal derangement or lively delirium, occurring in the progress to recovery: yet the frequency of these appearances *does not furnish a characteristic mark*." (*History and Cause of Fever*, pp. 213, 214, 216.) That is to say, all the leading symptoms, which make and determine the diseases, are the same: and though practically and in fact they run into each other and are the same, yet speculatively and theoretically they are not the same, and never can run into each other in the opinion of this valuable writer, because Dr. Cullen has laid down the dictum, that intermittents must proceed from paludaniasm and be uncontagious, and contagious fevers from the morbid effluvia of animal bodies alone. Yet, after all, the substantive part of the tenet seems to be relinquished by Dr. Jackson in the following passage, which occurs in his remarks on the yellow fever that ravaged the Spanish coasts in 1800, notwithstanding the firmness with which the Cullenian doctrine is ostensibly maintained. "The case may perhaps be thus explained. The yellow fever, during the reign of epidemic influence, often strikes like a pestilence by the mere concourse of people in a close place; and if a mass of sick persons be collected into a hospital during the epidemic season, the common emanations from the sick bodies, whether saturated with contagious particles or not, often act offensively on those who enter the circle, and often appear to be the cause of the explosion of a disease, which, without accessory or changed condition of the medium in which man lives, would have probably remained dormant for a time, and perhaps for ever."*

In the typhus, or the fever that originates in crowded jails, and other thronged and noisome abodes, there is no longer a question concerning its human origin, or emanation from sick bodies, and its contagious property; at least, among practical writers. But typhus does not differ more widely in its symptoms from some of the modifications of the fever we have just contemplated, than such modifications do from others of the same fever, varied by the varying power of its co-operating agents.—(*Caizerques, Mémoires sur la Contagion de la Fièvre Jaune*,

* Remarks on the Epidemic Yellow Fever, &c., on the South Coasts of Spain, p. 44, London, 8vo., 1821.

Paris.) And hence we have reason to conclude, that typhus also is generated from the same common febrile miasm, modified in its action by influential contingencies.

In effect, the yellow fever itself, under peculiar circumstances, assumes something of a typhous character even in its first origin, and where the source has unquestionably been marsh miasm. The second form of the Andalusian fever, as described by Dr. Jackson, and especially characterized by defective energy, peculiarly exemplifies this remark; and such was expressly the case with the asthenic remittent at Breslaw in 1757 (*Chisholm, Manual of the Climate and Diseases of Tropical Countries*, &c., p. 38, 1822), as well as in the Island of Edam on the coast of Batavia in 1800, and is still oftener found in the remittent that takes place along the Gambia, after rain in the spring or early part of the summer; when there is less organized matter remaining on the surface of the earth to be decomposed, and what there is has been acted upon by a lower temperature and a shorter duration of heat than in the autumn. "In the month of June," says Dr. Lind, "almost two thirds of the white people were taken ill. Their sickness could not well be characterized by any denomination commonly applied to fevers: it however approached nearest to what is called a *nerve fever*, as the pulse was always low, and the brain and nerves seemed principally affected. It had also a tendency to frequent remissions." The patients were often attacked with a delirium, and ran into the open air, where they received benefit from an affusion of heavy rains upon their naked bodies. The delirium, however, it seems, "soon returned; they afterward became comatose, their pulse sunk, and a train of nervous symptoms followed; their skin often became yellow." And even where the disease commenced with symptoms of great excitement, and an intermittent type, it is so much disposed, under peculiar incidents, as great fatigue, disappointment, and short provisions, to run into a typhus fever, as at Walcheren,* and during the retreat of the British army to Corunna, that many nosologists have thought themselves called upon to make this form a distinct variety or even species of fever, which they have usually distinguished by the name of *typhus icterodes*, or yellow typhus.

In like manner, where the yellow fever has commenced originally from contagion, or, in other words, from a decomposition of human instead of marsh miasm, it has been under the very same auxiliaries of filth, poverty, crowded numbers, and a stagnant atmosphere, that give rise to typhus. Thus, the fever of Malaga in

1803, uniformly admitted to be of the same kind as that of Cadiz in 1800, spread first, according to Professor Arejula's description, through the narrow, crowded, and offensive lanes of the district de Perchel; and that of Cadiz itself, according to Sir James Fellowes, made its earliest appearance in the Barrio de Santa Maria, a part of the town in which the streets are narrower, less ventilated and cleanly, than any other part, and where the poor inhabitants, dirty in their persons, and crowded in filthy rooms, generally live together. It is true, that it was conjectured by many persons, and among others by both these writers themselves, that the contagion did not originate in either of these situations, but was introduced into them by foreign shipping; but such a conjecture has, in the first place, no trustworthy evidence for its support; and, in the second, the mere testimony of the captain of the ship referred to was directly contradicted by the chief physician of the hospital at the Havannah, who was on board the whole time, and was privy to the cases in question. In effect, a cause thus secondary seems to have been superfluous; for the local causes, enumerated by Sir James Fellowes and Professor Arejula (*Breve Descripcion de la Fiebre Amarilla*, p. 229, Madrid, 1806), appear to have been perfectly adequate. They are, as near as may be, the same as those which operate so fatally on the miserable and crowded cabins of Ireland; and if the fever had shown itself at a cooler season of the year, and the subjects of it had been still more broken down in constitution by mental dejection and low diet, it would probably from the first have assumed a continued and typhous character, instead of a remittent and more energetic. The proofs offered upon this subject, from personal and accurate observation, by Dr. Jackson and Dr. O'Halloran, are in full confirmation of this view; for there can be no doubt that the fever of 1820 and 1821, which they described, was the same as that of 1800 and 1803.

"From an impartial consideration," says Dr. O'Halloran, "of all the circumstances attending the epidemics of Spain in the year 1821, the conclusion is, I think, fairly deducible, that the disease was not, and is not occasioned by imported contagion, and that its origin cannot be attributed to the germe of a former epidemic, resuming original activity from the operation of a peculiar state of atmosphere, without which it would remain dormant, perhaps, for ever. All the towns and cities which suffered from the yellow fever, were, with the exception of Cadiz, filthy in the extreme, disgustingly so, and very objectionable on the score of ventilation, situation, and form of construction; while the different towns of Arens, Matero, Badalona, Tarragona, Vinaros, Benicarla, Valencia, Aliama, Velez, Malaga, Marabella, Estepona, Vejer, Conil, Puerto Real, Rota, Chipiona, Orcos, and Medina Sidonia,—all of which are in the vicinity of the sea, and which, it may be presumed from their relative situations, communicate freely with the theatres of disease, were not affected by the malady. They seldom, indeed, suffered in any other years; because, independent of

* Id. *ibid.* Here the change of an intermittent fever to typhus is accounted for by the author himself, without any necessity for having recourse to the hypothesis that the infectious principles of malaria from decaying vegetables, and of animal exhalations, may give rise occasionally either to continued or intermittent fevers. What is stated in the text merely proves, that a person labouring under ague, if exposed to fatigue, disappointment, certain privations, &c., may become typhoid.—ED.

their localities, being better chosen for health, they are comparatively clean.”*

The febrile miasm, then, generated by a decomposition of human effluvia and of dead organized matter, appears to be essentially the same, modified alone in one or two of its qualities by the co-operation of the heat, moisture, stagnant atmosphere, and perhaps some other unknown agents, that are necessary to give it birth or activity.

The chief difference produced in this miasm under these distinct modes of origin, is, that when generated by the decomposition of effluvia issuing from living human bodies, it is less volatile (*Hist. and Cure of Fever, by R. Jackson, M. D., part i., chap. iii., p. 102.*) and has at the same time a power more directly exhausting, or debilitating the sensorial energy, than when generated by the decomposition of dead organized matter. Whence fevers, originating in jails or other confined and crowded scenes, contaminate the atmosphere to a less distance than those from marshes or other swamps, but act with a greater degree of depression on the nervous system when once received into it. Yet, even the latter have a definite atmosphere of action, beyond which they lose their power, and an atmosphere of a more limited diameter than we might at first be tempted to conceive: for, we learn from Sir Gilbert Blane, that, in the unfortunate expedition to Walcheren, the crews of the ships in the road of Flushing were entirely free from the endemic of the country, as were also the guard-ships, which were stationed in the narrow channel between Flushing and Beveland;—the width of which channel is only about six thousand feet.—(*Select Dissertations, &c., p. 107.*)

In whatever mode derived, the remark of my excellent and distinguished friend Dr. Hosack will still hold, not indeed that it is altogether capable of taking effect in a pure atmosphere, but that “an impure atmosphere is indispensably necessary to extend the specific poison.”† And I should also fully concur with him and Professor Brera† in censuring the application of the term *epidemic* to any of the febrile dis-

eases hereby produced, provided this epithet were usually confined, which I am not aware of, to disorders supposed to result from some primary intemperament of the atmosphere itself; and provided also every attempt at distinction were not likely to perplex, rather than to simplify, a subject sufficiently intricate *ab ovo*; of which M. Devèse has furnished us with an ample specimen in his late treatise.—(*Op. cit., p. 354.*)

Why a corrupt state of the atmosphere should be necessary to the general action of the febrile miasm, is a question which still remains to be discussed. Dr. Hosack supposes that the latter “produces its effects by some chymical combination with the peculiar virus secreted from the diseased body,” and which is floating in the atmosphere; of the nature of which virus, however, he has not given us any information: while Dr. Chisholm conceives that it is the impurity of the atmosphere itself, which operates by “increasing the susceptibility of the system to the action of the poison introduced.”—(*Letter to Haygarth.*) But to this explanation Dr. Hosack successfully rejoins, “that the predisposition of those who are most exposed to such impure air is less, while those who reside in the pure air of the country, are most liable to be infected when exposed to the contagion.”

In a pure atmosphere, the miasmatic materials easily become dissolved or decomposed; but slowly and with great difficulty, perhaps not at all, in a corrupt atmosphere, already saturated with foreign corpuscles. In a state thus crowded, moreover, they less readily disperse, or ascend beyond their proper periphery of action, and, perhaps, by their tenacity, adhere to bodies more ponderous than themselves, and thus loiter for a still longer period within the stratum of human intercourse. And as it is from the same tenacity they adhere to various kinds of clothes and filth, we may easily perceive why, on the shaking or agitation of such substances, as in clearing a ship’s hold, or unpacking its cargo, a pestilence may be generated of which the crew have hitherto given no signs.—(*Blane, Select Dissertations, &c., p. 307, Lond., 1822.*)

Upon this explanation it is not necessary to suppose that febrile miasm has a power either of concentrating its virulence (*Jackson, ut suprâ, part i., chap. x., p. 246.*) so as to render itself more active, or of multiplying its own form, so as to increase its numerical strength; against both which views there are weighty objections. Every distinct particle thus suspended, and withheld from dissolution, becomes an active individual in the field of battle, and is almost sure to grapple with its man. So that hereby alone we have a force equal to any degree of mortality that can be conceived.*

* Remarks on the Yellow Fever on the South and East Coasts of Spain, &c. By Th. O’Halloran, M. D., &c., p. 184, Lond., 8vo., 1823. Dr. Haygarth believed that the contagion of fever is confined to a very narrow sphere (*Letter to Dr. Percival, p. 8.*) and Dr. Clarke is of opinion, that the most malignant fever does not render the atmosphere infectious further than a few feet from the patient, or from the contagion retained in the clothes or furniture.—(*Report of the Committee on the Newcastle Dispensary, 1802.*) The plague is sometimes alleged to be infectious to so small a distance from the sick person, or infected articles, as almost to require contact for its propagation. It is probable, as Dr. Brown thinks, that these limits of the extent of the action of contagious disorders have been fixed with more minuteness, than facts altogether justify.—Ed.

* While treating of this portion of our subject, we would again quote a note by Dr. Francis, in the Am. edition of Brewster’s Encyclopedia, vol. xii. Dr. Francis remarks, “Much light has unquestionably been thrown on the subject of contagion and febrile infection, by American physicians. It was not, however, until 1796, that an

While, then, the remote causes of fever are of different kinds, its chief and most effective is febrile miasm; the origin and laws of which, so far as we are at present acquainted with it, may be expressed in the following corollaries:

1. The decomposition of dead organized matter, under the influence of certain agents, produces a miasm that proves a common cause of fever.

2. The whole of these agents have not yet been explored; but, so far as we are acquainted with them, they seem to be the common auxiliaries of putrefaction, as warmth, moisture, air, and rest, or stagnation.

3. The nature of the fever depends, partly, upon the state of the body at the time of attack; but, chiefly, upon some modification in the powers or qualities of the febrile miasm, by the varying proportions of these agents, in relation to each other, in different places and seasons. And hence, the diversities of quotidian, tertian, and quartan, remittent and continued fevers, sometimes mild and sometimes malignant.

4. The decomposition of the effluvium, trans-

attempt was made to distinguish between contagion and infection, and to arrange the diseases arising from these two sources. The author of this distinction was Dr. Richard Bayley, an eminent practitioner of New-York, whose views on this subject have been widely circulated in his own country and in England, and procured for him much reputation, though unfairly assumed as his own by Dr. Adams of London.—(See Bayley's Treatise on the Epidemic of New-York in 1795, and Adams on Epidemics.) In 1796 and 1797, Dr. Mitchell published his doctrines on the pestilential fluids, usually termed the Theory of Septon.—(See Duncan's Annals of Medicine and New-York Medical Repository.) In 1804, the late Dr. Edward Miller, of New-York, communicated to the public an essay, entitled, 'An Attempt to deduce a Nomenclature of certain Febrile and Pestilential Diseases from the Origin and Nature of their Remote Cause.' The miasma which excites yellow fever, and all the inferior grades of disease, termed remittents and intermittents, Dr. Miller contends, is emitted from dead animal and vegetable substances, immersed in a certain degree of moisture, and undergoing decomposition by means of solar heat. Hence, he observes, these diseases are found in the neighbourhood of low and swampy grounds, known to abound in this kind of filth, at that season when such filth is powerfully acted upon by heat; or they are found in large and crowded cities. On the other hand, the miasma of typhus, while it bears an obvious relation to that just described, exhibits also many important differences. Typhus, says Dr. M., is generally, and it is believed always, originally the pestilence of poverty, of low life, of crowded habitations, of personal and domestic filth. In the evolution of the miasma of typhus, the matter of perspiration, and, generally, of all the excretions of the human body, constitutes the material, and animal warmth supplies the degree of heat necessary to set loose the poisonous gas. In order to distinguish these two *miasmatic atmospheres*, the author resorts to the Greek language for suitable terms. 'That portion of air charged with miasmata exhaled by solar heat from the surface of swampy grounds, or from masses of filth overspreading the open area of cities,' to use the

mitted from the living human body, produces a miasm similar to that generated by a decomposition of dead organized matter, and hence capable of becoming a cause of fever, under the influence of like agents.

5. The fever thus excited is varied, or modified, by many of the same incidents that modify the miasmatic principle when issuing from dead organized matter; and hence a like diversity of type and vehemence.

6. During the action of the fever thus produced, the effluvium from the living body is loaded with miasm of the same kind, completely elaborated as it passes off, and standing in no need of a decomposition of the effluvium for its formation. Under this form, it is commonly known by the name of febrile contagion. In many cases, all the secretions are alike contaminated; and hence febrile miasm of this kind seems sometimes to be absorbed, in dissection, by an accidental wound in the hand, and to excite its specific influence on the body of the anatomist.

7. The miasm of human effluvium is chiefly distinguishable from that of dead organized

author's language, 'is denominated *atmosphæra koino miasmatica*'; that portion of air charged with miasmata emitted from and surrounding the body, clothes, bedding, and furniture of persons immersed in the filth of their own excretions, and of those associated in the same family with them, accumulated, long retained, and acted on by animal heat, is denominated *atmosphæra idio miasmatica*. Or, in other words, the koino-miasmatic atmosphere is that which is derived from a common or public mass of putrefying matter, expanded to the solar influence; while, on the contrary, the idio-miasmatic is derived from a personal or private source, being produced from the filth of individuals and their habitations, and diffused around them only for a small distance.'

"In July, 1803, Dr. Hosack, in a letter to Dr. Chisholm of Bristol, England, proposed a new theory on the laws governing the communication of contagious and infectious diseases. Those diseases which are communicable from one person to another, and are generally considered of a contagious or infective character, are distributed by Dr. H. into three classes. First, such as are communicated exclusively by contact; as itch, syphilis, scabies, lauda Africana, frambesia, elephantiasis, variola, vaccina, and hydrophobia: secondly, such as are communicable by contact and the *atmosphæra*; as smallpox, measles, chickenpox, hoopingcough, scarlatina, and cynanche maligna: thirdly, those diseases generally communicable only in an impure air; as plague, yellow fever, typhus in its different forms, and dysentery."

In 1824, was published the Elements of the Etiology and Philosophy of Epidemics, by Prof. Joseph M. Smith, of New-York. Dr. Smith considers the arrangement and terms proposed by Dr. Miller, which we have mentioned above, as the most valuable improvement which has been made in the classification of the remote causes of fever; but he has seen cases of fever arising from the intimate union of both these causes; from a combination of human effluvia with the exhalations of the soil. Dr. S. remarks, that this compound source of disease is highly interesting in a practical and scientific point of view, and is sufficiently distinct and well characterized to be ranked as a genus. He terms it *Idio-Koino miasma*.—D.

matter, by being less volatile, and having a power of more directly exhausting or debilitating the sensorial energy, when once received into the system. Whence the fevers generated in jails, or other confined or crowded scenes, contaminate the atmosphere to a less distance than the emanations from marshes and other swamps; but act with a greater degree of depression on the living fibre.

8. The more stagnant the atmosphere, the more accumulated the miasmatic corpuscles, from whatever source derived; and the more accumulated these corpuscles, the more general the disease.

9. The miasmatic material becomes dissolved or decomposed in a free influx of atmospheric air: and the purer the air, the more readily the dissolution takes place: whence, *è contrario*, the fouler as well as more stagnant the air, the more readily it spreads its infection.*

10. Under particular circumstances, and where the atmosphere is peculiarly loaded with contamination, the miasm that affects man is capable also of affecting other animals.

* In relation to this subject, it deserves attention, that certain other states of the atmosphere affect different contagious disorders in different ways: "the diffusion of plague, for instance, is favoured by a temperature high within a certain degree; while it is checked, if not altogether extinguished, by the cold of winter, and likewise by very high temperatures, such as the heat of certain parts of Africa in summer, as mentioned by Alpinus, and that of the Harmattan winds. Typhus, we know, prevails at low degrees of heat, as likewise do measles and scarlatina; and so, with regard to contagions in general, we find the effect of temperature on them varies in the case of different diseases. A moist and still atmosphere may, if we mistake not, be declared favourable to the propagation of all contagious disorders; while it is sometimes suddenly checked by strong commotions in the air, such as storms and hurricanes. But, besides these appreciable atmospheric states, which, in one way or another, influence the diffusion and action of the matter of contagion, there are conditions of the air favourable to its diffusion, or otherwise, of the real nature of which we are ignorant, beyond their influence over the propagation of the disease. It has occurred to every medical man to see diseases, justly considered contagious, unusually prevalent in one season compared with another, though there may have been no discoverable difference in the atmospheric states to explain this variety in their prevalence; and to see them, on the other hand, decline and finally disappear long before individuals, susceptible of the contagion, were scarce, and without there having been any appreciable change in the air to account for that in the state of the disease. This atmospheric peculiarity, to which the name *epidemic constitution* has been assigned, occasionally appears to possess a limited locality; for, we find a contagious disease prevailing in a town or village, while places in the neighbourhood escape, though there is a constant intercommunication between the infected and healthy districts: or, such a disease may spread extensively in one town, while, in another, similar as to the habits and characters of the population, and not remote in situation, it may exist, but be by no means so prevalent."—See Cyclop. of Pract. Med., art. CONTAGION.—ED.

11. By a long and gradual exposure to the influence of febrile miasm, however produced, the human frame becomes torpid to its action (*Brera De' Contagi e della Cura de' loro Effetti*, &c., ut *suprà*, Padua, 1819), as it does to the action of other irritants: whence the natives of swampy countries, and prisoners confined in jails with typhous contamination around them, are affected far less readily than strangers; and, in numerous instances, are not affected at all.

12. For the same reason, those who have once suffered from fever, of whatever kind, hereby produced, are less liable to be influenced a second time; and, in some instances, seem to obtain a complete emancipation.*

It only remains to offer a few remarks upon the DOCTRINE OF CRISES; or that tendency which fevers are by many supposed to possess, of undergoing a sudden change at particular periods of their progress.

A sudden and considerable variation of any kind, whether favourable or unfavourable, occurring in the course of the general disease, and producing an influence on its character, is still loosely expressed by the name of crisis. The term is Greek, and pathologically imports a separation, secretion, or excretion of something from the body; which was in truth the meaning ascribed to it when first employed, agreeably to the hypothesis of concoction which we have just considered. The original hypothesis is abandoned; but the term is still continued in the sense now offered. "If the matter of the disease," says Professor Frank, "be expelled by some one convenient outlet in the skin, kidneys, bowels, or bloodvessels, the crisis is simple; if by several of these at the same time, it is compound; if the whole be carried off at once, it is perfect. If it be carried off at different times, it is a *lysis* (Op. cit., tom. i., *De Febr.*, p. 26), or resolution."

That changes of this kind are perpetually occurring in the progress of continued fevers, must, I think, be admitted by every experienced practitioner. Nothing is more common than to behold a patient suddenly and unexpectedly grow decidedly better or worse in the progress of a fever of almost any kind, and pass on rapidly towards a successful or an unsuccessful termination.

But the important question is, whether there be any particular periods in the progress of a fever, in which such changes may be expected? Hippocrates conceived there were: he endeavoured to point out and distinguish them by the name of critical days. Asclepiades and Celsus denied the existence of such periods; and the same diversity of opinion has prevailed in modern times.

It is not very easy to determine the point at the present day, and especially in our own country. For, first, fever, like many other complaints, may have undergone some change in

* An extremely learned paper, on the comparative influence of vegetable and animal matter in generating disease, by Prof. U. Parsons, of Providence College, is published in the Am. Journ. of Med. Sc., vol. vii., p. 80.—D.

its progress from a like change in the nature of its remote causes, or in the constitution of man. And next, it seems to be generally allowed, that sudden transitions, whether regular or irregular, are more apt to take place in almost all diseases in warm, than in cold climates. On these grounds, it is probably a subject which will never become of great practical importance at home. Yet, it is well worthy of attention as a question of history, and one that may yet be of great importance to many parts of the world.

If we examine the phenomena of the animal economy, as they occur in a natural series, we shall find that they are in almost every instance governed by a periodical revolution. A man in a state of health and regular habits generally becomes exhausted of sensorial power within a given period of time, and requires a periodical succession of rest; his appetite requires a periodical supply; and his intestines a periodical evacuation. This tendency equally accompanies and even haunts him in disease; he cannot disengage himself from it. Gout, rheumatism, mania, rapidly and pertinaciously establish to themselves periods of return. The hemorrhoidal discharge often does this; and the catamenia constantly. The same occurs in fevers, but especially in intermittents; for the quotidian, the tertian, the quartan, have, upon the whole, very exact revolutions. And, though accidental circumstances may occasionally produce a considerable influence on every one of these facts, whether morbid or natural, the tendency to a revolutionary course is clear and unquestionable.

Now, although Hippocrates has not appealed to this reasoning, it forms a foundation for his observations: and, when stripped of the perplexities that encumber his writings upon this subject, partly produced by erroneous transcripts, and, in a few instances, perhaps, by his own irresistible attachment to the Pythagorean hypothesis of numbers, he may be regarded as laying down the following as the critical days of continued fever: the 3d, 5th, 7th, 9th, 11th, 14th, 17th, 20th; beyond which it is not worth while to follow the series; for it is not often that they extend further.

In other parts of his works he regards also the 4th and 6th, and even the 21st, as critical days; so that in the first week, every day, after the disease has fully established itself, evinces a disposition to a serious change; in the second week, every other day; and in the third week, every third day. It is not easy to determine why the 21st day should be a critical day, as well as the 20th. Various conjectures have been offered upon the subject: by some it has been regarded as a mistake in the Greek copy, and by others, as a piece of favouritism in Hippocrates for this number, in consequence of its being an imperfect one in the Pythagorean philosophy, as the commencement of a septenary.

De Haen, with rigid and patient assiduity, has put Hippocrates to the test upon these data; for he has accurately analyzed Hippocrates's own journal of the numerous cases of fever he has so industriously collected and recorded, and

finds the positions, in most instances, to be strictly justified; and that out of 168 terminations of fever, not less than 107, or more than two thirds, happened on the days denominated critical, not reckoning the 4th, 6th, or 21st, and that the 4th and 6th were very frequently critical. There are a few anomalies; but it is not necessary to notice them, because they are easily referable to accidental causes, similar to those that retard or accelerate the paroxysm of intermitting fevers.

Now, admitting the Hippocratic table to be true, the continued fever, in its progress, is measured by the various types exhibited by intermitting fevers. Thus, the quotidian prevails through the first seven days; there is on each day a slight exacerbation, and no one day is more critical than any other. After this period, the tertian type commences, and runs through the ensuing week; the principal changes occur on the 9th and 11th days, and would occur on the 13th, but that the quartan type now assumes its prerogative; and the principal transitions, after the 11th, take place on the 14th, instead of on the 13th; on the 17th; and on the 20th. Dr. Cullen, who has examined this subject with great attention, and simplified it from many of its difficulties, directly asserts, that his own experience coincides with the critical days of Hippocrates. Dr. Fordyce, who scarcely does justice to Cullen upon other points, unites with him upon the present, and justly compliments him upon his ingenious examination and explanation of the Greek distribution of critical days; and Dr. Stoker of Dublin has arrived at a like conclusion, after what appears to have been a very patient, discriminating, and extensive inquiry.* It is, nevertheless, admitted on all hands, that the order of succession is far less distinct, as well as less regular, in cold, than in warm climates; and that it requires a thoroughly attentive and practised eye to notice these changes in our own country, or, indeed, in any part of northern Europe. And hence Craanen says, it is lost time to look for them (*De Homine*); Stoll, that they are only to be found in inflammatory fevers (*Rat. Med.*, part iv., p. 283); Le Roy, that the supposed critical days have no influence, and can lead to no prognosis or peculiarity of practice (*Du Pronostic dans les Maladies Aigues*, 8vo., Montpel., 1778); and Frank, that nature has fixed upon no one day rather than another, for a solution of fever, nor at any time forbids our attempt at executing a present indication.—(*Op. cit.*, tom. i., 29.) Dr. Jackson, partly from the strength of his attachment to the doctrines of Cullen, and partly from having principally practised in hot climates, is a great advocate for the existence of critical days, and believes them to take place in fevers from human as well as marsh miasm; though less distinctly, as also less frequently, in the former than in the latter.—(*Op. cit.*, part ii., ch. ix., p. 242.) Why the first week of a fever should

* Medical Report of the Fever Hospital, &c. for 1816. Trans. of the King's and Queen's Coll., Dublin, vol. ii., p. 434, 8vo., 1824.

incline to a quotidian type rather than to a tertian, or the second to a tertian rather than to a quartan, we know no more than we do why fevers should ever intermit, or at any time observe the distinctions of different types. We are in total ignorance upon all these subjects. We see, moreover, that intermitting fevers, whether quotidian, tertian, or quartan, have their paroxysms recur regularly in the daytime; the quotidian in the morning, the tertian at noon, and the quartan in the afternoon—and that, in no instance, do the paroxysms take place at night: and we see also that, in continued fevers, the exacerbations uniformly take place later in the day, than the paroxysms of the latest intermitting; for these rarely occur later than between five and six o'clock in the evening, while the paroxysms of the quartan return commonly before five. Of these interesting and curious scenes we are spectators; but we are nothing more; for we are not admitted to the machinery behind the curtains.

By some pathologists, the source of these phenomena is sought in the influence of the heavenly bodies, and especially in those of the sun and moon. In ancient times, these luminaries were supposed to produce an effect on all diseases, and especially on mania, epilepsy, catamenia, and pregnancy. And when the Newtonian philosophy first illumined mankind with the brilliant doctrine of universal attraction, Dr. Mead stepped forth into the arena, and revived and supported the ancient doctrine with great learning and ingenuity: and as an ingenious conjecture and possible fact, of which no practical use could be made, it was contemplated till towards the close of the last century: about which time Dr. Darwin, by interweaving it with his new hypothesis, once more endeavoured to raise it into popular notice, and gave it an air of serious importance. Dr. Balfour, of British India, however, has still more lately brought it forward as a doctrine capable of direct proof, and as peculiarly affecting the progress of fevers. His opinion, which he endeavours to support by weighty facts and arguments, is, that the influence of the sun and the moon, when in a state of conjunction, which is named *sollunar* influence, produces paroxysms or exacerbations in continued fever, in all cases in which a paroxysmal diathesis (for such is his expression) exists; and as this influence declines, in consequence of the gradual separation of these luminaries from each other, and their getting into a state of opposition, a way is left open to the system for a critical and beneficial change, which is sure to take place, provided the critical disposition is at this time matured. In other words, paroxysms and exacerbations in fever may be expected to take place (and do in fact take place) at spring-tides, and crises at neap-tides.

This is a new view of the influence of the heavenly bodies upon the human frame; and a view which, though feebly supported by facts, is advanced with all the dogmatism of an established science. Dr. Stoker, at the particular request of Dr. Balfour, put his doctrines to the

test of 276 patients between July 6 and September 6, 1817, in Dublin. He has candidly given us his tables, and as candidly observes, that "very little coincidence indeed is to be remarked from a view of these tables."—(*Trans. of the King's and Queen's Coll.*, Dublin, vol. ii., p. 435, 8vo., 1824.) There is, nevertheless, more in medical astrology than is, perhaps, generally supposed; it is an important branch of meteorology, and, as such, is well worth studying. Nor can there, I think, be a question in any impartial mind, that, under certain circumstances, and especially in tropical climates, many diseases are influenced by lunation, as we are sure they are, in all climates, by insolation. The concurrent observations of a host of candid and attentive pathologists, who have been witnesses of what they relate, are sufficient to impress us with this belief: but, till we know more fully what these *circumstances* are, we cannot avail ourselves of their remarks, and can only treasure them up as so many isolated facts. And hence, in no age or country whatever has the study been turned to any practical advantage, expedited the cure of a disease, or enabled us to transform the type or interval of one kind of fever into that of another. Nor is it any exclusive reproach to the art of medicine that it should be so; for, of all the subdivisions of general philosophy, there is none so little entitled to the name of a science as meteorology itself. And, till the naturalist has explained the variations of the barometer, the physician need not blush at being incapable of turning to account the supposed influence of the planets, or of unfolding the origin, or tracing the capricious courses, of epidemics and pestilences.*

* It is remarked by Dr. Copland, that, since the overturn of the humoral pathology, the doctrine of critical evacuations has undeservedly fallen into disrepute. In our own country, at the present time, he thinks too little attention is paid to these evacuations, and still less to the periods at which they occur. "In temperate climates, a number of diseases, particularly fevers, run on for certain periods with regularity, and, after an exasperation of the symptoms, or some violent perturbation of the economy, terminate by evacuations of different kinds, which tend to remove the train of morbid actions, and to restore the healthy functions. In other cases, the exasperation of the disorder is followed by imperfect evacuations, occurring in a regular manner; while, in some, it gives rise to additional phenomena of a dangerous or fatal character. Hence *crises* have been denominated *salutary, complete, imperfect, and fatal*."—(*Dict. of Pract. Med.*, art. *CRISES*.) Yet, it has been observed, that the crisis of fever often takes place without sensible evacuation; notwithstanding it is, in a large proportion of cases, preceded or accompanied by some change in the secretions, or by diarrhoea, or hemorrhage. In the progress of fever, the urine exhibits particular changes. In the early stages, its quantity is lessened, but there is no change in its colour or chymical properties. "As the symptoms advance, the urine becomes darker in colour, but does not deposite a sediment till the fever begins to decline, when it is increased in quantity, and deposites a cloud or sediment on cooling. This urinary deposite, which is sometimes copious, appears in the bottom of

GENUS I.

EPHEMERA.

DIARY FEVER.

ONE SERIES OF INCREASE AND DECREASE; WITH
A TENDENCY TO EXACERBATION AND REMIS-
SION, FOR THE MOST PART APPEARING TWICE
IN TWENTY-FOUR HOURS.

This is the simplest form in which fever at any time makes its attack; and hence, Dr. Fordyce has distinguished it by the name of SIMPLE FEVER. It is probably that which is intended by the term *essential fever*, as used by the French writers. It is, in truth, the basis of all other fevers, which are hence arranged by Elsner as mere species of this.—(*Beyträge zur Fieberlehre*, Königsb., 8vo., 1789.) For the purpose, however, of entering into the full character, not only of the present, but of all the subsequent genera, and their respective species, it is necessary to bear in mind, that the ordinal definition forms a part of that character, and is essentially included, in a less or greater degree, in all the subdivisions that appertain to it.

The ephemera rarely exceeds a duration of twenty-four hours. Some practitioners, however, have called by this name a fever that has extended to three days; and Sauvages has arranged this mode of fever under his own genus of ephemera, as has also Professor Frank, distinguishing the proper ephemera by the adjunct *simplex*, and its elongated form by that of *protracta*.—(*De Cur. Morb. Hom. Epit.*, tom. i., pp. 156, 185, 8vo., Mannh., 1792.) But this is to confound different species under one generic name. Fordyce asserts, that he has often seen the ephemera commence its attack with all the essential appearances of fever, and terminate in eight, ten, or twelve hours.—(*On Simple Fever*, Diss. i., p. 33.) And hence, in defining

the vessel some hours after the urine has been voided: from its resemblance to brickdust it has been called *laticious*, and by evaporation it may be collected in minute crystals of lithate of ammonia. This sediment is by no means peculiar to patients labouring under fever, but is often observed in the urine of healthy persons, or in that of others, whose function of digestion is impaired. In other instances, the sediment is of a pinkish white colour, and to this deposit, which, according to Dr. Wilson Philip, consists of the phosphates of the urine, the term *furfuraceous*, or *branny*, has been given. He regards both these urinary deposits as indications of returning health, and particularly of a renewal of a free secretion by the skin, which, in fevers, is generally a favourable symptom. In some fevers, terminating favourably, there is an unusual tendency to sweat, which only exhausts the strength. In these the furfuraceous sediment is observed, but without removing the fever: this is the case in hectic fever.—(*Cyclopædia of Pract. Med.*, art FEVER.) Among other remarks made by Dr. Tweedie, he says, that when the sweating is so profuse as to induce exhaustion, or when it is partial or clammy, it is unfavourable; and though as a general rule critical sweats should not be interfered with, yet, if the strength be evidently lowered by them, or if there be not a corresponding amendment in the general symptoms, they should, if possible, be

ephemera, the symptom of duration ought not to exceed the limit here allotted to it.

In this simple shape of the disease, the pathognomonic symptoms are few and striking; for, however violent, it is confined to a single paroxysm of three distinct stages, shivering or languor, heat, and perspiration; each most probably dependant on the other, and ceasing, when true to itself, after having followed up the movements of the animal frame through a single diurnal revolution. The cold stage, however, is often scarcely perceptible, and sometimes altogether imperceptible, the general languor taking place without it.

The genus exhibits two common and very distinct species; and if the ephemera *sudatoria* of Sauvages, the sweating-sickness or English plague of other authors, be regarded as belonging to it, as unquestionably it ought, it will then afford us another after the manner following:—

1. Ephemera Mitis. Mild Diary Fever.
2. ——— Acuta. Acute Diary Fever.
3. ——— Sudatoria. Sweating Fever.

SPECIES I.

EPHEMERA MITIS.

MILD DIARY FEVER.

WITHOUT PRECEDING RIGOUR; LASSITUDE AND DEBILITY INCONSIDERABLE; PAINS OBTUSE, CHIEFLY ABOUT THE HEAD; HEAT AND NUMBER OF THE PULSE INCREASED SLIGHTLY; DRYNESS OF THE TONGUE AND FAUCES; TERMINATING IN A GENTLE PERSPIRATION.

THE common exciting causes are, excess of corporeal, and especially of muscular exertion; long-protracted study; violent passion; suppressed perspiration; sudden heat or cold.

There are few persons who have not felt this species of diary fever at times, from one or other

checked. When moderate diarrhœa comes on towards the termination of fever, it is generally a favourable circumstance, and ought not to be stopped. When there has been a disposition to relaxation of the bowels throughout the disease, which is not uncommon in some epidemics, and at particular seasons, the irritation commonly subsides spontaneously. Should it even continue through the period of convalescence, provided it do not interfere with the recovery of the patient, it is only necessary that the diet and general management be regulated. When the diarrhœa appears to retard recovery, and produce gradual emaciation, the practitioner should never lose sight of the possibility of the affection being the result of inflammation of the mucous membrane of the bowels, or of other intestinal lesions, and therefore requiring the most vigilant care. Dr. Tweedie has not met with hemorrhage as a crisis of fever: he has, indeed, seen hemorrhage from the nose, when there was considerable cerebral affection, and always remarked great relief from the evacuation; but he has never known an instance in which the fever disappeared with epistaxis. In typhoid fevers, hemorrhage from mucous surfaces and from the skin (*petechiæ*) is not unusual; but, according to Dr. Tweedie, they are never critical: they reduce the patient still more, and always indicate a severe, if not a fatal, form of fever.—Ed.

of the causes just enumerated. When a man has worked himself up into a violent and long-continued fit of wrath, whether there have been reason or no reason, and more especially in the latter case; when he has taken a long and fatiguing journey on foot, walking with great speed, and suffering beneath great heat and perspiration; or when he has devoted the whole of the day to a particular study, so profound and abstracting as to exhaust almost the entire stock of sensorial power that can be drawn from other parts of the system at the single outlet of the attention;—and when beyond this he still urges his abstruse and protracted train of thought into a late hour of the night or the morning—there is a general irritation or undue excitement produced, that simple rest cannot at once allay; his sleep is short, hurried, and interrupted, if he sleep at all; he yawns, stretches his limbs, turns himself again and again in his bed for an easy, perhaps for a cool place, for his skin is hot and dry; but for a long time he turns in vain. The morning strikes upon his eyes, but he has had little sleep, and no refreshment: he is indisposed to leave his bed; and if he rise, he is still feverish, and unfit for business. He passes the day in disquiet, which perhaps increases towards evening; but at night he feels a moisture breaking forth over his skin, and comfortably succeeding to the heat and dryness that have thus far distressed him; he recovers, perhaps, even while sitting up; but if, as he ought to do, he goes to an early bed, a quiet and refreshing sleep supervenes, and he wakes to the health he before possessed.

It is not easy to explain why the febrile paroxysm should be more disposed to close its career sometimes towards the evening, but more generally later at night, except for the reason, whatever that reason may be, that all fevers are far more apt to commence their paroxysms in some part or other of the daytime, and especially intermittents, and consequently to drop them as the day declines. Thus the quotidian makes its assault in the morning, the tertian at noon, and the quartan in the afternoon: as though the diurnal revolution were somewhat regularly divided between febrile attack and febrile cessation or truce. It is possible, indeed, that a fever of any kind may open its onset at any hour; but this is so contrary to the ordinary rule, that Dr. Fordyce affirms, from his own observation, that ten fevers commence in the day to one at night.

The species before us forms scarcely a case for medicine: since nature, or that instinctive power which is ever operating to the general welfare of the animal frame, will be usually found competent to its object. So that if any thing remedially is attempted, it should be confined perhaps to abstinence from animal food, a slight increase of the peristaltic action of the intestines by a dose of neutral salts, and to a removal of the dry heat of the skin by diluents and small doses of ipecacuanha, which combines admirably with most aperients, and increases their power, while its own diaphoretic quality continues at least undiminished, and is

often improved. This is now well known, though not a discovery of recent date; for Gianella, Vater, and various writers of credit, strongly recommended the same from personal experience nearly a century ago.*

Gamesters, after sitting up all night, and being worked up to madness by the chances and reverses of their ruinous stakes, are peculiarly subject to this species. A very cold and wet towel, tied round the temples, seems to give some check to the violent excitement of the brain; but, in the long run, I have generally found persons who have adopted this practice become debilitated and dropsical, and sink into an untimely grave, or creep on miserably through the fag end of a lingering life, that affords no retrospective comfort, with a hospital of diseases about them. But whether this proceed from the practice adverted to, or from the habitual exhaustion which naturally accompanies a course of gambling, may admit of a doubt.

SPECIES II.

EPHEMERA ACUTA.

ACUTE DIARY FEVER.

SEVERE RIGOUR; GREAT HEAT; PULSE AT FIRST SMALL AND CONTRACTED, AFTERWARD FULL AND STRONG; PERSPIRATION COPIOUS; GREAT LANGOUR.

In a few instances the accession is slightly marked, and there is little chilliness or rigour. The heat that succeeds, however, is always considerable; the face is red and bloated; and there are often pungent and throbbing pains in the head, corresponding with the pulsations of the arteries; though at times the pain in the head is dull and heavy. The high-coloured urine deposits a sediment with a tinge of orange-peel.

We cannot always trace the remote causes of this species; but it is usually produced by some morbid affection of the stomach, or of the collatitious viscera.

The most obvious and common cause is that of a surfeit, whether of eating or drinking: and there is no great difficulty in interpreting the means by which this cause operates.

The stomach, in the language of Mr. J. Hunter, is the great seat of general sympathy, and associates with almost every other organ in its action. The digestion of even an ordinary meal is a work of some labour to it, and especially in weakly constitutions; a greater degree of heat is regularly expended upon it during this process, and unquestionably also a greater degree of sensorial power; both which are taken from the system at large as from a common stock; and the consequence is, that in infirm habits, a considerable degree of chill and debility is felt during this process, and other organs become torpid while the stomach is in a state of increased action. Hence infants and old persons sleep during digestion; delicate females

* Gianella, *De admirabili Ipecacoanhæ Virtute in curandis Febris, &c.*, Patav., 1754. Vater, *Diss. de Ipecacoanhæ Virtute febrifugâ, &c.*, Witeb., 1732.

feel a coldness shooting over their extremities; and those of irritable fibres become flushed in the face, and show other signs of irregular action. Now, if this be the case in the digestion of ordinary meals, what disturbance may we not expect during the digestion of a meal that overloads the stomach, and with which the stomach is incapable of grappling? what more especially, when at the same time, by an immoderate use of wine or spirits, the brain becomes exhausted of its energy by the excess of stimulus applied to it? The general chill over the surface, which, in the digestion of an ordinary meal, is only felt by the weak and delicate, is here often felt severely, and sometimes amounts to a horripilation. The first stage of fever is hence produced; and as the heat and perspiration are most probably a necessary result of the first stage, a foundation is hereby laid for the entire paroxysm. With the reaction that ensues a greater degree of sensorial power returns; the general frame as well as the brain is roused to an increased energy; the diaphragm and its associate muscles instinctively or remedially contract, and the stomach disgorges its contents, or thrusts them forward half digested into the duodenum.*

The only and well-known mode of cure consists, in the first place, in imitating the above natural process of relief; in unloading the stomach of its mischievous freight by a powerful emetic, and the alvine canal of whatever portion of the heating and crapulous mass has passed into it, by a brisk cathartic. The fever hereby excited will often subside in a diurnal revolution, and no tendency to a return of the paroxysm be produced.

If the species before us, however generated, do not subside within this period of time, or a few hours beyond it, the disease becomes a cauma, or inflammatory fever of the continued kind, and consequently belongs to the genus *ENECIA*.

There are, however, a few exceptions to this rule; for Forestus gives a case, in which the paroxysm led to a fatal hectic (Lib. i., obs. 7): and Borelli gives another of equal singularity, in which it kept true to a triennial revolution, returning punctually once every three years.—(Cent. ii., obs. 100.)

SPECIES III.

EPIHEMERA SUDATORIA.

SWEATING FEVER.

TENSE PAINS IN THE NECK AND EXTREMITIES;
PALPITATION; DYSPNEA; PULSE RAPID AND
IRREGULAR; HEAT INTENSE; INTOLERABLE
THIRST; DROWSINESS OR DELIRIUM; EXCES-
SIVE SWEAT.

I HAVE followed M. de Sauvages in introducing sweating fever, the *Ephemera maligna* of Borsieri (*Institut. Med. Pract.*, 8vo., 4 tomes, Ven., 1782-5), or Burscrius, as he is more

commonly called, and the *sudor Anglicus* of most foreign writers, into the present place.

Dr. Caius, who practised at the time of its appearance at Shrewsbury, and has written one of the best accounts of it extant, calls it “a contagious pestilential fever of one day. It prevailed,” says he, “with a mighty slaughter, and the description of it is as tremendous as that of the plague of Athens.” And we are told by Dr. Willis, “that its malignity was so extreme, that as soon as it entered a city it made a daily attack on five or six hundred persons, of whom scarcely one in a hundred recovered.” It was certainly a malignant fever of a most debilitating character, but without any tendency to buboes or carbuncles, as in the plague; though, during some parts of its career, as fatal. It ran its course in a single paroxysm (*Holinshed*, vol. viii., 4to., Lond., 1808); the cold fit and hot fit were equally fatal; but, if the patient reached the sweating fit, he commonly escaped.

Hence, the cure consisted in exciting the sweating stage as quickly as possible, and in supporting the system with cordials throughout the whole of the short, but vehement course of the fever. At Shrewsbury, it continued to rage for seven months, and, during that period of time, a thousand fell victims to its violence. But after the discovery of the benefit of the sweating plan, it was certainly far less fatal.

It made its first appearance in London in 1480 or 1483: Caius says, in the latter year, first showing itself in the army of Henry VII., on his landing at Milford-Haven. In London, to which, however, it does not seem to have travelled till a year or two afterward, it took up its abode, with various intermissions of activity, for nearly forty years. It then visited the continent, overran Holland, Germany, Belgium, Flanders, France, Denmark, and Norway; among which countries it continued its ravages from 1525 to 1530: it then returned to England, and was observed for the last time in 1551.

It commenced its attack with a pain in the muscles of the neck, shoulders, legs, or arms, through which a warm aura seemed to creep in many instances; and after these symptoms, broke forth a profuse sweat. The internal organs grew gradually hot, and at length burning, the pungent heat extending to the extremities; an intolerable thirst, sickness, and jactitation followed speedily, occasionally with a diarrhoea, and always with extreme prostration of strength, headache, delirium, or coma, and a wonderful wasting of the whole body. The sweat was

it is scarcely necessary to remark, that it is as improbable as it is destitute of proof. The various circumstances which in the preceding paragraph are fancied to prove or illustrate it, only show that languor, chilliness, and flushings of the face occasionally take place during the process of digestion, which also sometimes causes a tendency to sleep. These facts, particularly the flushings, constitute so weak a support for the doctrine, that they need no serious refutation. Why should we not here be content with the simple truth, that excesses at table frequently give rise to ephemeral fever?—ED.

* With respect to the hypothesis, that the heat and nervous influence of the whole system are diminished during digestion, because a part of the general stock is then withdrawn to the stomach,

tenacious, saburral, and of an offensive smell; the urine thick and pale; the pulse quick, often irregular; and the breathing laborious from the first. The modes of treatment were often puerile, and offer nothing instructive. A good constitution, and exposure to free air, seem to have been most successful in promoting a cure.

Dr. Caius asserts, that a thick noisome fog preceded the distemper, especially in Shropshire, and that a black cloud uniformly took the lead, and moved from place to place; the pestilence in a regular march following its direction.—There may be some fancy in this: but it is an unquestionable fact, that the most fatal pestilences of ancient and modern times have been ushered in by stinking fogs or mists, or some other intemperament of the atmosphere, of which the reader will find various instances in the sequel of this work.

The disease is generally, however, supposed to have been produced by inclement harvests and vitiated grain, particularly wheat, which is less hardy than other grains, and sooner infested with albugo (mildew), ustilago (smut), and clavus (ergot or spur). And, in proof that this last was the actual cause, it is observed by Dr. Willan, that the contemporary inhabitants of Scotland and Wales, who fed on oats or barley, instead of on wheaten bread, were not affected. Nevertheless, whatever was the primary cause, a peculiar miasm or contagion seems to have been generated by the disease itself, which chiefly contributed to its spread and continuance. For we are told concurrently by all the writers, that Englishmen, who withdrew from their own country into France and Flanders with the hope of escaping the attack of the disease, fared no better than their countrymen at home: to which Dr. Freind adds, that, while Englishmen abroad were thus subject to the contagion, foreigners, and even the Scotch in England, were rarely or never seized with it (*Hist. of Physic*, vol. ii., p. 533); a feature that has been copied by Dr. Armstrong in his very forcible description of the complaint, which is perhaps better adapted for poetry than for sober prose.

"Some, sad at home, and, in the desert, some
Abjured the fatal commerce of mankind;
In vain: where'er they fled, the fates pursued.
Others, with hopes more specious, cross'd the main,
To seek protection in far distant skies;
But none they found. It seemed the general air,
From pole to pole, from Atlas to the East,
Was then at enmity with English blood:
For, but the race of England, all were safe
In foreign climes; nor did this fury taste [ed.]"*
The foreign blood which England then contain-

Something may, perhaps, be set down to the score of a national diathesis; but, without examining very closely into the accuracy of this wonderful part of its history, we may at least indulge a hope, that this peculiar, most virulent, and fatal contagion, has long since worn itself out, and become decomposed; though it may be still only latent, and waiting for its proper auxiliaries, once more to show itself in the field.—(*Navier, Maladies Populaires, &c.*)

* Art of Preserving Health, b. iii.

It is said, indeed, by Dr. Coste, the learned editor of Dr. Mead's works in French, that the disease continued to manifest itself occasionally as an epidemic in Picardy; but that, instead of terminating in a single day, it ran on to the third, fifth, and sometimes even to the seventh. It is hence sufficiently obvious, that the two fevers, though possessing many points of resemblance, are not precisely the same. Yct M. Bellot, in his thesis "An febri putridæ Picardii SVETE dictæ, sudorifera?" has maintained Dr. Coste's opinion.

GENUS II.

ANETUS.

INTERMITTENT FEVER. AGUE.

PAROXYSM INTERMITTING, AND RETURNING DURING THE COURSE OF THE DISEASE; THE INTERMISSIONS GENERALLY PERFECT AND REGULAR.

UNDER the preceding genus, the remote cause, whatever it consists in, lays a foundation for not more than one paroxysm. In the genus before us, the cause introduces a tendency to a recurrence of the paroxysm from the first; and, in most cases, with an interval that continues true to itself as long as the disease lasts. I say in most cases, because we shall see presently that, when intermittent fever has raged very extensively, it has not unfrequently established a type of one kind in one person, and of another kind in another; while, in the same patient, quotidianians have changed to tertians, tertians to quartans, quartans to quotidianians, and all of them in a few instances to continued fever, in the most capricious and anomalous manner.*

Dr. Cullen unites intermittents and remittents into one section of fevers, merely distinguishing them as intermittents with an interposed apyrexia, and intermittents with remission alone; and, as already observed, he makes it a part of the pathognomonic character of both that they are derived from marsh miasm—*miasmate paludum orta*—as though there were no other cause of their production, whence Dr. Young gives to intermittents and remittents the common name of *paludal fever*.

The only ground, then, assumed for this union of intermittents and remittents, is the supposition, that the cause which generates them is

* "In hot climates, and even here, many intermittent fevers become remittent, and from being remittent, they will become continued, unless vigorous measures are adopted, and they may rapidly prove fatal by congestion of the head, thorax, or abdomen. Now and then this may be the case here, from some peculiarity in an epidemic. We have no idea in this country of what aguish fevers, intermittent or remittent, are in hot climates. In Italy these are called pernicious fevers; for, as soon as a person is seized, he may fall into a comatose state, from which he never recovers; and, on inspection after death, the greatest degree of congestion is found in the lungs and head, and also in the abdominal viscera."—Professor Elliotson's Lectures at Lond. Univ., Med. Gaz., 1831-2, p. 926.

single, common to the two, and never generates any other fever. Now, although the febrile miasm, issuing from marsh lands, is by far the most common cause of intermittents, it is by no means the only cause; for we find intermittents, like all other species of fever, produced from various sources; existing in hot countries as well as in cold, in high lands as well as in low lands, sporadically as well as epidemically; sometimes excited by sympathy, sometimes by contagion. Even in tertians, Dr. Cullen is obliged to admit of instances in which other agents are necessary; but then, says he, they are only *co-agents*, and would not operate alone. "*Has polestates excitantes pro parte principii hic admittimus licet nequitum excitassent, si miasma paludum non antea applicatum fuisset.*" But this is the very point of controversy; for, in many instances, they produce the disease where marsh miasm cannot be suspected. I have seen an isolated case of a regular tertian on the highest part of Islington; and another on the dry and gravelly coast of Gosport, a situation so healthy that all the inhabitants escaped, when, in the year 1765, a most fatal and epidemic fever, originating unquestionably from the miasm of swampy grounds, pervaded the whole Island of Portsea, situate at not more than a mile distant on the other side of the water, and exhibiting, in different individuals, and often in the same person, all the diversities of the intermittent, remittent, and continued type. Dr. Fordyce affirms, that he has seen an intermittent communicated by infection, meaning the miasm from human effluvium;* and where the yellow fever has

long existed, or become widely diffusive, this is common. Where it arises from sympathy, or organic affection, the case is still clearer. "Two children," says Mr. J. Hunter, "had an ague from worms, which was not in the least relieved by the bark; but by destroying the worms they were cured. We have in like manner agues from many diseases of particular parts, more especially of the liver and the spleen, and from an induration of the mesenteric glands."*

But one of the most singular and convincing proofs, that the decomposition of marsh lands is not essential to the production of intermittent fever, is to be found in the epidemic intermittent of 1780, as described by Sir George Baker, and which we shall have occasion to advert to more particularly hereafter; for, du-

tions of animal substances." He then notices that butchers, leather-dressers, fellmongers, and others, whose business exposes them continually to the effluvia of putrid animal substances, do not suffer from intermittent fever. Dr. Brachet then shows how you may at option render the most healthy village the seat of intermittent fever, by forming pools about it, in very hot weather, for the watering of hemp, and then removing them. This he regards as a convincing proof, that intermittent fevers are the product only of emanations from putrefying vegetable substances. He observes, likewise, that intermittent fevers never prevail to any extent in winter, but at the commencement of the warm weather of the spring, or in the autumn. The reason of this is, that the cold of winter prevents vegetable matter from putrefying, while the warmth of spring promotes the decomposition of it. The active vegetation which then follows, furnishes no detritus till the end of summer, when intermittents begin again; a little earlier or later, in different years, according as vegetation may be more or less advanced, and the period when its detritus is blended with stagnant waters.—(See Archives Gén. de Méd., tom. ix., p. 380.)—Ed.

* Dr. Cleghorn, in his work upon the diseases of Minorca, expresses a similar belief. "Dr. Wells, a colleague of Dr. Fordyce at St. Thomas's Hospital, accounts for Dr. Fordyce's opinions by remarking, that he (Dr. F.) fancied that continued and intermittent fevers were mere varieties of the same disease; and, as it appeared in those days, that continued fever was contagious, so he was obliged to maintain that ague was contagious. Dr. Cleghorn's mistake is supposed to have arisen from his having observed, that most of those who were about the sick in Minorca had the disease, forgetting that it did not arise in consequence of emanations from the sick, but from the situation in which they were placed."—(Elliotson's Lectures at the Lond. Univ., Med. Gaz., 1831-2, p. 921.) This want of discrimination is evident in much of the argument brought forward by writers in proof of the extension of certain diseases by contagion. In opposition to Dr. Fordyce's hypothesis, let us hear what conclusion Dr. Brachet, physician to the Hôtel Dieu of Lyons, has adopted, as the result of his investigations:—"I have seen," he remarks, "tanyards situated in the midst of intermittent infection; and to my inquiries the reply has been, that the disease leaves these places untouched. I attended for a long while the anatomical theatres and hospitals, yet never found my fellow-students suffer from intermittent fevers. I have seen the horrors of war bring typhus among us, but not intermittent fever. I have consulted authors: everywhere have I seen typhus arise from the infection of animal miasmata, and never are intermittent fevers the consequence of the crowding of human beings or patients together, or from the action of the putrid emana-

* On Blood, part ii., chap. iv., p. 411. Here, perhaps, it would be more correct to say, occasionally, but without any regularity, from local irritation. Thus, when matter forms in deep-seated parts, there is frequently one or more rigours, followed by heat, &c.; and when patients have strictures, for which they are using bougies, the same kind of constitutional disturbance is not uncommon; but it has not the regular type of intermittent fever; and, even if it had, the case would throw no light on the question, whether common ague can be excited by effluvia from animal substances? Dr. Elliotson admits, in his Lectures, that sporadic cases, even of ague, which cannot easily be traced to malaria, are frequently met with; but he has no doubt, that, if we could ascertain all the circumstances, we should find, that the individual had a striking tendency to it, and had been exposed to malaria by passing through a market, or some other place, in which there was vegetable matter in a state of decay. The same excellent physician also reminds us, that, though the influence of malaria is so great, yet, cold and wet, and other causes of debility, will induce ague without the reapplication of malaria, when a person has once had it. Sometimes, too, when malaria has been applied, the disease does not occur till such circumstances as these have taken place. These observations are of great value in accounting for circumstances in the history of ague, which would otherwise lead to most erroneous views.—Ed.

ring this, the intermittent harassed very extensively the elevated parts of Lincolnshire, while the inhabitants of the neighbouring fens were free from its ravages.—(*Med. Trans.*, vol. iii., art. xiii.) And, in like manner, the dry and healthy climate of Minorca is sometimes attacked with remittent or intermittent fever, while Sardinia, proverbial for its insalubrity and febrile epidemics, escapes.—(*Cleghorn, Disease of Minorca.*) "In the year 1812," says Dr. Macmichael, "I was detained several months at Trichiri, a small seaport in the mouth of the Gulf of Volo, in Thessaly. The town is built on a dry limestone rock, but it is notorious for malaria. During my stay here, I made an excursion to visit the celebrated pass of Thermopylæ, and slept one night near the marshy district in that neighbourhood. On my return, the friends whom I had been waiting for arrived from Athens, and we all embarked on board a Greek vessel, to cruise in the Archipelago. On the following day I was seized with a most severe fit of the ague, and, at the same time, a servant belonging to the party suffered a similar attack. It might be said that I had caught my intermittent at Thermopylæ, but the servant had not quitted the dry rock of Trichiri, upon which he had remained more than a week."—(*New View of the Infection of Scarlet Fever, &c.*, 8vo., 1822.) In like manner, Sir Gilbert Blane informs us, that while the village of Green Hithe, nearly on a level with the marsh of Northfleet, is unaffected with intermittent fevers, the adjacent hills suffer considerably from them: and he refers to other anomalies of the same kind.*

To unite remittents, therefore, with intermittents, from an idea of their having a single and common origin, is to depart from the clear line of symptoms into a doubtful region of etiology. If intermittent ought to be separated (as unquestionably they ought) from continued

fevers, so ought remittent to be separated from intermittent. To say that intermittents often run into remittents is to say nothing, for remittents as often run into continued fevers; and it is now an established doctrine, that there is no continued fever whatever without occasional remissions. In effect, all fevers have a tendency to run into each other, and many causes are perhaps common to the whole. The difficulty is in drawing the line; yet a like difficulty is perpetually occurring to the physiologist in every part of nature; and equally calls for discrimination in zoology, botany, and mineralogy; and Dr. Parr has correctly observed, that "if a specific distinction can be established in any branch of natural history, it must be in the separation of remittents from intermittents." Vogel unites remittent with continued fevers, to which Cullen, rightly enough, objects; but the former has as much reason on his side, as the latter has for uniting them with intermittent. Sauvages, Linnéus, Sagar, and most modern writers, correctly distinguish each from the other. It must nevertheless be admitted, that marsh miasm is by far the most frequent cause of intermittents; and hence the frequency and severity with which they visited our own country in the sixteenth and seventeenth centuries, before the lowlands were artificially drained of their moisture, and, consequently, the atmosphere of its taint; during the former part of which, Dr. Caius tells us, that the mortality from agues in London was such, that the living could hardly bury the dead; and Bishop Burnet, that at one time, 1558, they raged like the plague.

When an intermitting fever or ague is, by the operation of marsh miasm, or any other cause, once introduced into the system, and has once discovered its type, or given an interval of a particular measure between the close of the first and the commencement of the second paroxysm, it continues true, as a general rule, not

* Select Dissertations, &c., p. 111. Such anomalies may perhaps be explained on principles which leave the Cullenian doctrine as firm as ever. "A certain degree of moisture," as Professor Elliotson observes, "is necessary for the production of ague by the fermentation and putrefaction of vegetable matter, which gives rise to the exhalations. Hence, in a moderate swamp, you see why dry weather may put a stop to the disease, namely, by putting a stop to putrefaction; and you also see why, in extremely wet situations, there is often no ague, because too much fluid impedes putrefaction; but this wet, by dry weather, may be reduced to just sufficient swampiness for vegetable decomposition to take place, and malaria to be produced. Just as dryness would prevent decomposition, so extreme wetness and moisture will likewise stop it. If the matter which is to be decomposed be diffused in a very large quantity of water, the putrefaction of course ceases, or is not evident; so that some places which were very wet and healthy, have been made unhealthy by being dried just sufficiently for putrefaction to go on vigorously; and again, other parts, which were dry, and which never gave out any exhalations, have been caused to do so by a certain degree of moisture falling upon them. Thus, you see, that according to situation, the same additional moisture

may produce an ill or a salutary effect. High grounds may, therefore, suffer from the same cause, which removes all unhealthiness from low grounds. A certain degree of rain, falling upon high ground will not all remain there, but will roll down; still, it has moistened the parts sufficiently for decomposition to take place above; whereas, when it comes on the low grounds, and there collects, it may be so abundant as to dilute all the vegetable matter, and prevent it from putrefying, and so put a stop to the unhealthiness of the part."—(*Lect. at Lond. Univ., Med. Gaz.*, 1831-2, p. 845.) Considerations of this kind throw light on various circumstances, which would otherwise be completely perplexing, or lead to erroneous inferences. Even supposing no rain at all had fallen on high lands, where ague prevailed, while none existed in lower situations, we are to remember, that the nocturnal dews in many places are nearly equivalent to rain. The fact that malaria is more likely to produce ague when a person has been exposed to it at night, or in a state of health impaired by fatigue, privations, and other causes, is generally acknowledged. Strangers, also, who visit situations where malaria is present, are more frequently attacked with intermittent or remittent fevers than the natives themselves.—*Ed.*

merely to the same measure or extent of interval, but to the length and severity of paroxysm, through the whole course of the disease; the character of the cold stage determining that of the hot, and both together that of the sweating stage; and the paroxysm ceasing because it has completed its career. But the first interval, like the first paroxysm, which regulates the rest, is of different duration in different cases: of the reason of this difference we know nothing; sometimes it seems to depend upon the season or the temperament of the atmosphere, operating upon the febrile miasm that is diffused through it, and all who have agues in the same place, or at the same time, have them of the same kind.* Sometimes, on the contrary, it seems chiefly to depend upon the time of life, the idiosyncrasy, or the particular condition of the constitution, for, as already observed, different individuals, even in the same place and under the same roof, exhibit different types. But upon this subject we have no clear information. It seems expedient, however, to observe, that the fact itself of such regularity of recurrence and interval is an insurmountable objection to the doctrine of M. Broussais, that all fevers consist in an inflammation of the mucous membrane of the stomach or intestines, as in truth it is to every hypothesis that contemplates fever as a local inflammation of any organ. And hence the doctrine of types is an intractable stumbling-block to all such writers; who, from the difficulty of encountering them, are too apt to ejaculate with M. Monfalcon, "peu importe le type d'une pyrexie" (*Histoire des Marais et des Maladies causées par les Emanations des Eaux Stagnantes*, 8vo., Paris, 1824); and then dexterously to reach forward to some point of much easier solution.—(From "*It seems*," &c., an addition from the author's MS.)

Nevertheless, whatever be the cause of these discrepancies, it lays a good foundation for dividing the intermittent genus into distinct species, and the five following are sufficient to comprise all its principal diversities:—

1. Anetus Quotidianus. Quotidian Ague.
2. ——— Tertianus. Tertian Ague.
3. ——— Quartanus. Quartan Ague.
4. ——— Erraticus. Irregular Ague.
5. ——— Complicatus. Complicated Ague.

As the connexion between all these is peculiarly close, and they occasionally run into each other's province; and, more particularly, as the same mode of treatment is common to the whole, it will be most convenient to defer the general history and praxis, till we have taken a survey

* Agues occurring in the spring, are generally tertians and quotidians, and readily give way to proper remedies; while those prevailing in the autumn are more intractable; and quartan intermittents (the most intractable of all) constitute then a more considerable proportion of the cases. Dr. Joseph Brown, in Cyclop. of Pract. Med., art. FEVER.

"Febris autumnalis
Est longa aut lethalis."

of these species in their respective definitions, and the varieties they often exhibit.

It may, however, considerably assist the student, and simplify his pursuit in acquiring a knowledge of their characters, to attend to the three following remarks:—

Firstly, the shorter the intermission, the longer the paroxysm.

Secondly, the longer the paroxysm, the earlier it commences in the day.

Thirdly, the more durable the cold fit, the less durable the other stages.

Thus, the quotidian has a longer paroxysm and a shorter interval than the tertian; and the tertian a longer paroxysm and a shorter interval than the quartan. And thus again, while the quotidian has the longest duration, it has the slightest cold stage; and while the quartan has the shortest duration, it has the longest cold stage. It is also the most obstinate to cure.

Each of these species, however, admits of considerable variations: for sometimes we find the paroxysm protracted beyond its proper period; sometimes anticipating, and sometimes delaying its proper period of return. In other cases, we find each of these species catenated with, or giving rise to foreign symptoms or other diseases. And we also meet with a peculiar variety of the quotidian ague, in its being sometimes limited to a particular part or organ, in which case it is usually accompanied with very distressing pain.

The most irregular of all the species is the fourth, for this is sometimes found to deviate from all the three rules I have just laid down; but particularly in the greater length of its interval, which is sometimes double or even treble that of the quartan, whose interval of seventy-two hours is the longest of the three more disciplined species; it is hence found under the various forms of a five-day, a six-day, a seven, eight, nine, and even a ten-day ague; and sometimes is so extremely vague as to bear no proportion whatever between the violence of its paroxysm, the duration of its stages, and the period of its return.

The fifth species is distinguished from the rest by its peculiar complexity, consisting of double tertians, triple tertians, unequal tertians, duplicate tertians, together with as many varieties of the quartan type; the nature and key of which will be more particularly noticed under the species itself.

SPECIES I.

ANETUS QUOTIDIANUS.

QUOTIDIAN AGUE.

INTERMISSION ABOUT EVERY TWENTY-FOUR HOURS; PAROXYSM COMMENCING IN THE MORNING; USUAL DURATION UNDER EIGHTEEN HOURS.

The genuine quotidian is of less frequent occurrence than the other species; but it has a considerable resemblance to that variety of the complicated intermittent, which has generally been denominated a double tertian, and with which it is often confounded. It is distinguish-

able, however, to an attentive eye, by the regularity of its paroxysms, which are true to themselves on every return; while, in the double tertian, the alternate paroxysms only are true to each other, as we shall have occasion to observe more particularly in the proper place. The quotidian, like the tertian and quartan, has sometimes been epidemic.

The quotidian intermittent is occasionally limited in its attack to a particular part, and is occasionally connected with other affections. It deviates also now and then from its common rule, in having an imperfect intermission, and in precipitating or procrastinating every subsequent paroxysm; and hence affords us the following varieties:—

α Partialis.	Partial quotidian.
β Comitatus.	Catenating quotidian.
γ Protractus.	Protracted quotidian.
δ Anticipans.	Anticipating quotidian.
ϵ Cunctans.	Retarding quotidian.

In the PARTIAL QUOTIDIAN, the febrile attack is confined to a particular part or organ, and usually accompanied with distressing pain.

Under this modification, sometimes one side of the body has suffered, while the other has escaped; sometimes one or both eyes; but more generally the whole or half the head, not unfrequently resembling cases of cephalæa, and particularly that species of it which is called hemicrania.

In the CATENATING QUOTIDIAN, the disease associates with, or gives rise to, various foreign symptoms or other diseases; and hence is often found in union with rheumatic affections, particularly lumbago and sciatica. Sauvages quotes a case, in which it associated with daily attacks of a frightful epilepsy.—(Class ii., *Febr. Intermitt.*, Quot. Spec. iv.) And Dr. A. Monro narrates a similar instance, though less severe, and alludes to several others.—(*Edin. Med. Essays*, vol. ii., art. xix.) Torti has made a collection of numerous examples of this variety, and has united them into one family, under the name of *febres intermittentes comitatæ*. Galen has described one or two of them under the name of *epiala*.

In the PROTRACTED QUOTIDIAN, the intermission is inordinately short or imperfect. In the former case, the paroxysm is lengthened beyond the usual period of eighteen hours; and, in the latter case, it does not so completely subside as to leave the intermission totally clear of febrile symptoms. On which last account the Latins describe this variety under the name of *quotidiana continua*; and the Greeks under that of *amphemerina*.

In the ANTICIPATING QUOTIDIAN, which is the name given to our FOURTH VARIETY from Dr. Fordyce, the paroxysm precedes its antecedent period usually by about two hours, and continues the same fore-march at every recurrence; so that the accession may hereby be thrown into any hour of the day or night. This form is denominated a *febris subintrans* by Professor Frank and various other writers.—(Op. cit., tom. i., p. 41.)

The RETARDING QUOTIDIAN, which, like the last, has been particularly noticed and named by Dr. Fordyce, forms a direct counterpart to the anticipating; the paroxysm delaying its antecedent period usually by about two hours, and continuing the same delay at every recurrence; so that here also the accession may be thrown into any hour of the day or night.

There are few diseases, moreover, in which the quotidian is not occasionally to be found as a symptom; but it occurs especially in hysteria, catarrh, gout, peripneumony, ischury, quinsy, and several species of odontia.

SPECIES II.

ANETUS TERTIANUS.

TERTIAN AGUE.

INTERMISSION ABOUT FORTY-EIGHT HOURS: PAR-OXYSM COMMENCING AT NOON; USUAL DURATION UNDER TWELVE HOURS.

THE tertian ague, the *tritæus* of the Greeks, occurs most frequently in the spring and summer months; though there is a spurious kind that shows itself in the autumn. The chill, during the cold fit, is intense, with convulsive shivering, rigidity, and gnashing of the teeth. It is, however, of shorter duration than that of the quartan, and sometimes passes off in less than half an hour; and is succeeded first by nausea or vomiting, and afterward by a pungent penetrating heat, frequent respiration, urgent desire for cold drink, wakefulness and headache, sometimes delirium. At length, a moisture on the skin, gradually advancing to a copious sweat, breaks forth, the urine commonly deposits a lateritious sediment, and there is often some looseness of the bowels. The entire paroxysm sometimes ceases in six hours, but more generally extends to eight or ten; if it exceed twelve, as it does occasionally in the autumn, the disease forms the spurious tertian I just have alluded to. As the quotidian is mostly common to infants and persons of delicate habits, the tertian chiefly affects those of riper years or of firmer fibres, and especially persons of a bilious temperament. It was the opinion of Hippocrates, that the tertian ague, if left to nature, would run itself out in seven paroxysms; and Vogel adds, that when this is the case, there is usually the appearance of a dry scabby eruption about the lips on the fourth or fifth paroxysm. But the period, pointed out by the former, does not hold in our own day; and the disease has often continued obstinate in spite of cutaneous eruptions, not only about the lips, but over the body. Sydenham asserts, that, in the autumn, in which, however, a genuine tertian is rarely to be met with, its ordinary natural course is double the term allotted by Hippocrates, or rather, that the term of its paroxysms amounts to the space of fourteen days. The tertian exhibits occasionally the two following varieties:—

α Comitatus.	Catenating tertian.
β Protractus.	Protracted tertian.

To both which the explanation already given

under the same terms in the preceding species will equally apply. As an associate disease, it is chiefly to be found united with syncopal and soporose affections, indicating some oppression of the brain; or with cholera or dysentery, mostly indicating irritation or congestion in the liver.

SPECIES III.

ANETUS QUARTANUS.

QUARTAN AGUE.

INTERMISSION ABOUT SEVENTY-TWO HOURS;
PAROXYSM COMMENCING IN THE AFTERNOON;
USUAL DURATION UNDER NINE HOURS.

THIS, which is also the quartana of Celsus, is the tetartæus of the Greek writers. It is rarely found in the vernal season, but is common in the autumnal, in which quarter, also, it is far the most obstinate of all the species, and especially if, as Celsus observes, it show itself only a short time before the commencement of winter. Its chief subjects and sufferers are those of advanced years, and of a melancholic habit; for children and young persons, who principally feel the effects of the two former species, are but little obnoxious to it. It commences usually about, or a little before five o'clock in the afternoon. The cold fit is less vehement than in the tertian, but of longer duration, and will sometimes continue for two hours, but usually without sickness or diarrhœa. It yields to a heat that is rather troublesome from its dryness than from its intensity, and which is rarely succeeded by a sensible perspiration. There is a heaviness or dullness in the head, rather than acute pain: and often, during the intermediate days, a sense of soreness over the body, as though it had been generally bruised, which strikes through to the bones. It is here also we principally meet with paralytic tumours, and especially of the spleen and liver: in the former of which organs they are vulgarly called *ague-cakes*.

The quartan offers the following varieties:—

α Comitatus.	Catenating quartan.
β Protractus.	Protracted quartan.
γ Anticipans.	Anticipating quartan.
δ Cunctans.	Retarding quartan.

Of all which an explanation will be found, by turning to the same varieties under the first species.

From the tendency which this species has to affect the abdominal viscera, it is often met with as a symptom in diseases of the spleen, liver, and various adjoining organs. And hence it occasionally interchanges with dysentery, and particularly when the latter is a prevailing or epidemic disease. This remark will also apply to the preceding species, and under the one or the other form was often found exemplified in the fatal dysentery that ravaged a large part of Ireland in the year 1818 (*Cheyne, in Dublin Hospital Reports*, vol. iii.), and which still more frequently occurs in tropical climates.—(*Climate and Diseases of Tropical Countries, &c.*, by C. Chisholm, M. D., p. 52, Lond., 1822.)

Z 2

SPECIES IV.

ANETUS ERRATICUS

IRREGULAR AGUE.

INTERMISSION AND PAROXYSM POSSESSING LITTLE REGULARITY: THE FORMER MORE THAN SEVENTY-TWO HOURS.

We have already perceived that there is occasionally some degree of irregularity in all the preceding species, least of all, however, in the quartan. And hence all the above might, in such instances, be named erratic. But the peculiar character of the present species is, that the duration of the intermission exceeds that of all of them; on which account it can never be confounded with any of the rest.

The chief varieties are the following, which, however, might be considerably enlarged, but it is unnecessary. They are principally taken from Sauvages and Vogel; and, for other authorities, the reader may turn to the volume of Nosology:—

α Quintanus.	Five-day ague.
β Sextanus.	Six-day ague.
γ Septanus.	Seven-day ague.
δ Octanus.	Eight-day ague.
ε Nonanus.	Nine-day ague.
ζ Decimanus.	Ten-day ague.
η Vagus	Vague and irreducible.

Several of the above have occasionally persevered with great obstinacy; in some instances, for upwards of two years without ceasing. The last variety is equally irregular as to the violence of its paroxysm, the duration of its stages, and the period of its return. Several of Sauvages's species of hemicrania may be properly referred to this place, and especially those which by some writers have been denominated INTERMITTENT LARYNGE, or disguised intermittents.

SPECIES V.

ANETUS COMPLICATUS.

COMPLICATED AGUE.

PAROXYSMS INTRICATE, MULTIPLICATE, OR BOTH.

THERE are numerous examples of ague, which, to an inattentive eye, are as irreducible to any regular order as those which belong to the last variety of the preceding species, but which, when minutely examined, are found, however intricate, to be composed of types, not that uniformly resemble each other, but that recur in alternate sets, every set being true to itself, while it differs from that with which it alternates in the duration of its intervals, or of its paroxysms, or of the time of its accession. And hence, although in some shape or other, most of them return perhaps every day, and are often mistaken for irregular quotidians, they are, in fact, double or triple tertians or quartans, discovering their real nature by these alternating distinctions:—

The following are the chief varieties:—

α Tertianus duplex.	The paroxysms of the
Double tertian.	one tertian occurring in the intermissions

- of the other; and the two sets evincing a difference of duration or of violence.
- β Tertianus triplex. Triple tertian. A double tertian, taking place as above; but one of the sets having regularly two paroxysms on the day of its return, and the other one alone.
- γ Tertianus impar. Double unequal tertian. The one set evincing a more perfect, the other a less perfect intermission.
- δ Tertianus duplicatus. Duplicate tertian. A single tertian with two paroxysms on the regular day of attack, the intervals being of ordinary duration.
- ε Quartanus duplex. Double quartan. The paroxysms of the one set occurring in the intermissions of the other, and evincing a difference of duration or of violence: with an interval on the third day alone.
- ζ Quartanus triplex. Triple quartan. Consisting of a single quartan with regularly returning paroxysms; while each of the intervening days is marked with a slighter or separate attack.
- η Quartanus duplicatus. Duplicate quartan. Consisting of a single quartan with two paroxysms on the regular day of attack: the intervals being of ordinary duration.
- κ Quartanus triplicatus. Triplicate quartan. Consisting of a single quartan with three paroxysms on the regular day of attack: the intervals being undisturbed, and of ordinary duration.

Having thus distinctly noticed the several species and chief varieties of intermittent fever, I shall proceed to offer a few remarks upon its general history and medical treatment.

Whenever the accession of an intermittent is violent, be its type what it may, it is sometimes attended with very alarming symptoms, as syncope, apoplexy, vehement spasms over the whole system, or a coldness or torpor which threatens death.* Yet, when not violent, nor of very long duration, especially when of the tertian

type, it is often serviceable to the general health, and carries off many disorders of other kinds. Dr. Fordyce affirms (*On Fever*, Diss. ii., p. 16), that he has seen it of considerable use in curing or alleviating chronic rheumatism, habitual indigestion, cutaneous eruptions, protracted inflammations, epilepsies, and hysteria. And his assertion is corroborated by other authorities.—(*Salmuth*, cent. ii., obs. 14; *Ephem. Nat. Cur.*, dec. iii., ann. iii., obs. 30.) It is to this kind of remedial fever that Professor Frank gives the name of *depuratory*.—(Op. cit., tom. i., p. 48.)

The duration of intermittents is of great uncertainty. The vernal agues generally disappear with the advance of summer; the autumnal are more obstinate, and especially the quartan. Where they have remained long, and have become habitual, even their removal must be attempted with great caution; for, when abruptly suppressed, they have been known to lay a foundation for a host of other maladies, often of a more fatal description, as paralysis, various visceral affections, and even sphacelus.

Ludolf gives an instance of an eight-day ague (*anetus erraticus octanus*) continuing for eighteen years; yet this was probably a double quartan; while we have abundant examples of a continuance of the regular quartan for nine (*Eph. Nat. Cur.*, dec. ii., ann. viii., obs. 45), twelve (*Avicenna*, canonum i., lib. iv., tr. ii., cap. vi.), eighteen (*Madai*, *Von Weekscheibern*, sect. 144), twenty (*Eph. Nat. Cur.*, dec. iii., ann. ix. and x., obs. 51), twenty-four (*Marcellus Donatus*, lib. iii., cap. xiv., p. 291; *Pontanus*, *De Febr. Concl.*, lib. viii.), and thirty years (*Binninger*, obs. cent. v., N. 64; *Wierius*, obs., p. 37), and one instance of its lasting for not less than forty-eight years.—(*Gabelchover*, cent. vi., obs. 74.) It is in this species, therefore, that we chiefly meet with those congestions in the spleen which are called ague-cakes, as also with scirrhusities in the liver, pancreas, and other abdominal organs, which by Bonet, Swalwe, Senac, and other writers, have been regarded as causes of the disease, but by Van Hoven, and most pathologists of the present day, excepting, perhaps, Cruveilhier, are more correctly resolved into effects.

Schenck gives a case of congenital quartan, or in which it appeared in an infant immediately after birth (*Obs.*, lib. vi., N. 36); and Paullini another, in which though not strictly congenital, it appeared in very early infancy.—(Cent. i., obs. 94.) But such examples are rare. Among other singularities, I may observe, that the accession has sometimes been so violent as to destroy the patient in the course of the first paroxysm, of which an instance will be found in Senac (*Von Weekscheibern*, b. ii., cap. vi.), while, at other times, it has been so slight and rapid, that the entire paroxysm has run through

* It once occurred to Dr. Joseph Brown to see a person die in what appeared to be the cold stage of a first fit of ague. Heat applied in various modes, ammonia, ardent spirits, ether, and other stimulants, failed to bring on reaction. The patient lay as cold as marble, and shivering violently, without any pulse at the wrist, and his heart act-

ing very feebly, for eighteen hours, at the end of which he expired, his intellect having been unclouded till within a few minutes of his dissolution. The principal morbid appearance discovered was in the liver, which was very much enlarged, had a lobulated appearance, and was gorged with blood.—Cyclop. of Pract. Med., art. FEVER.—Ed.

its course in a minute.—(*Reil, Memorab. Clin.*, vol. ii., Fasc.)

The character of the intermittent seems in a considerable degree to depend upon the age or idiosyncrasy of the individual, and the temperament of the atmosphere. We find, also, that variations more usually take place in the quotidian than in any other type, which we should, perhaps, ascribe to its occurring more frequently in early life, when the frame is more irritable; and to the debility which the constitution suffers from this type, above that of any other, in consequence of the greater length of its paroxysms, and the greater brevity of its intervals, by which means the prostrated strength of the system has no time to rally.

In this metropolis, from causes which have not been handed down to us, and which, indeed, do not appear to have been traced at the time, intermittent fevers were more than ordinarily frequent from the year 1781 to 1785: and the remarks I have just made apply in an especial manner to all these. As a single example, let us select those of 1782, as described by Sir George Baker and Dr. Reynolds, in an article drawn up by the former, with an admirable combination of learning and liberality, sound critical judgment, and inquisitive research.

"The type of the fever of 1781-2," says Sir George, "was either tertian or quotidian; the former being more common in the first part of the winter; the latter, from the middle of February to the end of June. With respect to the former, NOTHING OCCURRED to my observation which is worthy of notice"—(*Med. Trans.*, vol. iii., art. xiii.) On the latter, Dr. Reynolds communicated to him the following information:—

The quotidian fevers were irregular in their invasion, and uncommon in their appearance; and no cases resembled each other, except in very few circumstances. The first attack generally commenced with a horror; but the subsequent paroxysms, though often beginning with a sense of cold, were chiefly without horror. The intermission was short, and seldom perfect. The symptoms were very severe, and in many cases dangerous, and leaned strikingly to a typhous form. Great and sudden oppression of the head, anxiety, depression of spirits, a dry, parched tongue, yet less covered with hardened mucus than might be expected; a pulse low, quick, and intermitting; bowels variable; urine dark-red and clear, without any sediment, constituted the ordinary signs. Many had a low muttering delirium; two or three a laborious respiration; a few spasms and twitchings of the tendons: aphthæ appeared occasionally: and one patient exhibited symptoms of violently acute rheumatism. The bark was universally successful; and, "I was as much pleased," says Dr. Reynolds, "with its present efficacy, as I was in the year 1781 mortified by its extraordinary want of power. Half the quantity of it which I used on that occasion was sufficient on this."

In other words, idiosyncrasy and atmospheric temperament were both peculiarly visible, and gave a peculiar character, in the one instance,

to particular cases, and, in the other, to the general disease. In plethoric habits, the head was greatly oppressed with a tendency to delirium. In those of a nervous and irritable disposition, the intermittent was connected with spasms and twitchings of the tendons. And those disposed to rheumatism, had acute arthritic pains. The state of the atmosphere, and the general character of the season, Dr. Reynolds has forgotten to notice; but we see evidently, and indeed he himself allows, that they give a typhous impression to the epidemic; which, from the same, or from other causes, is also peculiarly distinguished by the easy victory it yielded to the use of the bark, as that of the preceding year was distinguished by its obstinate resistance to this medicine.

If we ascend a year higher, or to 1780-1, we shall meet with an equal diversity of symptoms. "These fevers" (intermittents), says Sir George Baker, "were in general no other than the common ague; but in the more inland countries of England, they were often attended with peculiarities extraordinary and alarming. For the cold fit was accompanied by spasm and stiffness of the whole body; the jaws being fixed, the eyes staring, and the pulse very small and weak. In many cases, delirium was added to spasm, under both which symptoms the patient laboured quite to the end of the paroxysm. And though the senses returned when the fever subsided, yet a convulsive twitching of the extremities continued, even in the intermissions, to such a degree, that it was not possible to distinguish the motion of the artery at the wrist.

"This fever had every kind of variety: and, whether at its first accession it were a quotidian, a tertian, or a quartan, it was very apt to change from one type to another. Sometimes it returned two days successively, and missed the third, and sometimes it became continual. I am not informed that any died of this fever while it intermitted. It is certain, however, that many country people, whose illness had, at its beginning, put on the appearance of intermission, becoming delirious, sunk under it in four or five days. It is a remarkable fact, and very well attested, that in many places, WHILE THE INHABITANTS OF THE HIGH GROUNDS WERE HARASSED BY THIS FEVER IN ITS WORST FORM, THOSE OF THE SUBJACENT VALLEYS WERE NOT AFFECTED BY IT. The people of Boston and of the neighbouring villages, in the midst of the Fens, were in general healthy, at a time when this fever was epidemic in the more elevated situations of Lincolnshire: and other examples of a like kind have already been noticed.* It is

* Sir Gilbert Blane, *Select Dissertations*, p. 111, 8vo., Lond., 1822. In order to form a correct judgment of this part of the subject, we should have been informed of the state of the weather, not merely in respect to temperature, but quantity of rain that fell in the different places alluded to. The occurrence of ague sometimes in high situations, while it ceases in lower ones, will admit of explanation on principles already noticed in a preceding note.—Ed.

likewise singular, and worthy of notice, that, in many families, the female servants were nearly exempted from a disease which very few male servants, especially the labourers in the open air, escaped. But the distinguishing character of this fever was its obstinate resistance to the Peruvian bark; nor, indeed, was the prevalence of the disease more observable, than the inefficacy of the remedy. Though the quantities of the bark usually given were exceeded, the fit was apt to return, rarely altered, either with respect to the time of invasion, or the intensity of the symptoms; and just as if no means had been used to prevent it. A drachm of the bark in powder was frequently administered every second hour, without averting the fit."

In casting our eyes over the great diversity of medicines that have been employed for the cure of intermittents,* we shall find that, innumerable as they are, they may be arranged under two general heads, tonics and antispasmodics; as though, long before the time of Dr. Cullen, his two principles of the disease, debility and spasm, had been uniformly admitted and acted upon.

The antispasmodics, consisting chiefly of stimulants, sedatives, and relaxants, have been confined to the term of the paroxysm, with a view to weaken and shorten it; and the tonics, consisting principally of bitters and astringents, have been employed throughout the intervals, with a view of fortifying the system against a recurrence of the attack.

In discussing the medical treatment of intermittent fevers, it will be sufficient to limit ourselves to these two indications.

It was a favourite practice with Bergius to anticipate the cold fit, constituting the accession of the paroxysm, by pungent stimulants, in the hope that, if he could successfully combat this first stage, he should gain a complete victory, not only over the individual paroxysm, but over all future incursions. His favourite medicines for this purpose were garlic, mustard-seed, and capsicum. And he boasts of having, in numerous instances, completely succeeded, with each of these; though he admits that the mustard-seed answered best in vernal intermittents, but did not, in general, prove sufficient for the autumnal quartans. The Indian practitioners, I may here observe, employ chakka or ginger, and sometimes the sison ammi for the same purpose, and Dr. Chisholm has occasionally succeeded with scallions.—(*Clim. and Dis. of Trop. Coun.*, &c., 1822, p. 53.) Bergius, however, placed his chief reliance on the capsicum, six grains of which he was in the habit of giving, combined with two scruples of bay-berries in powder, "incipiente primo rigore;" and of repeating it every day, at the same hour, for three

or four times in succession. And he assures us that he has very frequently seen obstinate intermittents removed by this powder, and without any relapse.

The practice, however, has not been equally successful in other hands; not even when capsicum has been given in a much larger quantity, or exchanged for ammoniac, treacle-mustard (*clypeola jonthlapsi*), or black or white pepper, the latter of which is only the former denuded of its outward tunic, mixed up with brandy or Hollands. They have all, indeed, sometimes answered, but the result is uncertain; and, as was long ago observed by Van Swieten, if the medicine do not succeed upon a full dose, and especially when combined with ardent spirit, it will often extend its influence to the hot fit, and greatly exacerbate it; and not unfrequently convert an intermittent into a continued fever. Upon the whole, therefore, this plan is not to be recommended, however varied. The least pernicious material is the ammoniac; but then it is also the least effective.

A large draught of cold water has been not unfrequently had recourse to for the same purpose, and also, in a few instances, with success. The object is, by taking it about half an hour before the cold fit is expected, to excite a strong reaction and powerful glow over the entire system against the time when the cold fit returns, and thus to preoccupy the ground; and, by disturbing the regularity of the type, to subdue the intermittent altogether. But this plan has, perhaps, more frequently failed than the preceding; and when the shivering or horripilation produced by the cold water has not been followed with a stimulant effect, as in delicate habits more especially, it has often continued so long as to run into the term of the febrile cold fit, and very considerably to increase its power. Ballonius relates a case in which it proved fatal.*

The next division of antispasmodics, which have been directed against the paroxysm, and especially against the rigour with which it makes its onset, is sedatives: and of these the chief have been opiates, which, when given in the form of laudanum, in a dose of from thirty to forty drops at the commencement of the chill, has, in many cases of intermittents, been highly beneficial; diminishing the duration of the stage, and moderating its symptoms. Dr. Trotter says, that he practised this plan with general advantage in an epidemic intermittent that attacked the Vengeance, one of the Channel fleet under Lord Howe; and adds, that, "if the first dose of opium did not produce a sensible relief

* Intermittents are sometimes cured merely by diet and regimen. Of twenty-three patients sent to the hospital la Charité, for the purpose of testing the efficacy of the misletoe (*Ilex aquifolium*), M. Chomel states that the disease ceased immediately in seven of them, although no medicine was administered.—See *Mem. de l'Acad. Royale de Med.*, vol. iii.—D.

* Op., tom. i., p. 193. Venesection has been recommended as a means of shortening the cold stage, and of preventing the hot stage, or lessening its duration and violence. Dr. Mackintosh, in his work on the Practice of Physic, is in favour of such treatment. On the other hand, Dr. Stokes rather disapproves of venesection in the cold stage; though he admits that it is beneficial in removing the symptoms of congestion about the chest and abdomen.—(*Edinb. Med. and Surg. Journ.*, 1829.) Dr. Elliotson has never seen a case of ague which required venesection in the cold stage.—*Lect. at Lond. Univ.*, *Med. Gaz.*, 1832, p. 2.—Ed.

and exhilaration of spirits in half an hour, he repeated it, and never found it necessary to go beyond a second dose."* Sir Gilbert Blane adverts to the same plan, as pursued at Walcheren during the English expedition to that island, and with an equal success.†

We have already seen, however, that there is some cause or other, probably the peculiar temperament of the atmosphere at the time, that baffles on one occasion the remedy that has best succeeded on another. And hence opium has often failed in other intermittents in every form, but especially when given in the cold fit. And owing to this diversity of effect, Dr. Lind thought it most useful in the hot fit; and asserts that, if administered to the extent of twenty or five-and-twenty drops of laudanum half an hour after the beginning of the hot fit, it produced the advantage of shortening and moderating the heat, calmed the anxiety and headache, which are usual concomitants, expedited the sweating stage, made the paroxysms more regular, and sometimes stopped the fever altogether.

Other physicians have commenced with relaxants; and where these are selected, the antimonial preparations are to be preferred to ipecacuanha. They tend more directly towards the surface, and, where it is useful to excite vomiting, which is often the case, they act sooner, and maintain the action longer, and hence make a double effort to accelerate the sweating stage. The antimonial preparations differ chiefly from each other by having the reguline part of the antimony they contain in a more or less fusible state; and their operation will very often vary according to the quantity or quality of the acid they meet with in the stomach; and hence the different effect of the same preparation in different persons, and even in the same person at different times.

The most efficacious practice which I have witnessed, consists in uniting relaxants with opiates; and, where this joint effort is pursued, ipecacuanha may answer as well as any of the preparations of antimony. We cannot have, for this purpose, a more useful medicine than Dover's powder; and it should be commenced with much earlier than is consistent with the

usual practice, so as not to regulate the hot and sweating stages, but to anticipate the cold fit. And we may still farther add to the ingredients of the medicine a full dose of ammonia with great advantage; for, it is in this form, if in any, that we can employ stimulants with a certainty of doing little mischief, and very nearly a certainty of considerable benefit. In the case of a quartan in St. Thomas's Hospital which had lasted two years, Dr. Fordyce determined upon this plan; and prescribed a full dose of Dover's powder, with a sweating draught of carbonate of ammonia, two hours before the paroxysm was expected. It succeeded perfectly. A profuse perspiration anticipated the period of the cold fit, and hereby entirely prevented it; bark was next given freely, and this obstinate ague was cured in a few days.—(*Edinb. Med. Comm.*, vol. vi., p. 359.)

Whatever be the relaxant or sudorific employed, it should be assisted by plentiful potations of warm diluents, and by placing the patient between the blankets instead of in the sheets of his bed: for, I have already had occasion to observe, that upon these auxiliary means depend, in many instances, the accomplishment of the object we have in view, without which the most urgent diaphoretic exerts itself to no purpose.*

The most important season, nevertheless, for medical operation, is in the intermission of the paroxysms: since, however successful we may be in moderating the febrile attack, it is rarely that we can depend upon any plan which may then be adopted, to prevent a recurrence of the fit.

The opinion of mankind seems to have concurred in most ages, in regarding debility as either the proximate or predisponent cause of intermittents, since almost the only medicines that have been brought forward to guard against the recurrence of their periodic attacks have been tonics, with the sensible qualities of bitterness or astringency, or of both.

In what way these act upon the moving fibre at any time, and particularly in the diseases before us, we cannot say with any degree of precision. The tone of the moving fibre depends unquestionably in some degree upon the state of the fibrous material itself, but perhaps in a much greater degree upon the state of the nervous influence. We have great reason for believing, that astringents, in producing tone, act upon the fibrous material itself, for we find them operating in like manner upon animal fibres both in a living and a dead condition. But whether, as Dr. Cullen conjectures, it be the

* The administration of opium to arrest the invasion of intermittents, is one of long and extensive use in the United States. It is largely indebted for its popularity to the authority of Sir Gilbert Blane. Sixty or eighty drops of laudanum, blended with a few drops of sulphuric ether, or of aqua ammonia, are often administered a short time previous to the invasion of the cold chill. Many physicians will testify to the efficacy of this treatment, and few be disposed to question its efficacy, even in plethoric subjects. Plethora and local congestion however should always be considered, and bloodletting may sometimes be found an important preliminary measure. Dr. Gallup (*Epidemic Diseases of Vermont*) strongly condemns the use of opium in every form of intermittent fevers.—D.

† Select Dissertations, &c., p. 105, Lond., 8vo., 1822. Dr. Elliotson has given opium with very great success; yet, says he, "if I found great congestion of the head or other parts, I would order bleeding in preference to opium."

* Dr. Elliotson conceives, that in the cold stage, the plan of surrounding the patient with hot air would be better than putting him into the warm bath, as is sometimes done. Air in any quantity, and of any temperature, may be conveyed under the bedclothes by means of something like an inverted funnel, a tube, and a spirit-lamp. Dr. Elliotson has also a favourable opinion of the usefulness of friction. The warm drinks which are given, he thinks, should not contain wine or brandy, as such stimuli would be likely to increase the subsequent hot stage, bring on delirium, and cause congestion and inflammation of the head and internal organs.—Ed.

part of bitters alone to act upon the nervous power or living principle, and especially in the very singular manner in which he represents them as acting, is a different question; and the present is not the place for entering upon it.

If we contemplate the brain and spinal marrow as the sources of nervous energy, we can readily conceive that the component parts of these organs, as well as of any other, may be invigorated by medicines that have a peculiar influence on their structure; and that consequently, such organs may be rendered capable of distributing the nervous power in greater abundance, or of producing it in a more elaborate perfection. And we can also readily conceive, that such effects may be produced by both bitters and astringents, as well as by medicines that possess some other sensible qualities, though these are the most obvious in their operation. But should we, with Dr. Cullen, affirm that the same bitter, employed in the same proportion, produces both tone and atony, energy and debility; that it both cures the gout and occasions it; that, employed for a certain time it effects the former, and, after such time, the latter; and should we beyond this affirm, with him also, that the nervous energy is not the production, but an inherent power, of the brain; that it admits neither of increase nor diminution; is changeable in its state, but unchangeable in its essence; becomes excited and collapsed, or rises and falls in its energy, but experiences nothing of the decomposition or recruit of every other part of the living frame around it; we should travel into a labyrinth of incongruities, and only enlighten ourselves with a will-o'-the-wisp. Dr. Cullen's system, like himself, is a work of no ordinary stamp; it is full of immortality, but mixed up with weak and perishable materials.

Of the remedies appertaining to the one or the other of the two divisions we are now considering, those of astringents and bitters, the cinchona, or Peruvian bark, which unites both qualities in itself, is on every account entitled to our first attention.

This valuable medicine, which some practitioners are apt to despise or think lightly of in the present day, has never been altogether without its opponents; and there are many facts respecting its operation, which, if not altogether anomalous, are of very difficult solution.

Peruvian bark, according to the authority of Don Joseph Villerobel, a Spanish physician noticed by Badus, was first brought to Spain in the year 1632; but here, as in every other country, it had for a long series of years to encounter the prejudices of the medical profession; and consequently was very rarely made use of, and unquestionably would have sunk into oblivion but for the activity of the Spanish jesuits, who continued zealously to recommend it, and to import large quantities of it from their brethren in South America. Through these means, it was at last recommended by Pope Innocent X., in 1661, as a medicine perfectly innocuous and salutary; and a *Schedula Romana*, drawn up under the sanction of the phy-

sician to his holiness, pointed out, in express terms, the time and proportion in which the bark was to be taken. Unfortunately, the time stated was *frigore febrili incipiente*, "at the commencement of the cold fit;" and it being administered in this manner, with only temporary benefit, to the Archduke Leopold of Austria, a year or two afterward, it immediately fell into great discredit with a very large and learned part of the medical community of Europe; and a most acrimonious warfare was instantly waged in every quarter on the subject, in which the combatants on both sides seemed more desirous of victory than of truth.

In our own country, the bark began to become popular about 1655. In 1658, Mr. Underwood, an alderman of the city of London, died while using it, and was instantly reported to have fallen a sacrifice to its power; and so prejudicial was the effect of this rumour, that Cromwell, who was attacked with an ague in the same year, was suffered to languish and at length to die without an exhibition of the bark, his physicians being afraid to make a trial of it, in consequence of the fatal accidents that had so lately accompanied its use: in the words of Morton (*Pyretolog.*, p. 17), "*nondum vires corticis in hoc veneno subigendo, saltem hic loci, comprobatae erant.*"

In England, therefore, as well as on the continent, there was a great conflict of opinion. Dr. Prejean, who both preceded and succeeded Dr. Harvey as president of the College of Physicians, appears openly to have advocated its employment in 1658, according to facts adverted to by Sir George Baker in his admirable article on intermittent fevers (*Med. Trans.*, vol. iii., art. xiii.), from which these hints are chiefly drawn up. Dr. Brady, professor of physic at Cambridge, appears equally to have countenanced it; as does Dr. Willis, according to his own statement: while Dr. Morton professed himself inexperienced upon its virtues, and Dr. Sydenham was decidedly adverse to its use.

Sydenham, however, was a man of reason and liberality. His prejudices, and especially those derived from the hypothesis, that a fever is a fermentation in the blood, raised by nature to throw off some peccant matter at the surface, and which ought not therefore to be checked in its course, however wise it may be to moderate it in its violence, were all at arms against the use of the bark under any circumstances: and the mischievous effects to which he had been an eyewitness in some instances, and its total inertness in more, gave a sanction to suspicion, if it did not justify hostility. But he was determined to watch it for a still longer period, through all its variable effects, and to abide by the result when fairly cast up. He soon became sensible that it was, in most cases, a powerful engine; that in many instances, it was highly serviceable; and that, in those in which it failed, the miscarriage was rather to be ascribed to some error in handling it, than to a want of power in the drug itself.

Sydenham had sufficient ground for this last conclusion. The mode in which it was, at this

time, usually administered, was in doses of two drachms given twice in the twenty-four hours; and, as already observed, the time selected for the purpose was during the existence of the paroxysm. It is, moreover, highly probable, that it was sometimes considerably adulterated, from the difficulty of obtaining it in any considerable quantity.

In 1658, we learn from Sturmius, who warmly patronised its use, that pure bark was so scarce on the continent that twenty doses of the powder were sold at Brussels for sixty florins, for the purpose of being sent to Paris; and that this order so completely exhausted the apothecary's stock, that he himself was incapable of obtaining any even at that price. And hence, for the use of one patient, who was attacked with an obstinate intermittent fever in the month of February of the same year, he was obliged to wait till the June following before he could obtain a supply.—(*Febrif. Peruv. Vindictiarum Pars prior*, p. 84, Antwerp, 1659.) Nor was it less difficult to be procured at Brussels than in many other parts of Europe; for Bartholine, then residing at Copenhagen, having received as a great rarity a present of three doses, or six drachms, of the powder from some friends who had brought it from Italy, was induced to make a trial of it on a lady who had a quartan fever. Of this small portion, the first dose, or two drachms, was rejected from the patient's stomach; and, in order to prevent a repetition of this accident, and consequently the loss of his entire stock, the administrator macerated his two remaining doses in wine for forty hours, and gave the infusion during two successive paroxysms. The only effect was, that the fever was changed from a double to a single quartan. And here the experimenter was obliged to stop, as having no more materials to proceed with.—(*Thomæ Bartholini Hist. Anat. et Med.*, cent. v., hist. 1., Hafnia, 1661.) But, even in 1678, when the same pretext for sophisticating it no longer existed, Morton complains that the bark offered for sale was become so inert, corrupt, and adulterated, that it was necessary to increase the proportion from two drachms, to one, two, or even three ounces for a single dose. And, thus given by wholesale, we cannot wonder that still more mischief should result from its abundance than from its scarcity, whatever might be the purity or impurity of its quality.

To guard against all the evils that seemed to accompany its use, Sydenham proposed to himself the following regulations:—

First, To be peculiarly cautious in the quality of the bark he employed; and to allow of no intermixture, whether from fraud or a view of increasing its virtue.

Secondly, To administer the bark in the intervals, instead of in the paroxysms of a fever.

Thirdly, To give it after the rate of two scruples every four hours, instead of two drachms twice a day, after the *Schedula Romana*.

Under these regulations, the bark seems to have acquired all the success to which it has at any time pretended; and modern practice has added little to their value.

The most important of them is that which

effected a change in the period of exhibiting the bark. But, whether the merit of first suggesting this improvement be due to Sydenham, or to some contemporary of his, we cannot at present very accurately determine. He is, indeed, the only person who openly lays a claim to it, and asserts that he was led to this alteration after deeply pondering the subject—*diu multumque apud se agebat*: yet Morton, who published his *Pyretologia* in 1692, only three years after the death of Sydenham, asserts, somewhat loosely indeed, that, during twenty or five-and-twenty years (*Pa.* 114, 132), he had been in the habit of giving this antidote, as he calls it, in every season of the year, and to persons of all ages and constitutions; that he had cured every species of intermittent with it quickly and radically, and had found it more expedient to give it in the intervals than in the fits. While Lister, who was contemporary with both Sydenham and Morton, and who treats neither of them with respect, directly accuses Sydenham, a few years after his death, of having copied his mode of giving the bark from the miserable mountebank Talbor, who was its inventor,—*auctoresuo, misero illo, agyrta, Talbor*.—(*Octo Exercitat. iones Medicinales de Cort. Peruv. exhibendi tempore*.) Talbor, or Tabor, however, is scarcely open to the stigma of being a mountebank. He concealed, indeed, his preparation of the bark, but he had been regularly initiated into a knowledge of medicine by an apprenticeship to an apothecary at Cambridge; was the most successful, and, therefore, the most popular employer of the bark in his day; acquired a higher reputation in this line of practice than any other individual whatever; was appointed one of the physicians to Charles II., against all the influence of the college; was specially sent for to Paris to take the Dauphin under his care; succeeded in curing him, and afterward divulged his arcanum, for a stipulated sum, to Louis XIV., by which it was found to be an infusion of the powder of bark in port wine as a cordial.

The best form of administering it used to be considered its powder, "*potissima virtus in toto jacet*," says Professor Frank. But it is often found that the stomach will not bear it in this form; and hence, modern chymistry has been at work to provide various others, the best of which appear to be those which consist of its essential principle, now sufficiently ascertained to be a peculiar bitter alkali, separated from the woody fibre, and neutralized into a salt by means of sulphuric acid. The French chymists have put us into possession of two distinct salts of this kind—QUININE and CINCHONINE, of which the former is the more powerful, and both appear to have been employed with great success in the removal of intermittent fevers, in cases where the stomach has uniformly rejected both the gross powder and the decoction.—(*De Cur. Hom. Morb. Epit.*, tom. i., p. 64.) The dose of the first, for an adult, may vary from two to five grains and half a scruple, and still more has been given without ill effects: of the second, the dose may be from ten grains to half a drachm. The ordinary ill effects from an over-

dose are, nausea, headache, and vomiting.—(*Magendie Formulaire pour la Prép. et l'Em. de plus. Médic.*, p. 49, Paris, 1822.) [It is related by M. Andral that, in some cases of tertian ague, M. Lerménier gave between 16 and 17 grains of the sulphate the first day of the treatment. The fever was arrested, and no unpleasant symptom followed. In some other individuals, similarly affected, this medicine, in the dose of only a few grains, produced violent palpitations, oppression, globus hystericus, giddiness, and fugitive pains in the chest and abdomen. This he imputes to idiosyncrasy.—(*Clinique Médicale*, tom. i., p. 488.) But, as Dr. Elliotson observes, quantities that can disagree are not required: five grains of the sulphate, every six hours, is the largest dose that can be necessary, at least in this climate; for, from the reports of Professor Speranza, doses of 12, 24, and 30 grains are common in Italy; and, in one case, 108 grains were given as a dose, before the fever was arrested. The medium dose prescribed by Dr. Perrine, of Adams county, in America, is eight grains every hour.—(*Edinb. Med. Journ.*, No. xciv., p. 218.) Many cases of intermittent fever in England have been cured with three, two, or even one grain, every six hours.—(*Elliotson in Med. Chir. Trans.*, vol. xii., p. 56.) Every case of ague which the editor has met with in the prisons of the King's Bench and Fleet has yielded to doses of two grains. Dr. Elliotson has also tried the simple quinine, the tonic properties of which he considers as corresponding to those of the sulphate. It never disordered the stomach, though given in doses of ten grains every six hours. One fact, adverted to by the same physician, is important, namely, that the foregoing medicines cure cases of intermittent fever which resist bark, even when retained in the stomach and freely administered. In a later communication on this subject, Dr. Elliotson mentions having attended nearly 150 cases of ague, and treated all with the sulphate of quinine. Many were combined with so much inflammation in the abdomen, chest, or head, that venesection was necessary; some with dropsy, and others with chronic diseases of the lungs or liver; but, *every one was cured*. Having never found the sulphate of quinine augment inflammation, or interfere with antiphlogistic measures, he has always given it under all circumstances, and adopted with it any other measures required by the symptoms. Some cases, generally quartans, would not yield to less than five grains every four hours; but this quantity never failed, after being exhibited a week or ten days.* In London, he finds that

the disease may be generally arrested *immediately* by the exhibition of ten grains at once, just before or after the paroxysm. Dr. Home, he remarks, found the bark much more successful after, than before the paroxysm; and this, also, is his own experience with quinine. He is convinced that the best practice is, first to give ten grains, as soon as the paroxysm is over. Excepting in quartans, this almost always prevents the paroxysm next expected, and, if repeated daily at the same hour, often cures the disease. But, he says, it is sometimes necessary, in addition to these ten grains after the fit, to give small doses every six or eight hours, so as to make the whole quantity in twenty-four hours amount to a scruple or half a drachm.—(*Elliotson in Med. Chir. Transac.*, vol. xiii., p. 464.) From what has been said, it would appear that the quantity of quinine and cinchonine contained in any one kind of cinchona, is the test of the comparative virtue of the different species; that the absence of these alkalis in vegetables which have been proposed as substitutes for cinchona, shows their difference, and accounts for their inferior efficacy; while others, in which these alkalis are found, may supplant the cinchona. Thus, the experiments made by MM. Robiquet and Petrotz prove the existence of an alkali analogous to quinine in the bark of *carapa*, which has been known in America to cure agues, though they had defied the power of cinchona.—(*Quarterly Journal of For. Med.*, vol. iv., p. 68.)

From the investigations of M. de Martin (*Rev. Méd.*, Septembre, 1827), it appears, that when the sulphate of quinine is finely pulverized, mixed with cerate, and then applied to a blistered surface, it is soon absorbed, and thus a cure of intermittents may be performed; a fact worth remembering in examples where the stomach is very irritable.*]

It ought to be known, that one of the best preparations for a successful use of the bark, is calomel in small doses, particularly in intermittent fevers. "I have known," says Dr. Baillie, "a good many cases in which bark alone would not cure an ague. In all of these cases, as far as I now recollect, when a grain of calomel was given every night for eight or ten

and then the disorder immediately ceased.—(*Lectures, &c.*, Med. Gaz. for 1832, p. 4.) No general rule can be laid down respecting the quantity of sulphate of quinine which may be required.—Ed.

* Many persons when taking bark experience nausea, or even vomiting and purging; "and, in all such cases, a few drops of tincture of opium will frequently enable the stomach and intestines to bear it. If it be only the stomach that is disturbed, an effervescing draught will answer the purpose, and so will prussic acid. In the case of children, bark may be given in the form of clysters, and some persons have been cured, it is said, by its external application, by having it tied in fine muslin or linen, on different parts of the body. I recollect hearing Sir Henry Hallord say, that, when he was a child, he had ague, of which he was cured by wearing a jacket of bark. A double jacket was filled with powdered bark, and put next his skin."—Professor Elliotson's Lectures at the London University.—Ed.

* In February, 1829, Dr. Elliotson had a patient labouring under quartan ague, which did not yield to less than 45 grains in the 24 hours. He thought this a very considerable quantity; but, on his return from the continent in the ensuing October, he found a patient in the hospital, who was taking, by direction of Dr. Roots, a scruple every eight hours, with ten minims of liquor arsenicalis. The case, which was a quartan ague, did not yield to such doses until they were given every four hours.

nights, bark cured the ague in the course of a few days. This practice I learned from my friend Dr. David Pitcairn.*

But as, under whatever form, in whatever quantity, and at whatever time the bark is given, it is not found to be a specific, not only in every individual, but in every intermittent, we are again driven to a principle I have already ventured to lay down, that intermittents of all kinds are occasionally influenced in their character by idiosyncrasies, or the temperament of the atmosphere. And it is hence of considerable importance to know what other medicines have the strongest claim to attention, when, from accidental circumstances, the best fails of its common effect.

This, as we have already had occasion to observe, was the case in the singular intermittents that prevailed both in this metropolis and in the country in the year 1787, in which the bark seemed to have no energy whatever, notwithstanding that its genuineness was sufficiently tested and proved; in consequence of which the febrifuge powers of various other medicines were attentively studied and appreciated. In some instances other medicines were mixed with bark, and seemed to a certain extent to call forth its proper power; a mixture of bark and alum answered in some cases, but produced disappointment in others. "The crude sal ammoniac," says Dr. Petrie, who was physician to the hospital at Lincoln, "had not a more certain effect. Several women were cured in a hospital by what is called the Dutch remedy for an ague; which is compounded of the bark and cream of tartar, each two ounces, and sixty cloves powdered. A drachm and a half of this powder was taken every third hour. Yet this likewise frequently failed. We at last thought that we had fallen on a specific in the powder of bayleaves, plucked from the tree and dried in the shade. From one to two scruples of it were given in the beginning of the cold fit. This powder was very efficacious in preventing the fits in many cases, where the bark, in the largest quantity, had been unsuccessful. But almost all who used it had a relapse in the space of a fortnight, three weeks, or a month. One patient, just at the time the fit was expected, took sixty drops of thebaic tincture. On this he fell into a profound sleep, sweated profusely, and escaped the fever, not only then, but at two successive periods. Eight quartans in the hospital, and four in private practice, were entirely cured by one drachm of the theriaca andromachi, the same of the root of *calamus aromaticus* in powder, and fifteen grains of salt of tartar. This mixture was taken in warm ale or wine and water, an hour or two before the fit. Nevertheless I must confess, that I met with several cases where no medicine prevailed; and many patients, despairing of relief, left themselves to nature; some of whom went into a pulmonary consumption, jaundice, or dropsy. Many, whom I thought cured of quartans, lately

relapsed. I have now on the hospital books four patients, ill of quartan fevers, who have received no benefit; and I have no hope left, but in a long course of deobstruent bitters, and tinctura sacra, aided by the approaching summer."—(*Med. Trans.*, vol. iii., p. 165.)

Morton's medicine, of one scruple of chamomile flowers, ten grains of salt of wormwood, and the same quantity of calx of antimony, given every sixth hour, is said to have subdued, in the metropolis, an obstinate tertian in two instances. And Dr. Heberden found, that two drachms of the powder of myrrh, taken just before the time of the expected fit, relieved a patient from an ague, which for a long time had resisted the power of the bark, though taken in very large quantities.

The red-bark was now also tried for the first time: it was proved to be of unquestionably superior virtue to that in common use; but even a moderate dose of it so often oppressed the stomach and excited nausea and vomiting, perhaps produced by its containing a larger proportion of resin, that, writing at this very period, Sir George Baker tells us, "I have for some time avoided the use of it." It contains, however, by far the largest proportion of quinine, and is now usually selected for this purpose.

In the east a variety of other astringent and bitter barks are also employed both by native and European practitioners, and apparently with considerable advantage; as that called, in honour of Van Swieten, *Swietenia febrifuga*, so warmly recommended by Dr. Roxburgh: that of the bead-tea (*Melia Azedarach*), and the Tellicherry bark. All these have been now tried in Europe, but with a far less success than in India.

Arsenic was also tried, in combination with opium. It is admitted that it often effected a cure; but was frequently productive of violent vomitings, colic, and dysentery. It seems, however, to have been given at this period in a somewhat rude and unscientific form. "Arsenic," says the distinguished writer whom I have just cited, "is mentioned in books as a febrifuge, but it is one of those substances of which we are not as yet so far masters, as to be able, by any art, to render it transferable from the list of poisons to our *Materia Medica*; and it cannot be deemed to be a proper remedy for an intermittent fever, while an intermittent fever is less formidable than arsenic." But to this substance we shall have to return presently.

The chief BITTERS and ASTRINGENTS that have been called into requisition, independently of those already noticed, are, gentian, cascarrilla, willow-bark, nux vomica, and the leaves of the cherrybay, or *Prunus lauro-cerasus*; the chief ASTRINGENTS, tormentil, galls, and oak-bark; the bark of both species of the swietenia or mahogany-tree; avens or caryophyllata (the *Geum urbanum*, Linn.), the *Lycopus Europæus* of the same naturalist, called in Piedmont, where it is supposed to rival the bark, herb China, alum, and several of the metallic oxydes.

To all these a common remark may be applied, that, where they have been of real ser

* Lect. and Observations on Medicine, by the late Matthew Baillie, M. D., 1825. Unpublished.

vice, it has generally, though not in every instance, seemed to arise from their uniting the two qualities of a bitter and an astringent, and that they have rarely answered where there has been only one of these qualities to depend upon. Thus tormentil, one of the most powerful vegetable astringents we possess, and gentian, one of our most powerful vegetable bitters, succeed so rarely alone, that no dependance is to be placed upon them; but when given in combination, they almost rival the virtue of cinchona, and have occasionally succeeded where the latter has failed. "Joined," says Dr. Cullen, "with galls or tormentil, in equal parts, and given in sufficient quantity, gentian has not failed in any intermittents of this country in which I have tried it."—(*Mat. Med.*, part ii., ch. ii., p. 72.)

There is, however, a principle, independently of bitterness and astringency, that seems absolutely necessary to enter into conjunction with these, in order to give full efficacy to any medicine employed as a febrifuge in intermittents; and a principle that has hitherto eluded all research; [unless it be analogous to that of quinine, a principle similar to which has been detected in other barks besides the Peruvian.] If the cure depended upon the intensity of a bitter and an astringent quality alone, galls, oak-bark, and mahogany-bark ought to succeed better, not only than a union of tormentil and gentian, or chamomile and alum, which have also been found very serviceable, but than cinchona itself; which every one knows they do not; although, when Peruvian bark cannot be obtained, they become desirable substitutes.

The *nux vomica* and Ignatius's bean (*Strychnos nux vomica*, and *Ignatia amara*, Linn.) combine, with an intense bitter, a most active narcotic virtue; and how far the last may be peculiarly opposed to a recurrence of that spasm on the extreme vessels which constitutes the cold fit, it is difficult to determine. M. Bourieu (*Hist. de la Soc. R. de Méd.*, 1776, p. 340) from his own practice strongly recommends the latter, and Paullini (Cent. iii., obs. 45), and Aaskow (*Ant. Societ. Med. Hafn.*, tom. ii.) the former. If Dr. Fouquier's remark be well founded, which we shall have occasion to notice more at large when treating of paralysis, that these poisons have a power of augmenting energy in debilitated muscular fibres, while they leave those in health unaffected, we can account for some part of the success which has been so vauntingly ascribed to them in the case of intermittents. But, notwithstanding that they have been for this purpose before the public for upwards of a century, the infrequency of their use is a strong argument that they are not much entitled to commendation. "In a very small dose," says Dr. Cullen (*Mat. Med.*, part ii., ch. ii., p. 76), "the *fabæ Sancti Ignatii* has the effect of curing intermittent fevers." But whether he reports this from his own practice, or from that of others, we cannot exactly determine: nor does he tell us what is the small dose he refers to. I have tried the *nux vomica* to the extent

of eight grains in powder every six hours for an adult under palsy, without any mischievous effect except a slight stupor in the head. And much beyond this we cannot proceed with prudence. Hoffmann (*Philos. Corp. Hum. Morb.*, p. ii., cap. viii.) gives the case of a girl of ten years of age, who was killed by taking fifteen grains of it, divided into two doses, for an obstinate quartan.

The lauro-cerasus was at one time, as we are told by Dr. Brown Langrish, a common medicine in his neighbourhood for the cure of agues (*Experiments on Brutes*; see also *Phil. Trans.*, No. 418, 420), but he takes no notice of the dose or mode of administering it. Its properties are nearly the same as those of bitter almonds; and Dr. Bergius frequently prescribed an emulsion of bitter almonds with success in intermittents, in the quantity of a pint or two daily during the intermission; and it sometimes cured where the bark failed.—(*Mat. Med.*, p. 412.) This is an authority worth attending to; and as the same medicines are said to have a peculiar power of resolving visceral obstructions, they have an additional claim to a cautious series of experiments. It is known in the present day, that their poisonous property depends upon their containing a portion of native prussic acid [and consequently the latter would now generally be prescribed by those who desire to ascertain its power over ague].

The only metallic oxide really worthy of notice is that of arsenic; for although various oxides of iron, mercury, zinc, and copper, have been tried, and occasionally extolled, none of them have proved so decidedly beneficial as to render it worth while to try them over again.

Mercury, as we learn from Sir James Johnson, was tried extensively some years ago at the Bocca Tigris in the east, on the crews of two ships-of-war, the *Grampus* and *Caroline*, in consequence of the stock of bark being exhausted. The paroxysms, he tells us, were invariably put to as soon as the system was saturated; but he adds, that three fourths of the patients thus treated, relapsed as soon as the effects of the mercury had worn off; and this after three, and, in a few instances, four successive administrations, so as to excite pyralism.—(*Amer. Med. Repository*, July, 1822.)

Iron, though of little value in most of its forms, has been said of late to have succeeded completely in that of its prussiate. Dr. Zollickofer has given various instances of this in a foreign journal, and places its powers above those of arsenic or bark. It must be tried, however, upon a much larger scale before it is entitled to an established reputation. The ordinary adult dose is about four grains, two or three times a day, in a little sugar and water.

Arsenic, under various forms, has been employed from a very early period.—(*Act. Med. Berol.*, dec. i., tom. iii.) It is, strictly speaking, an oriental medicine, and has been in vogue immemorially in India, and indeed all over the east, but especially among the Tamul practitioners, as a most powerful alterant, as we shall have occasion to notice more at large when

treating of syphilis and elephantiasis. It was probably introduced into European practice by the medical students under the brilliant caliphate of Bagdad; and seems to have been first appropriated to the cure of intermittents by the Jewish physicians of Poland.—(*Gilbert, Adversar. Pract. Prim.; Slevogt, Pr. de Permissione Prohib. et Prohibitione Permiss.*, Jen., 1700.) In Sir George Baker's time, we have seen that it was in extensive use, but productive of such very different results, that, however successful it might prove occasionally, this distinguished pathologist thought it a worse evil than any ague whatever. At that period, however, it does not appear to have been tried in its most commodious forms, which are those of an arsenite or arseniate of potash. M. Macquer recommends the latter; Dr. Fowler, many years ago, introduced and gave abundant proof of the utility and general commodiousness of the former; and, under this modification, it has at length found its way into the Pharmacopœia of the London College, under the name of liquor arsenicalis. Sir Gilbert Blane tells us, that it was used with great success in our unfortunate expedition to Walcheren, where the stomach could not retain the bark: but was combined with opium, and, in most cases, with bitters and aromatics.—(*Select Dissertations*, &c., p. 105, Lond., 8vo., 1822.)

The cases of success from the use of this medicine are so numerous, and its employment is now become so general, as to render it unnecessary to advert to particular authorities in proof of its febrifuge power. With many constitutions there can be no question that it disagrees very considerably; and there are numerous instances of its failure: but it is a medicine of real and inappreciable value in many diseases, and in none more than in intermittent fevers. Dr. Fowler advises it to be taken in doses of from two to twelve drops, according to the age and strength of the patient, once, twice, or oftener, in the course of the day: and the directions are so broad, and at the same time so much within limit, that no actual harm can occur from following them literally. It will, however, often be found advantageous to combine a few drops of tincture of opium with each dose, to guard against the vomiting and griping which it is sometimes apt to excite; and the bowels should be kept open by warm aperients during its use. Under the French Directory a similar preparation of arsenic formed a part of the political constitution of the day; for an edict was formally published, commanding that the surgeons of the army of Italy should, within the course of two or three days, cure the vast number of soldiers suffering from agues caught in the marshes of Lombardy, by the use of this medicine, under pain of military punishment.*

It is a singular fact, and ought not to be

* It is best to begin with two or three drops of the liquor arsenicalis, two or three times a day, and to increase the dose by degrees. As Dr. Elliotson suggests, this medicine should not be given on an empty stomach.—E.

passed by without notice, that since the establishment of the large copper-works which are now carrying on in Cornwall, the intermitting fevers which used to be almost constantly present in the neighbouring marshes, are now rarely to be met with in any shape. It should hence seem, that the atmosphere is armed with a specific by becoming impregnated with metallic oxides or carbonates; and that Cornwall should be the spot recommended for change of air in many cases of chronic or other obstinate intermittents.

The result of this general survey is, that the cinchona (including its preparations, quinine and sulphate of quinine) offers by far the best remedy for intermittents of every kind; that arsenic is its best substitute; and that, where these fail, as fail they will occasionally, or if particular circumstances should prohibit their use, we must throw ourselves upon such other medicines as unite intrinsically, or by combination, a bitter and an astringent principle with a certain proportion of aroma or stimulant warmth.*

It is at the same time clear, that a bitter and astringent principle are not the only, nor even the most effectual qualities, for the cure of an intermittent; for the arsenical preparations contain neither of these in any prominent degree; while, as already observed, there are many medicines that possess them in far greater abundance than the bark, which have no claim

* Quinine is given so extensively by American practitioners, that little need be said to recommend it to more general use. When employed with prudence, it rarely produces any bad effects, not even in intermittents attended with local determination. It enjoys a supremacy over every article in the *matéria medica*, and seems entirely free from the objections urged to bark. Dr. Eberle, however, remarks (*Pract. of Med.*, vol. i.), "in cases of ague which from long continuance or from some previous malady, are attended with visceral indurations or enlargements, the quinine or bark must be given either after a gentle mercurial course, or in conjunction with mercurial remedies. The blue mass will in general answer best for this purpose, as it is mild, and less apt to pass off by the bowels than calomel." Arsenic must be considered as the most valuable of the minerals for the cure of intermittents. Dr. Mann observes (*Medical Sketches*), that it succeeded like a charm; and his remarks might be confirmed by quotations from many other medical writers of repute; but it sometimes leads to anasarcaous effusions, and even paralysis has been remarked by Currie and others.—(*Hosack and Francis' Med. and Phil. Register*, vol. ii., p. 36.) According to Dr. Firth, the sulphate of zinc has cured intermittents when the bark and arsenic have failed.—(*New-York Med. Rep.*, vol. x., p. 145.) And Eberle says of it, "I have very rarely failed to arrest the disease as promptly with it as with quinine."—(*Pract. of Med.*, vol. i., p. 81.) The list of vegetable substances employed by American practitioners for the cure of intermittent fever is very great.—See Bigelow's *Medical Botany*, Barton's *Collection towards a Materia Medica*, Chapman's *Therapeutics*, Bigelow's *Sequel*, &c.

Among the remedies in popular use, the strong decoction of coffee deserves notice; the coffee in powder is highly recommended by some German practitioners.—D.

to be put in competition with it as a febrifuge. In effect, of the three species of cinchona used officially in the present day, the lance-leaved, pale or quilled bark (*c. lancifolia*), heart-leaved or yellow bark (*c. cordifolia*), and oblong-leaved or red bark (*c. oblongifolia*), the yellow, which, as we learn from Mutis and Zea, is the genuine febrifuge of Spanish America, and whose superiority to the rest has been abundantly proved in this country as well as on the continent of Europe, is very considerably less bitter and astringent than the red, and not more so than the pale bark: it has less resin than the first, and less gum than the second. Dr. Cullen preferred the red, but Zea's communications upon the subject (*Annal. de Hist. Nat.*, tom. ii., Madrid, 1800) were not then published; and Cullen was not in possession of the experiments by which the statement of the latter has been confirmed. Sir George Baker, as already noticed, found the red bark produce so much oppression and nausea, that he was obliged to discontinue its use. It affords, however, the largest portion of quinine.

In administering the bark, little needs to be added to the rules laid down by Sydenham, and copied in a preceding page. Dr. Home has sufficiently shown, not only that the best time for commencing the medicine is soon after the paroxysm, but that it should be discontinued some time before a recurrence of the cold fit, since, if persevered in till its accession, this fit is almost uniformly rendered more violent.—(*Clinical Experiments*, 8vo., Edin., 1780.)

If in the proportion of half a drachm or two scruples to a dose, as recommended by Dr. Sydenham, or such other quantity as may sit without uneasiness on the stomach, it should not succeed, it should be tried in combination with some aromatic, or omitted altogether; and by no means be increased to the enormous quantities some practitioners have ventured upon, who seem to have conceived that they could force the system to yield to its powers, by the overbearing arms of weight and measure. It is singular that Borsieri should have so far lost sight of moderation, as to have prescribed occasionally from four to six drachms of the powder in a single draught. In the extremity of the yellow fever such doses have, indeed, been given, and perhaps with advantage; but opium and old port, in large abundance, have been given at the same time.

It will also be judicious to abstain from the use of bark in every instance in which any of the abdominal viscera appear to be labouring under parabysmic enlargements, whether antecedently to its employment or during its use; and, in these cases, to alternate small doses of calomel with whatever tonic may be found to agree best with the system. [Yet, as the editor has already stated, the experience of Dr. Eliotson proves, that the sulphate of quinine may be given beneficially, whether such enlargements be present or not: it has no power of preventing the cure of inflammation, nor does it interfere with antiphlogistic means.]

Among the endemic intermittents of the pres-

ent day particularly worthy of notice, are those in the neighbourhood of Rome, and especially about the Pontine marshes, which have often been drained to carry off the decomposing animal and vegetable materials that spread their *aria cattiva*, as it is called, over the whole of the Campagna. The disease hence produced is named, from its source, *malaria*. It is also found in like situations, and has the same name, about Syracuse, and other parts of Sicily. M. Rigaud de l'Isle has asserted, that the miasmatic particles which infect the air in these places, are heavier than the air in its loftier and lighter strata, and may be separated from it. He has found an elevation of 300 yards, at the Pontine marshes themselves, a complete security from infection; and he proposes for those who reside lower to sift the air which they breathe, by wearing a fine silk gauze over the mouth and nostrils.—(*Mém. de l'Institut. Royale de France*, March 24, 1817.) M. Brocchi has successfully employed the same remedy, and hence recommends sleeping under a fine moschetto-net in all places where intermittents are endemic.—(*Dello Stato fisico del Suolo di Roma*, &c., Di G. Brocchi.)

GENUS III.

EPANETUS.

REMITTENT FEVER.

SYMPTOMS STRIKINGLY EXACERBATING AND REMITTING, BUT WITHOUT INTERMISSION; ONE PAROXYSM EVERY TWENTY-FOUR HOURS.

This genus offers the three following species, which will be found sufficiently distinguished from each other by their specific characters:

1. *Epanetus Mitis*. Mild Remittent.
2. ——— *Malignus*. Malignant Remittent.
3. ——— *Hectica*. Hectic Fever.

In the last, the remission is perhaps more perfect than in either of the others: and it serves to show how little foundation there is for referring all remittent as well as all intermittent fevers to the individual cause of marsh miasm; for it would be difficult, though, perhaps, not impossible, to find a single example of a genuine hectic originating from this source.* Marsh

* The possibility of hectic fever arising from marsh miasm is a suspicion that may be dispensed with, as it is entirely destitute of foundation. There may be hectic fever in consequence of visceral disease, that has originated during an ague, and has not yet been cured; but as for malaria being ever itself the cause of hectic, the opinion is groundless. Perhaps, with the exception of remissions, hectic fever has no analogy whatsoever to what is commonly implied by remittent fever. As a judicious writer has observed, "remittent fever may be considered as holding a middle rank, as to external character, between intermittent and continued fevers; but, with respect to its nature, the localities in which it chiefly prevails, and the cause whence it principally, if not solely arises, it bears a closer affinity to the former than the latter. It may be regarded more properly as forming the mean degree

miasm, however, is the most common cause of the second, perhaps of the first species; though we shall presently find it probable that even here, and particularly in the second species, human contagion has also occasionally proved a cause, as it assuredly has in those cases of hectic fever, produced by perpetually attending upon, or sleeping with a consumptive patient.

SPECIES I.
EPANETUS MITIS.
MILD REMITTENT.

PULSE REGULAR, THOUGH FREQUENT; DEBILITY SLIGHT; REMISSION DISTINGUISHED BY SWEATING, OR A CLOUD IN THE URINE.

This species occurs most frequently among persons of relaxed fibres, debilitated habits, and sedentary occupations; and is usually preceded by an irregular action of the alvine canal, flatulence, abdominal tension, dyspepsy, or some other affection of the viscera of the lower belly; and is hence called by Professor Frank, as well in the ensuing as in the present species, *gastric fever* (*De Cur. Morb. Hom. Epit.*, tom. i., § 50, 99, 8vo., Mannh., 1792), intermittently remittent, or continued, according to the type it assumes. It occurs at all seasons of the year, but more frequently in the autumn; the ordinary temperament of the season uniting with the patient's infirm state of health, and thus adding an exciting to a predisponent cause. Fatigue, cold, or long exposure to the rays of the sun, are also, at this time, powerful concomitants, and quicken the appearance of the disease.*

in the scale of periodic or marsh fevers, of which intermittent and yellow fever constitute the extreme points. A more intense operation of the febrile cause than is required for the production of intermittent fever engenders remittent, and the more violent the latter, the more remote is its character from that of intermittent; or, in other words, the less perceptible the remissions. That a more powerful action of the morbid cause is demanded for the production of remittent fever, is indicated by the circumstance, that when periodic fevers are prevailing in certain countries, the permanent residents are often observed to have the disease in the form of ague only, and the mortality among them is small; but strangers unaccustomed to the climate and its diseases, suffer from remittents, with a proportionably greater loss of life. In more sickly seasons, remittents will be the prevailing form among both classes of persons; but strangers are more violently affected, and the mortality among them is greater. Its affinity to intermittents is shown, too, by the tendency which it has to pass into that form, and inversely, by the proclivity of ague to assume the remitting type."—(Dr. Joseph Brown, in *Cyclop. of Pract. Med.*, art. FEVER.) From such facts and reflections an argument might easily be deduced, which would shake very much the hypothesis of malaria, or marsh miasm, and the contagious principle of human effluvia, being capable of exciting similar fevers.—Ed.

* Here no reference is made to the commonly received doctrine, that ordinary remittent fevers spring from the influence of marsh miasm, or malaria. Thus, as Dr. J. Brown has stated, remittent is

The patient complains of drowsiness, and feels languid; is occasionally chilly, and afterward flushed, but without perspiration; for the skin is hot and dry, the thirst considerable, commonly with nausea and a total loss of appetite. In the course of the day, but usually towards the evening, the pulse quickens, the heat increases, and at length terminates in a sweat, which, however, is sometimes only partial, rarely free and copious, and never critical; for, on its ceasing, the skin is still dry and heated, and the pulse accelerated. Sometimes the exacerbation occurs about noon, and sometimes in the middle of the night.

If the disease be left to itself, the symptoms augment in severity daily; the head occasionally, but more generally the liver, or some other abdominal viscus, gives proof of being loaded and oppressed, and the restlessness is intolerable; or a sudden cholera supervenes, and carries off the complaint by a salutary crisis.

This species seems to be primarily dependant upon torpidity, or obstruction in some one or more of the chylipoetic organs, and generally yields to a course of active purgatives, among which calomel ought to take the lead. These should be repeated two or three times a week, and the intervals be filled up with mild diaphoretics. The pulse will generally be found from ninety to a hundred strokes in a minute; but, as soon as it sinks below this, and the heat and dryness of the skin have yielded to a general softness, columbo alone, or combined with sulphuric acid, will easily complete the cure; though the disease not unfrequently runs on for ten days or a fortnight.*

THE REMITTENT FEVER OF INFANCY, which is generally ascribed to worms, does not essentially differ from the present, regard being had to the greater irritability in early life. Worms, there can be no doubt, are sometimes the cause of this infantile fever, but perhaps rarely; and there is no instance on record of their having been traced in the bodies of those who have fallen victims to it. Dr. Hunter expressly declares, that he has often searched in vain. The ordinary cause is crude accumulations in the first passages, whence the digestion proceeds imperfectly; there is great general irritation, with considerable languor: the belly becomes tumid and often full of pain; the food is nau-

the endemial fever of warm climates; but it is also met with in temperate regions, and in our own country, especially in seasons of unusual heat, and in those parts of it where, under ordinary temperatures, agues are prevalent.—*Cyclop. of Pract. Med.*, art. FEVER.—Ed.

* Prescribe six grains of calomel, which are to be followed by an active cathartic, and a mixture composed of four grains of tartarized antimony and eight ounces of camphire mixture, three table-spoonsful of which are to be given every fifth hour. As soon as the tongue becomes clean, the skin natural, and some impression is made on the disease, the fourth part of the following mild aperient mixture, given three times a day, will complete the cure:—R. Magn. sulph. ʒvj, infus. gentianæ comp. ʒvj, acid. sulph. dil. ʒj; ft. mist.—Ed.

seated: the head is hot, heavy, and often comatose; as though there were water in the ventricles, which is sometimes suspected, though without foundation: the skin is pale or livid, with occasional flushes in the cheeks. It is a singular fact, that, if the exacerbation or increase of fever take place in the night, there is wakefulness and perpetual jactitation; if in the daytime, drowsiness and stupor.*

Dr. Butter recommends as an aperient, small doses of neutral salts, and, when the bowels have been opened, nitrate of potash; or, if there be considerable irritation, the extract of hcmlock. Generally speaking, however, there is such a sluggishness in the peristaltic action of the bowels, as well as in the intestinal secretions, that neutral salts will not answer the purpose; and, in consequence, rather add to the irritation than carry it off. And hence, much stronger purgatives should be employed from the first; as calomel, resin of jalap, or gamboge dissolved in milk; and it may be safely prognosticated, that, till this plan is had recourse to, the disease will in most instances maintain its ground, if it do not make a fearful advance.† But with a course of brisk cathartics, in conjunction with perfect quiet, good ventilation, and light nutritive food, it will usually give way in a week or fortnight.‡

* “By *infantile remittent fever* is now commonly understood a species of fever to which children from one year old, up to ten or twelve, are very subject, characterized by one or more daily exacerbations and remissions, by pain of the belly, and sometimes also of the head, and by an unnatural state of the alvine discharges.”—Dr. Joy, *Cyclop. of Pract. Med.*, art. FEVER.

† In this insidious and often fatal form of disease, the first indication is to remove all causes of irritation, and to unlock the intestinal and cutaneous secretions. For this purpose, to the means mentioned above may be added the employment of small doses of ipecacuanha, alone or combined with rhubarb; say one or two grains of the former, with some three or four of the latter, administered once or twice a day for a few days, according to the exigencies of the case; the neutral salts will also be found useful. In a form of this complaint, the late Dr. Ed. Miller, of New-York (*Medical Writings*, N. York, 1824), recommended small doses of calomel combined with opium; this practice may often be useful where cerebral determination and vascular fulness are absent.—D.

‡ In France, *infantile remittent fever* is treated as a species of gastro-enteritis. That the secretions from the mucous surface of the alimentary canal are in a depraved state, is a fact generally admitted; but whether in consequence of inflammation, is a disputed point. Dr. Joy expresses his belief, that medicines which slightly increase and modify those secretions, will usually be attended with more success than the sole employment of directly antiphlogistic measures.—(*Cyclop. of Pract. Med.*, art. FEVER.) In very obstinate cases, Dr. Hamilton combined calomel with opium and antimony. On the other hand, Dr. Clarke, after the exhibition of an emetic, and one or two active purgatives, prescribes bark. The editor has seen, in the public services with which he has been connected, many cases of this fever; and the practice which he has the most favourable

SPECIES II.

EPANETUS MALIGNUS.

MALIGNANT REMITTENT.

PULSE SMALL, HURRIED, IRREGULAR; DEBILITY EXTREME; OFTEN WITH SIGNS OF PUTRESCENCE.

EXTREME debility may be inferred from the symptoms of great weakness and irregularity of the voluntary motions; weakness of sensation; weakness and wandering of the mind; weakness of the pulse and of respiration; coldness and shrinking of the extremities, and a tendency to faint in an erect posture; nausea, vomiting, and a total disinclination to nourishment; difficult deglutition, depending upon atony of the muscles of the fauces; involuntary excretions, depending upon an atony or paresis of the sphincters.

A putrescent state of the fluids may be determined from the following symptoms:—pulse quick and tremulous; heat of the surface sharp and pungent, giving to the finger a peculiar tingling for some minutes afterward; the skin parched, or soaked with sordid, fetid sweat; the smell offensive to a considerable distance; the breath hot and fetid; the mouth aphthous; the tongue clammy, fetid, livid, greenish-black; the lips swollen, puckered, cracked, and purple; the urine brown or blackish, and offensive; black discharge, often in profuse quantity, from the stomach; the stools blackish, colliquative, very offensive, parted with profusely and insensibly; the mind wandering; twitching of the tendons; swelling and tension of the belly; petechial spots, vibices, and hemorrhages from different parts, without proofs of increased impetus.*

This species may be traced under four varieties, each sufficiently marked by its own symptoms:—

α Autumnalis.	Autumnal Remittent.
β Flavus.	Yellow Fever.
γ Ardens.	Burning Remittent.
δ Asthenicus.	Asthenic Remittent.

THE AUTUMNAL REMITTENT is that which so frequently shows itself in our own country, in the season from which it derives its name, with a strong tendency to assume the tertian or double tertian type: or, in other words, with striking exacerbations every other day, or, where the double tertian is imitated, every day, the exacerbations commencing at noon, and the duration being usually under twelve hours; the intervals consisting of remissions, which, however, are not always very clearly determined. Where the double tertian type prevails, and the patient has to labour with two distinct sets of tertian exacerbations, it is obvious that one of

opinion, consists in giving at first calomel and James's powder, and a cathartic mixture, followed by small doses of rhubarb and the hydrargyrum cum cretâ.—Ed.

* No writer has given a better account of the fluids in their putrescent state than Dr. Dyckman.—See his *Dissertation on the Pathology of the Human Fluids*, New-York, 1814.—D.

these must take place every day, as it must occur in the remission of the other. Consequently, this variety is often mistaken for a quotidian remittent. But a little attention will point out the real nature of the disease. For, while the one set will usually be found distinguished from the other by evincing some difference in its duration or its violence, both will be distinguished from the quotidian by the time of their attack, which is at noon, while the quotidian attacks in the morning; and by the comparative brevity of the paroxysm, which is always under twelve hours, while that of the quotidian runs on towards eighteen.

The perfect apyrexia which takes place in the interval of intermittent fevers, gives the constitution a full power of recovering its energy and recruiting its sensorial supply; and hence there is great difficulty in accounting for a return of the paroxysm: I mean in cases in which the patient is removed from the miasmatic atmosphere; for otherwise, the cause that commenced the disease will be present to continue it. Habit may possibly effect this after a recurrence of several paroxysms; but this will scarcely apply to the second, in which no habit can, with great strictness of language, be said to have taken place. In remittent fevers, however, something of this difficulty is removed; for the constitution, even during the remissive interval, is still struggling with disease, and has not an opportunity of recovering its sensorial power.

There is no perplexity in accounting for a greater tendency to febrile affections in the autumn than in any other quarter of the year: and this, whether we allow the operation of a specific febrile miasm from marshes or not. When the animal frame has for some months been exposed to the stimulus of a high atmospheric temperature, and not unfrequently, perhaps, to that of the direct rays of the sun, all its organs become relaxed and debilitated. The nervous energy is diminished, or, in the language of Dr. Cullen, is in a state of collapse; a general languor and inertness prevail over every part of the system, and most of the functions are performed feebly and laboriously. And hence, if debility be the first stage of the proximate cause of fever, this part of the cause is continually present. But this is not all: the calorific rays of the sun act more powerfully upon some organs than upon others; and most of all upon the liver. The liver is hence in a state of perpetual irritation; and an unusual proportion of bile is secreted, a part of which is very generally absorbed and carried into the circulation; and, in tropical climates, so large a part as to form one of the causes of that tawny hue, by which the skin is there characterized: and as the greater proportion of the surplus often passes off by the bowels, we see an obvious foundation laid for that variety of diarrhoea which we have already described under the epithet of *bilious*. The liver, moreover, becomes weakened and torpid in proportion to its degree of excitement, and hence more disposed to congestion; and where congestion or

any other obstruction takes place in a large organ, there is instantly a disturbance in the balance of the circulating fluid; and a disturbance which, in so irritable a state of the general system as we are now contemplating, can rarely exist without fever, or a tendency to fever.

There is no question that this general disturbance of the balance of the circulating fluid and increased excitement of the digestive organs may terminate in actual inflammation in some part of these organs, and especially in their mucous membrane;* and hence those pathologists who regard fevers of all kinds as consisting in inflammation, contemplate the remittent before us as an enteric, or gastric phlegmasia: but this, as we have already had occasion to observe, is rather to denominate it from its result than from its essential nature, and to make the cause and effect change places: a remark which will apply to yellow fever, as well as to the present variety.

All this mischief is apt to occur in autumns of temperate climates, that are peculiarly dry, and uniform in the range of the thermometer. But it often happens that even in the most temperate and healthy climates, like our own, the autumnal months are checkered with sudden vicissitudes of heat and cold: and the pools and rivers are suddenly inundated with equinoctial rains, overflow their banks, and cover a wide surface of land with stagnant water. And the animal frame has hence to contend against the dangers of invisible damps, and abrupt changes of temperature, as well as against solar excitement: all which become occasional causes of fever, operating upon a state of body already predisposed to its influence.

And hence, even without the existence of febrile marsh miasm, we see sufficient causes for a more frequent appearance of fever in the autumn than in any other season of the year: whence, indeed, one reason for its appearing in warm seasons in fleets that are cruising at a considerable distance from ports, as has been justly observed by Sir William Burnet.† But in many districts, perhaps even in some sporadic cases, we have reason to believe that marsh miasm does co-operate, and itself form the remote cause; and more especially where such cases are frequent, the residence a lowland, and the season hot and rainy. Dr. James John-

* The frequency of increased vascularity and ulceration of the mucous coat of the intestines in fever, has been amply proved by dissection.—See particularly Broussais Phlegm. Chroniques; Andral's Clinique Médicale, tom. i.; and Bright's Reports of Med. Cases, p. 178 et seq., &c., Lond., 1827.—Ed.

† On the Bilious Remittent of the Mediterranean. The occurrence of remittent and intermittent fevers in ships, far distant from marshy countries, may appear at first to furnish an argument against the doctrine of malaria, or marsh miasm, being always concerned in the production of such disorders; but those writers who maintain the truth of the latter view would remind their opponents of the malaria frequently issuing from the bilgewater, in which the decomposition of vegetable substances is going on.—Ed.

son makes a like distinction between the causes of the ordinary endemic fevers of the east. "The fever in question," says he (bilious remittent), "frequently arises from atmospheric heat, or rather atmospheric vicissitudes, deranging the functions, or even structure, of important organs; and is, as Sir James M'Grigor supposes, sympathetic of local affection. Where marsh miasm is added, which is generally the case, then we have the endemic of the place, modified by the peculiar nature of the effluvia, and from which we are not secured but by local habitation to the cause."—(*Influence of Tropical Climates*, &c., 3d edit., p. 105.)

In consequence, the symptoms have often a close resemblance in both cases, so much so indeed, that when both diseases co-exist, it is sometimes found difficult to distinguish them. "The occurrences," says Dr. O'Halloran, "which preceded the appearance of the epidemic of Barcelona, in 1821, correspond with the old and recent observations on a similar subject in other countries; it almost invariably happening that the YELLOW FEVER of Spain is preceded by unusual diseases of various form and force; more particularly by BILIOUS REMITTENTS, which are not unfrequently so aggravated and MALIGNANT, that physicians themselves do not venture to define the lines of demarcation between them and the avowed epidemic."—(*Remarks on the Yellow Fever of the South and East Coasts of Spain*, &c., 8vo., 1823.)

There is still, however, a difficulty in determining why the type of any fever, hereby produced, should be remittent rather than intermittent or continued; and why its declinations should imitate one form of intermittents rather than another. Pathology has its mysteries as well as every other branch of science; and let the man who would accuse us of ignorance, because we are incapable of explaining these secrets of nature, first tell us, to adopt the language of Sydenham, "why a horse reaches his full growth at seven years old, and a man at twenty-one? or, why some plants flower in May, and others in June? If," continues he, "the most learned men are not ashamed to make an open avowal of their ignorance upon these points, I cannot acknowledge myself blameable if I modestly forbear reasoning upon a subject quite as difficult, and perhaps altogether inexplicable. At the same time I am persuaded, that the progress of nature is as certain and regular in these cases as in any others, and that the quartan and tertian intermittents are as subject to the natural laws, and as much governed by them, as any other occurrences whatever."

The autumnal remittent commences with lassitude, a general soreness over the body, yawning, inquietude, and most of the other concomitants of a febrile incursion. As some of the larger organs have been more affected by the influence of the season than the rest, we find them giving way in proportion. Hence the head is sometimes severely tried with pain or heaviness; the bowels are overloaded with bile, or the stomach is exquisitely irritable, and

rejects whatever is introduced into it. Generally speaking, the stomach, from this symptom, suffers more than any other organ; and, along with the sickness, we have often a very troublesome and debilitating looseness, which resists every attempt to check its course. Sometimes, however, the bowels are costive from torpor, and the stomach is but little affected.

The violence of the symptoms is commonly in proportion to the violence of the incursion; but not the duration of the disease: for I have often seen a fever that commenced mildly and insidiously hold on for upwards of three weeks, while another that commenced with great severity, and threatened the utmost danger, has softened its aspect in a week, and entirely quitted the patient in a fortnight. The exacerbation ordinarily takes place at noon, or early in the afternoon, and consists in an increase of heat and pulsation, for there is rarely any preceding chill, and as rarely any salutary moisture when the heat diminishes. The early part of the night is hence peculiarly restless, and no part of it tranquil: the patient dozes perhaps for a few minutes, but without being sensible of sleep, and talks incoherently while dozing; the images before him being partly furnished from dreaming and partly from delirium. And even during these snatches of unquiet slumber, he is perpetually turning from side to side in quest of ease, which no position affords him. Every symptom is obstinate; laudanum rarely produces sleep, and no sudorific, perspiration; the coolest and most refreshing drink is rejected from the stomach; and if looseness tease the bowels, it is retained, as already observed, with great difficulty. It is hence of little importance what nourishment is offered, and every preparation seems almost equally to fail in supporting the strength of the system. In effect, the debility increases with every fresh exacerbation; and if no favourable change take place before the fourteenth or fifteenth day, there will always be reason for alarm. The progress of this disease is admirably described by Professor Frank (*De Cur. Morb. Hom. Epit.*, tom i., sect. 100, 8vo., Mannh., 1792), under the name of febris continua gastrica, the remittent form being with him, as with Dr. Cullen, a section of the continued fever.

In the case of a young lady in her seventeenth year, whom I lately attended, the attack was slight, and no serious evil was at first apprehended. The pulse was about ninety in a minute, and rather small; the bowels were relaxed, the motions bilious, and the stomach suffered from nausea. A gentle emetic seemed to afford some relief to the stomach, and a dose of rhubarb and calomel to the bowels; but the fever continued, with a daily and increasing exacerbation, for the most part at mid-day or soon after. The stomach again became irritable and sick, and the sickness was again connected with a diarrhoea, but the stools were colourless and watery, and nothing was rejected from the stomach but the diluent food that was swallowed. The skin was now very hot and dry, the pulse from a hundred to a hundred and twenty strokes in a minute, the nights were passed in perpetual

jactitation, or in short and talkative dozings. Opium, rhubarb, neutral salts, diaphoretics, and mild astringents, in almost every form and combination, were tried with very doubtful advantage, and the first with evident mischief. Anodyne injections were of as little avail; but sponging the limbs with cold water, or brandy and water, which was employed as well during the remissive as the aggravated symptoms, diminished the pungent heat, and for a time afforded some refreshment. Still the fever continued its career; the stomach retained nourishment with difficulty; the bowels were daily teased with six or seven watery evacuations; the pulse was quicker and weaker, and the nights without rest. The heart at length became oppressed with a sense of fullness rather than of throbbing; the lips were considerably swollen, ragged, and black; a hemorrhage occasionally issued from the nostrils and the fauces; and the general debility was greatly augmented. Such was the appearance towards the eleventh day. The tongue was not much furred; the pulse, though small, and rarely under a hundred and twelve, was steady; but the heat was intense, and the thirst unquenchable. The mineral acids in dilution, sometimes singly, and sometimes in the combined form of aqua regia, with acidulated beverages, were now chiefly trusted to, in connexion with farinaceous foods, jellies, and beef-tea; and cold water was permitted in any quantity. This plan was continued till about the eighteenth day; when every thing allowed being rejected, and every evacuation accompanied with faintness, it appeared to me that the plan should be changed; that the chief cause of irritation was at this time debility; and that a more stimulant treatment should immediately be commenced. My colleagues, for whom I have a high respect, acceded with reluctance, as conceiving that we should only exasperate the febrile symptoms; and that, if the stomach could not retain tasteless things, it would instantly reject wine, or convert it into an acid. The attempt, however, was made; sound old Madeira was administered by teaspoonfuls, and shortly afterward a small portion of chicken-jelly. Both remained on the stomach; but the diarrhoea continued; and for this, as modern preparations had proved of little use, I recommended a scruple of the confectio Damocratis in half an ounce of cinnamon-water after every loose motion. The diarrhoea ceased as by a charm; the ensuing exacerbation was less marked; the night was passed more tranquilly, and columbo, in small doses of the powder, was commenced the next morning, and persevered in. The change of treatment, being thus found to succeed, was adhered to, and the patient slowly, but effectually recovered.

It is not often that the autumnal remittent is thus obstinate. But, whether there be sickness or not, an emetic should be administered, as one of the best means of determining towards the skin. And, singular as the advice may appear, it is rather to be recommended where there is little or no sickness than where the sickness is incessant; for, in this last case, the stomach is often so extremely irritable that emetics only

exasperate it, and add to the distress. It will also be useful to evacuate the bowels on all occasions, though the emetic alone will frequently be sufficient for this purpose, and hence Stoll allows of nothing beyond: for purging, says he, augments the fever, while an emetic strangles it as at a blow.—(*Rat. Med.*, part i., p. 227.)

The use of the lancet must depend upon the circumstances of the particular case. Where the onset is violent, and particularly where the patient is plethoric or of a vigorous habit, it should be employed instantly and freely; for, without it, from the urgency of the symptoms, there can be little doubt that some large organ or other will soon become locally affected with effusion or congestion, which is always to be avoided as one of the worst symptoms that can occur. And, if we have reason to believe that such local affection exists at the time of the attack, and, more especially, that it is the cause of it, copious depletion will be still more necessary; for, in this case, we have not only to contend with the fever, but to guard against phlogosis or inflammation in the infarcted organ.

But, except in such cases, there is no call for the lancet, and we may concede to Stoll that its use is injurious. [According to the observations of Dr. Bright, a tongue with red edges, more particularly when dry, almost universally indicates in fever great irritation of the mucous membrane of the intestines; and, when combined with loose, yellow, gritty dejections, generally denotes ulceration, or a state approaching to it. In this state, leeches and blisters may be applied to the abdomen; and the medicine in which Dr. Bright seems to put most faith consists of small doses of ipecacuanha, the hydrargyrum cum cretâ, and pulv. cretæ comp., generally in the proportion of a grain of the first, three of the second, and ten of the last article. The oleum ricini, with a few drops of tinct. opii, he prefers as the safest aperient. Two grains of hydrarg. c. cretâ, and ten of confect. opii, made into pills, and to be taken thrice a day, are also sometimes prescribed, with mucilaginous saline medicines, and ten or fifteen drops of vinum ipecac. to each dose.—(*Bright's Reports of Medical Cases*, p. 178, &c., 4to., Lond., 1827.)] Copious diluents, and small doses of antimonial powder in effervescing neutral draughts, will ordinarily take off the burning heat of the skin by exciting a breathing moisture; and, if this can be maintained through the day, the ensuing exacerbation will probably be mitigated in its violence. If not, eight or ten drops of the tincture of digitalis should be added to the antimonial draught, and all tendency to sickness be restrained by a few drops of laudanum; keeping the bowels in the mean time open with some gentle laxative, as rhubarb and the sulphate or supersulphate of potash in combination. Blisters are never of service, except when typically called for, or as stimulants in the last stage of debility. If the diaphoretic plan fail of effect, and the heat be pungent and augmentive, acids, vegetable, mineral, or both, will ordinarily constitute the best sedatives and refrigerants; and, where the debility is extreme,

the stimulant plan should be had recourse to, which is laid down in the preceding case.*

One of the severest and most fatal forms under which the malignant remittent shows itself is that of the **YELLOW FEVER**, constituting the **SECOND VARIETY** of the present species; so denominated from the lemon or orange hue which is thrown over the entire surface of the body, almost from the first attack of the disease, and which gives it a distinctive feature. The heat is here also intense, the thirst extreme, and the vomiting strikingly obstinate, but not, as in the preceding species, consisting of a colourless material, or the food that has been swallowed, but of a yellowish matter at the beginning and through the height of the fever, and of a chocolate-coloured coluvius towards its close.

The common remote cause of this fever is unquestionably marsh miasm; and hence it holds a stationary abode in the swampy soils and morasses of the intertropical regions, exposed to a high solar heat, and perpetually exhaling a decomposition of animal and vegetable materials: and is found occasionally in all climates that make an approach to the same character; where, in the correct picture of the poet,—

"The rivers die into offensive pools,
And, charged with putrid verdure, breathe a gross
And mortal nuisance into all the air."

It is nevertheless a striking fact, that, although such "mortal nuisances" have been exhaled into the atmosphere in all ages within the range of the tropics, the fever we are now entering upon is only of modern date in its malignant form. Whether this be owing to any degree of general change that has taken place in the human constitution, or to a larger accumulation of that mixed animal and vegetable compost which forms the hotbed of the present destructive miasm, or to any other cause, it is difficult to determine. It certainly seems, as Sir Gilbert Blane has observed, to have some bearing upon the slave-trade, with which it is precisely coetaneous. Smallpox, syphilis, and rickets, were equally unknown to the ancients; yet the causes of their origin, as, indeed, those of all other epidemic or constitutional diseases, are involved in inscrutable darkness; and, in the language of the poet,

—"Noctescunt tenebris caliginis atræ."

The yellow fever first showed itself, so far as we have any record of its origin, at Barbadoes, in 1647, whence it spread to various other West

* The treatment of the autumnal remittent, as stated above, is perhaps judicious enough for most cases, but it is not so efficient as that generally pursued by American practitioners. Bloodletting, leeches, emetics, cathartics, and calomel, are among their prominent remedies; the febrifuge compound of calomel and James's powder, is much used. Blisters are often applied during the continuance of the active character of the disorder, and after depletion. When the complaint, however, assumes a more malignant and typhoid character, these active remedies must be used with great circumspection.—D.

Indian Islands, and at length made its appearance at Boston, in North America, in 1693, to which place it was carried from Martinique by the fleet under Admiral Wheeler. In Europe, its earliest footsteps were traced at Lisbon in 1723 (*Sir Gilbert Blane, Select Dissertations, &c.*, p. 284, Lond., 8vo., 1822): after this period, it seems to have declined as well in its violence as in its visits, to the same regions, particularly in respect to North America and Europe. But, in 1793, a new era of its prevalence commenced; the disease showing itself then and down to the present day with a frequency and fatality it had never evinced before, especially in the West Indies and North America. This aggravated form, however, did not manifest itself in Europe till the year 1800, when, after an interval of six-and-thirty years, it appeared at Cadiz in all its horrors. Since this period, it has visited Cadiz several times, and has hence spread to neighbouring seaport towns in the south of Spain, at short intervals. Among other places in this line of coast, it has repeatedly visited Gibraltar, first in 1804, when more than one third of the garrison and population were carried off; and occasionally since, but with little comparative loss, on account of those precautionary means which had been entirely neglected on the first visitation.

To what extent the miasm of yellow fever, as it arises from its swampy and putrescent base, may spread, before it becomes dissolved and decomposed in the surrounding atmosphere, it is not easy to determine. "It is probable, however, that, where a tradewind or monsoon sets over a large tract fraught with febrile miasmata, these invisible agents may be carried to a much greater extent than where calms or gentle sea and landbreezes prevail. This is exemplified in the fever of Corimbatores, and ought ever to be borne in mind by navigators in anchoring ships in the vicinity of swamps, or by generals in pitching tents or stationing troops."—(*Influence of Tropical Climates, &c.*, by J. Johnson, M. D., 3d ed., p. 148.)

It is also satisfactorily proved, that the modification of miasm producing yellow fever does not spread so far, or rise so high, and, consequently, is not so volatile, as that producing the ordinary bilious remittent of hot climates; a feature by which it makes a nearer approach to the miasm of human effluvium, and shows that affinity to it, even from the first, which we have endeavoured to establish in the introductory remarks to the present order. Dr. Ferguson has given us a striking illustration of the truth of this remark, as also of the relative barometrical elevations of the respective regions of yellow fever, ordinary bilious remittent, and a pure and healthy atmosphere, in the following passage, in which he is taking a medical periscope of the Island of Antigua. "The autumn of 1816 became very sickly, and **YELLOW FEVER** broke out in all its low marshy quarters, while the **MILDER REMITTENT** pervaded the island generally. It was the office of the white troops to take the guards and duties of the dock-yards among the marshes below; and so pestiferous

was their atmosphere, that it often occurred to a *well-seasoned soldier*, mounting the night-guard in perfect health, to be seized with furious delirium while standing sentry, and, when carried to his barracks on Monk's Hill, to expire, in all the horrors of the black vomit, within less than thirty hours from the first attack: but, during all this, not a single case of yellow fever, nor fever of any kind, occurred to the inhabitants of Monk's Hill (a rock rising perpendicularly above the marshes to the height of six hundred feet). The result on the ridge (a hill about a hundred feet lower) was not quite the same, but it was equally curious and instructive. The artillery soldiers, seventeen in number, never took any of the night-guards, but they occupied a barrack about three hundred feet above the marshes, not perpendicularly above them, like Monk's Hill, but a little retired. Not a case of yellow fever or black vomit occurred among them; but every man, without a single exception, suffered an attack of the ordinary remittent, of which one of them died: and, at the barrack on the top of the ridge, at the height of five hundred feet, and still further retired from the marshes, there scarcely occurred any fever worthy of notice.*

There is another feature in which the miasm of the yellow fever shows its affinity to the febrile contagion of the human frame, and evinces its less diffusibility; and that is, in readily attaching itself to whatever bodies it meets with, though to some more than others. Even the leaves and branches of trees form powerful points of attraction, and, where they are in the immediate vicinity of a swamp, retain the contagious matter that rests upon them so effectually, as, in many cases, to keep the surrounding atmosphere free from pollution, and become a safeguard against febrile attack. "The town of New Amsterdam, in Berbice," says the same writer, "is situated within a short musket-shot to the leeward of a most offensive swamp, in the direct track of a strong trade-wind that blows night and day, and pollutes even the sleeping apartments of the inhabitants with the stench of the marshes; yet it brings no fevers, though every one is well aware that it would be almost certain death for a European to sleep, or even to remain after nightfall, under the shade of the lofty trees that cover the marsh at so short a distance. All, too, are equally aware, that to cut down the trees would be a most dangerous operation in itself, and would certainly be productive of pestilence to the town."

As almost every territory in which the fever hereby produced has committed its ravages has given it a new name, it is as gorgeously arrayed with titles as the mightiest monarch of the east. From the depredations it has committed in the West Indies and on the American coast, it has been called the St. Domingo, Barbadoes, Jamaica, and American fever; and,

from its fatal visitations on the Guinea coast and its adjoining islands, the Balam fever. In British India, it is distinguished by the name of the jungle fever, the Hoogly fever, or endemic of Bengal; and, still farther to the east, by that of mal de Siam. Nearer home, in the lowlands of Hungary, and along the south of Spain, it is called the Hungarian or the Andalusian pestilence. From its rapid attack on ships' crews that are fresh to its influence, the French denominate it *fièvre matelote*, as the Spanish and Portuguese call it *fiebre amarilla*, and still more frequently *vomito prieto*, or black vomit, from the slaty or purplish and granular saburra thrown up from the stomach in the last stage of the disease; while, as its ordinary source is marsh lands, it has frequently been named *paludal fever*. Its more common name, however, in the present day, and for the reason already assigned, is yellow fever; and, when the attack upon new-comers is slight, *seasoning*. It is the *febris gastrico-nervosa* of Professor Frank (Op. cit., vol. i., § 103), who justly regards it as an intense variety of the ordinary autumnal malignant of temperate climates, as already described under this name.

From its showing itself in so many parts of the world, and under circumstances so widely different, it is not to be wondered at, that it should often be accompanied with a considerable diversity of symptoms; and, consequently, that the paludal fever of one quarter should be regarded by many writers of considerable authority as essentially different from that of another. But an attentive perusal of the origin and laws of febrile miasm, as I have endeavoured to explain them, when treating of the remote cause of fever, will, I trust, be sufficient to account for all such local distinctions; and, if not to prove, at least to render it highly probable, that they depend "partly upon the state of the body at the time of attack, but chiefly upon some modification in the powers or qualities of the febrile miasm itself, by the varying proportions of the co-operative agents of moisture, heat, stagnant air, and other auxiliaries which have not yet been detected, in their relation to each other in different places and seasons."

How far the yellow fever is capable of *origination* from any other cause than febrile miasm from marshy lands, or places subject to like decompositions and plays of chymical affinity, we cannot at present determine. Such places, however, are numerous, as damp unventilated stations, stagnant water, thick impervious jungles, and woods that arrest the miasm as it ascends; even high and arid hills after heat and rain; but, above all, a foul state of the hold on board ships, whatever be the cause of such impurity. "Ships," observes Dr. Chisholm, "containing wine in their holds in a state of decomposition, are generally extremely sickly, and the character of the prevalent disease is that of YELLOW REMITTENT FEVER. Several instances of this took place in Fort Royal Bay in the years 1797 and 1798; and the situation of the ships in the open bay, far

* On the Nature and History of Marsh Poison, Medico-Chirurg. Rev., Dec., 1821; and compare with Chisholm on Tropical Climates, p. 34.

from the influence of marsh effluvia, precluded a suspicion of the fever from that cause. The ship *Nancy*, Captain Needs, from Fayal, with a cargo of wine for the army, arrived at Fort Royal, Martinique, in the month of October, 1799: she met with a gale of wind at sea on the 17th September, and several of the casks, from the motion of the ship, became leaky. The captain was taken sick at sea, and died with every symptom of the highest grade of yellow remittent fever. The mate and several of the crew were attacked with the same complaint: they recovered; but a mate, shipped at Fort Royal, fell ill on board and died. The ship lay out in the open bay; no vessel near her was sickly; and she herself became very healthy after the cargo was landed.*

Heat alone, however high the temperature, is not a cause of the fever before us: there must be moisture; and, as the result of both, a rapid decomposition and exhalation of organic remains. Provided the air is dry, even tropical climates are often found salubrious. "The burning province of Cumana," observes M. Humboldt, "the coast of Cora, and the plains of Caraccas prove, that excessive heat alone is not unfavourable to human life."

It has just been observed, however, that even high and arid situations, after heat and rain, may also furnish, by the chymical decomposition of their soil, the specific miasm of yellow fever: and it may here be added, that if, by the violence and redundancy of the rain, the swampy low grounds be at the same time overflowed, the latter will become an arena of health, while the heights are the seat of disease. Such the hilly ravines of Portugal were occasionally found by the British army, during its occupation of that country in the summer of 1809, when a most destructive remittent suddenly made its appearance, while the overflowed swamps at its feet were more than usually free from disease: "and such is frequently the case," as Mr. Irvine has justly observed, "on the lofty ridges of Sicily, when their fumari or water-courses, which are ordinarily dry and used for roads in the summer months, are filled and inundated with sudden torrents of rain. For here the malaria changes its station, and quits the overflowing lowlands for the heights of the primitive hills."†

But, whatever be the original source of the fever before us, when once it has established itself and rages with severity, it is now very generally admitted, that the effluvia from the

body of the affected "is loaded with miasm of the same kind, completely elaborated as it passes off,"—and that the disorder is from this time capable of communicating itself by contagion. And, from the statement already given, it appears far more probable, that the fever at Cadiz in 1800, that at Malaga in 1803, and that at both in 1820, had their *origin* in contagion, or, in other words, in febrile miasm, produced by a decomposition of the effluvia from the human body, than from the same miasm issuing from a decomposition of marsh lands. And, on this account, I have rather preferred the trivial name of *yellow* to that of *paludal* fever, which is too limited to express its source in every instance. The yellow fever at Xeres is ascribed by Don J. A. Ferrari entirely to this cause, as produced by importation; but its primary source he attributes to the decomposition of swampy lands, or other sources of putrefaction, which he seems to suppose may exist even in some parts of Spain.—(*Edin. Med. and Surg. Journ.*, July, 1823, p. 369.)

In all instances it has a near approach to the autumnal remittent we have just described: Dr. Rush contemplates them as merely different degrees of the same disorder; but Dr. Bancroft is, as it appears to me, more correct in considering them, after Professor Frank, as "varieties of one disease" (*Essay on the Disease called Yellow Fever*, &c., Baltimore, 1811), in unison with the present arrangement.

It should be observed, however, that, for the yellow fever to become contagious, it seems necessary that the thermometer should be above 80° of Fahrenheit: since, like the plague, it demands, for the activity of its miasmic corpuscles, a certain range of temperature, below which it ceases to operate, and its specific particles, perhaps, generally become decomposed. It has never been known in North America, nor in the south of Europe, but at the season of the year in which tropical heats, that is, those of 80° or upwards, prevail; and it has never failed to disappear in winter, even in the mild winter of Spain: though typhus may at the same time hold its full career of malignity.*

* Blane, *Select Dissertations*, &c., p. 314. Is not this a strong fact against the contagious nature of yellow fever? The proof of the extension of the disorder by the contagion of human effluvia must be exceedingly difficult, as long as the parties who are imagined to contract the fever from those first affected, are exposed to the influence of the same local circumstances. The notion of intermittent and remittent fevers being capable of transmission from one person to another by contagion, is, in all probability, as erroneous as the belief, prevalent in Italy, Malta, and other parts of the south of Europe, that consumption is a contagious disorder. When I was at Malta, in 1801, I wished to procure a lodging for an officer labouring under phthisis, but, owing to the belief universally entertained in that island of the disease being contagious, it was with great difficulty that any family could be persuaded to afford him accommodation. With regard to the malignant remittent fevers so often prevalent on the coast of Spain, it is a fact, that, although the commissioners sent by the French government to

* Essay on the Malignant Pestilential Fever, vol. i., p. 279.—See also Dr. Dickson's *Topographical Remarks*, &c., sect. iii.

† These facts confirm the observations introduced in a previous part of this work, in explanation of the occasional prevalence of agues in elevated parts of the country, or even on hills, while lower situations continue healthy. They also tend to refute the opinion of the identity or affinity of marsh miasm and of contagion from human effluvia to one another, inasmuch as one argument frequently adopted in favour of the latter hypothesis is founded upon seeming anomalies in the circumstances under which agues commence.—Ed.

From the different impressions produced on febrile miasm under these diversities of origin and adjuncts, we find, independently of other discrepancies, that the fever it excites sometimes assumes a caumatic or inflammatory cast, sometimes a typhous, and sometimes a synchous, or, in other words, begins with the first and runs rapidly into the second or third. And it is in effect into these three subsections that the Andalusian yellow fever has been lately restored by Dr. Jackson, in his excellent work on the subject. Generally speaking, the variety before us evinces the last of these characters, as does also the variety we have just treated of: the two varieties that yet remain, will afford examples of a typhous and inflammatory bearing.*

Its ordinary progress, among those who are fresh to the tainted atmosphere, is thus accurately described by Dr. Mosely, who, from its resemblance to the causus of Hippocrates, denominates it *endemia causus*: a term which has since been adopted by Dr. McArthur (*Account of the Causus or Yellow Fever of the West Indies, &c.*), and several others. "When a new-comer is seized with a sudden loss of strength, and a desire of changing, for rest, into every position, without finding it in any, those symptoms which constitute the *endemia causus* may be expected. The following day, but sometimes within twelve hours from the first indisposition, the violence of the disease will commence thus:—There will be a faintness, and generally a giddiness of the head, with a small degree of chilliness and horror, but never a rigour. Then immediately will succeed a high degree of fever, with great heat, and strong beating in all the arteries of the body, particularly observable in the carotid and temporal arteries; flushings in the face; gaspings for cool air; white tongue, but tinged with yellow, after the retchings have commenced; excessive thirst,

redness, heaviness, and burning in the eyes; heaviness and darting pains in the head and small of the back, and often down the thighs; pulse quick, generally full and strong, in some cases, quick, low, and vacillating; skin hot and dry; sometimes with a partial and momentary moisture; sickness of the stomach from the first, which increases with the disease; and, immediately after any thing is taken to quench the thirst, retchings succeed, in which bilious matter is brought up; anxiety, with stricture, soreness, and intense heat about the præcordia; great restlessness; heavy respiration; sighing; urine deep-coloured, and but little in quantity. This is the first stage of the fever, and may continue twenty-four, thirty-six, forty-eight, or sixty hours, and this constitutes its inflammatory period.

"The second stage begins with an abatement of many of the preceding symptoms, and the rise of others; sometimes with a deceiving tranquillity, but with perturbation if the patient should fall into a sleep: then a yellow tinge is observed in the eyes, neck, and breast; the heat subsides, and sometimes with a chilliness, but not with that sort of strong rigour which, when it happens, terminates the disease by sweat, or by copious bilious evacuations upwards or downwards. The retchings are violent, and turn porraceous; the pulse flags, but is sometimes high and sometimes soft; the skin soft and clammy; the urine in small quantity, and of a dark croceous colour; the tongue in some cases is dry, harsh, and discoloured, in others furred and moist; there is confusion in the head, and sometimes delirium, with the eyes glassy. This stage of the disease sometimes continues only for a few hours, sometimes for twelve, twenty-four, thirty-six, or forty-eight hours, but never longer.

"In the third and last stage of the fever, the pulse sinks, and becomes unequal and intermittent, sometimes very quick; frequent vomiting, with great straining and noise, and what is brought up now is more in quantity, and has the appearance of the grounds of coffee, or is of a slate colour. Nothing can be retained in the stomach; difficult breathing; tongue black; cold clammy sweats; eyes hollow and sunk; yellowness round the mouth and temples, and, soon after, over the whole body."

In the earlier remissions, the pulse often sinks from a hundred and thirty to ninety, and the general improvement is so considerable as to impress the young practitioner with the belief of a salutary crisis. He is soon, however, aroused from his deception, for the exacerbation soon returns with renewed violence; and, as the symptoms grow more aggravated, they are, in the end, accompanied with subsultus tendinum, black urine, deadly coldness of the limbs, delirium, faltering speech, hemorrhage, or oozing of blood from the mouth and nostrils, corners of the eyes and ears; black bloody vomiting and stools; vibices, hiccough, muttering, coma, death.

After the first prostration of strength produced by the symptoms of invasion or accession, the *prodromes* of M. Deveze, the disease runs

investigate the character of the fatal disorder which, in 1821, raged in the city of Barcelona, reported that it was propagated by infection, the doctrine never gained much belief in France, because it was considered to be sufficiently refuted by other views taken of the same epidemic by Dr. Chervin, whose able researches fully established the fact, that the propagation of the fever was chiefly, if not entirely, owing to the malaria of the place in which it prevailed, and not to emanations from those affected by it.—Ed.

* Here it ought to be noticed, that the contagious nature of typhoid fevers is a disputed point. If you allow the effluvia from too many human beings crowded together in a badly ventilated building to be, as it were, concentrated, you will see fever arise; but for typhus to be communicated to another person from a patient lying in an airy apartment, is a circumstance, at all events, so rare, as to be a matter of doubt. Whether the patients, crowded together, have one fever or another, or at first no fever at all, febrile disorders, with change of type if they have previously existed, will generally come on. The inflammations and alterations of the mucous intestinal tissues, and other parts, arising in the course of intermittent and remittent fevers, together with the influence of medical treatment, will also frequently account for change of type.—Ed.

on violently through its stage of excitement till the sensorial power is exhausted. Through its entire course, till the patient is sinking, the intellect is not particularly disturbed, and the organs chiefly affected are the abdominal; those which principally suffer in the malignant autumnal remittent of our own country, are especially the stomach and the liver. Hence, the intense heat and anxiety about the præcordia, the saffron die of the urine, the yellow teint of the skin, and the vomitings, first of a bilious, and afterward of a chocolate or sanguineous colluvies. In the Andalusian variety, however, according to Dr. R. Jackson,* the brain is sometimes the first organ affected, and the abdominal organs consecutively.

In some cases, the disease opens with great vehemence, and rushes forward at once to its acme, constituting the second stage of Dr. Mosely. The patient is sometimes cut off in four-and-twenty hours; and, from the violence so suddenly committed on the liver, its proper function is instantaneously suspended,—and, instead of an excessive emulgence of high-teinted bile, a chlorotic secretion takes place, which, forced into the sanguineous system, gives a ghastly lividity to the entire surface. Shortly after which, if the patient live long enough, the gorged bloodvessels of the inflamed and gangrenous liver itself, and sometimes also of the spleen or stomach (*Chisholm*, op. cit., p. 36), give way, and repeated tides of dark, granulated grume, like the grounds of chocolate, are ejected by the mouth.

Dr. Pym has very forcibly described this overwhelming onset of the disease in the following terms:—"There is, at the first attack, a peculiar shining or drunken appearance in the eyes; the headach is excruciating, and confined to the orbits and the forehead; has no remissions; when it terminates favourably, is rarely attended with yellowness of the skin, which, if it do take place, is of a very pale lemon colour. It runs its course from one to five days, is attended with a peculiar inflammation of the stomach, which, in most cases that prove fatal, terminates in gangrene, or in a diseased state of the internal or villous coat of that organ, accompanied with a vomiting of matter resembling coffee-grounds, and a livid or putrid appearance of the countenance which it is impossible to describe; but those wishing to form an idea of it, may see its fac-simile in the countenance of any person with a florid complexion, during the burning of spirit of wine and salt in a dark room, as is practised in the game of snapdragon during the Christmas gambols."—(*Obs. upon the Bulam Fever*, &c., 8vo., 1815.)

In this state, the disease is unquestionably for the most part, though not always, contagious: and, as Dr. Cullen has laid down contagion as a distinctive character of fevers originating from human effluvia, in contrast with those originating from the effluvia of marshes, Dr. Pym has endeavoured to draw a line of dis-

tinction between yellow fever in this state of intensity and in its ordinary career; contending that the former (to which he limits the name of Bulam fever) is in every instance derived from human effluvia, and, consequently, that the two must of necessity be distinct diseases. And to make the distinction still clearer, he has ventured to assert, that the symptom of a more pallid or bloated countenance, together with that of black vomit, or the discharge of coffee-like grounds from the stomach, is peculiar to the contagious fever, and is rarely, if ever, an attendant on that produced by marsh miasm, even in its most impetuous and fatal course.

This distinction, however, is in both instances at variance with the history of the disease as it has occurred in most other parts of the world, and, more especially, with respect to the symptom of black vomit; which, in its last stage or severer incursions, is common to it from whatever source derived. Nothing is more frequent in the Andalusian or Spanish variety, where the discharge is sometimes inky-black, like the fluid disgorged by the cuttlefish; and it is thrown forth from the anus as well as the stomach.—(*Jackson*, op. cit.) Black vomit occurred more especially in the fatal epidemic of Antigua in 1816, which was decidedly an offspring of marsh effluvia. "The island had for some years," observes Dr. Musgrave (*Medico-Chirurg. Trans.*, ix., 92), at whose description we have already glanced slightly, "been peculiarly healthy; and the disease first showed itself in a swampy part of it, and amid new-comers, who were sailors, but from a healthy ship, and themselves in good health on first landing. It soon spread widely, and at length indiscriminately among all ranks, and conditions, and situations; among blacks and whites, the newly-arrived, and the oldest settlers in town and country."

Nothing was better calculated than this fever, to show that almost all the different kinds of fever that occur to us are capable of issuing from a common source of miasm, merely modified by contingencies; for, in Antigua, they all occurred in different individuals. The disease sometimes commenced as an intermittent or remittent, and sometimes in a continued type; it sometimes ceased in four or five days, which was its usual course, and sometimes terminated in an intermittent. The head was in some cases chiefly affected; in others the stomach, liver, or some other organ: sometimes the patient died without hicough or black vomit, though he rarely recovered where these symptoms appeared; Dr. Musgrave recollects but one instance. Recovery was no exemption against a second attack. In new-comers, the teint was of a lemon hue; in native or assimilated constitutions, of a deep orange. The state of the atmosphere at the commencement of the disease presented nothing peculiar.

To the same effect, Dr. Dickson, in his valuable official report:—"At Barbadoes and Antigua, I had generally seen the disease of an ardent and continued form, and did not fully understand why authors talked of a bilious remittent yellow fever, until after the capture of

* Remarks on the Epidemic Yellow Fever, &c., on the south coast of Spain, 8vo., Lond., 1821.

the French and Danish islands. But the anomalies of fever, the shades and changes which it assumes, according to the intensity of the exciting causes, the state of predisposition, or the spot of residence, could nowhere be more strongly portrayed, than in the destructive epidemic of *Mariegálante* in the autumn of 1808, from the most concentrated marsh miasmata; where the different types of fever were converted into each other, of the worst and most aggravated species I have ever witnessed. Yellow fever in the *continued form*; others with comatose *remittents* or *intermittents*; the exacerbations of which were so violent as to carry off a patient in two or three paroxysms; while others sunk into a low protracted character of fever, resembling *typhus*."—(*Report, &c.*, pp. 143, 144.)

In the midst, however, of so much discrepancy, there is still much that is concurrent, and quite enough to establish the identity of the two diseases, if an abundance of other evidence to the same purpose were not at hand. The fever of Dr. Pym, specifically characterized by black vomit, is represented as being peculiarly dangerous and fatal; in that of Dr. Musgrave, this symptom only occurred in the most perilous cases. According to the latter, the severest and most deadly attacks were among the newcomers; the mildest among the natives, or those whose constitutions were assimilated to the climate. The yellow hue of the former (and I have already endeavoured to account for this) was of a *deep orange*; that of the latter, a *lemon colour*. Dr. Pym describes three species of fever as common to warm climates, but which differ from each other in their mode of origin and diagnostic character. In that of least danger, the colour of the surface, he tells us, is of "a *very deep yellow*;" in that of higher danger, it is of "a *deep yellow*;" and in the disease before us, which is by far the most fatal, where there is any yellow at all, it is of "a *very pale lemon colour*;" which is, in effect, the very hue ascribed to the severest cases of the Antigua fever by Dr. Musgrave, as the "very deep yellow," or "orange," is to the mildest. So that, examined by their external livery, as well as their internal disorganization, there can be no doubt that the two diseases are the same. Dr. Pym appeals peculiarly, as a distinctive character of the Bulam fever, to the deadly and chlorotic paleness exhibited by the countenance in its latest stage, or most fatal incursion. But even this only shows that, in such case, the disease makes a mortal attack upon the larger viscera, and especially the liver, from the first; and demonstrates the proposition I have ventured to lay down, that, in proportion as this organ is severely affected, is its inability to secrete proper bile, or indeed bile of any kind; and, consequently, that if the irritation only reach a certain point, its secretions will be stimulated to emulge a larger quantity and of a deeper hue; a considerable portion of which will be absorbed into the sanguiferous system, and produce the orange tinge, which, in the description of both these writers, peculiarly marks the dis-

ease before us in its less fatal attacks: while, if the febrile incursion be so violent as totally to derange the function, and still more the structure of the liver, no bile will be secreted at all, or, if secreted, less in quantity, and consequently less diffusive in colour; and hence only conveying a chlorotic or livid tinge to the face, which, at the same time, exhibits a bloated fulness from effusion or debility of vascular action.

In confirmation of this remark, Dr. Jackson's earlier cases of practice furnish numerous examples;—"examples indeed," to adopt his own words, "of that form of disease when there is a considerable degree of vascular excitement in the early stage, terminating commonly by deranging the functions of an organ of importance—most frequently the liver or stomach. Yellowness and black-vomiting are common; and it is *more especially* to this form, that the name of YELLOW FEVER has been applied: but though the yellowness and black-vomiting be common, they are *not constant* and essential. Determinations sometimes change suddenly; the brain becomes overwhelmed, and stupor and convulsion then cut short the ordinary rapid course."—(*Hist. and Cure of Fever*, chap. iv., p. 133.)

Yet, after all, it is not denied by Dr. Pym, nor, so far as I know, by any of the writers on the American or Andalusian fever, that the yellow fever from marsh miasm ever evinces either of the symptoms that are so essentially ascribed to the bilious remittent produced by contagion, but only that "it is rarely, if ever," to adopt Dr. Pym's own words, "attended with the fatal symptoms peculiar to the Bulam fever, viz., the black vomiting, and a peculiar bloated appearance of countenance."

There would, however, be an almost insurmountable difficulty in reconciling these different descriptions of the same disease, in consequence of Dr. Musgrave's telling us, very decisively, that not a single instance occurred in the Antigua fever of its being received by contagion, were there not strong reason for believing that this explicit writer suffered himself to be deceived upon this point; most probably, like Dr. Pym and Dr. Jackson, from too close an attachment to the doctrine laid down by Dr. Cullen, that the fever from marsh miasm does not produce contagion, which is specifically a result of a fever from human effluvium.

It is impossible to peruse the history of bilious remittents in warm climates, offered from all quarters, without seeing that it may originate from both sources; each sometimes operating alone, and sometimes in conjunction with the other, as was probably the case at Antigua, and certainly the case in the yellow fever that raged at Philadelphia in 1793, in which, says Dr. Rush, there were, for several weeks, two sources of infection, viz., exhalation and contagion. The exhalation infected at the distance of three and four hundred yards, while the contagion infected only across the streets. The more narrow the streets, the more certainly the contagion infected. Few escaped it in alleys. After the twelfth of September, the at-

mosphere of every street in the city was loaded with contagion; and there were few citizens in apparent good health who did not exhibit some mark or other of it in their bodies, particularly a preternatural quickness in the pulse, "which occurred in negroes, as well as in a few who had the disease before."

In like manner, the Minorca fever, uniformly originating, as Dr. Boyd observes, in marsh miasm, frequently becomes contagious (*De Febre Minoræ*, &c., 1817): of which, indeed, he has furnished us with a striking example in his own person: for we are told by Dr. Denmark that he caught the fever from one of his patients, and nearly fell a victim to it.—(*Medico-Chirurg. Transact.*, vi., 301.) But we have had occasion to examine this subject so much at length, in the introductory remarks to the present order, that it is unnecessary to pursue it further, except by introducing the following irresistible illustration:—

Sir Gilbert Blane, having been requested by the Board of Admiralty to examine into the dreadful mortality that took place at the Island of Ascension, in the summer of the present year, 1823, reported, and from the manuscript of this report I was permitted to copy, that the officers and privates of Ascension Island were first stationed there in September, 1821, in number twenty-eight, and continued in such full health as to be without the loss of a man till the arrival of the Bann sloop of war, in May, 1823. The Bann had left Sierra Leone towards the close of the preceding March, at which time the yellow fever was raging there with great mortality, and, at the time of sailing, had had no sickness of any kind on board: but, within a few days after sailing, the yellow fever made its appearance, and continued its ravages till the beginning of June: during which time, not less than ninety-nine men had been attacked by it, and thirty-three cut off, out of a crew of one hundred and seven Europeans and officers, independently of twenty-seven African supernumeraries, none of whom suffered from the disease. Upon the arrival of the Bann at the Isle of Ascension, an unrestricted communication took place between the sick crew and the healthful garrison, the medical officers of the station having adopted the opinion that the yellow fever is uncatagorical. For want of such restrictions, within a few days after the arrival of the Bann, the garrison became affected, now reduced from twenty-eight to twenty-two, in consequence of six men having been ordered to a distant part. And, such was the dreadful mortality with which the disease raged, that, out of this garrison of twenty-two officers and soldiers, not less than sixteen died, being rather more than three fourths of the whole. The medical officers were soon, though too late, convinced of their delusion, and most unreservedly admitted the quality of contagion; and that the disease they were called to contemplate was genuine yellow fever, will be placed beyond a doubt by the two following symptoms, that the surgeon of the Bann particularly notices as among its other characters:—"the skin tinged

with yellow, assuming a deeper and deeper hue," and, "before death, the vomiting of a dark-coloured fluid, like coffee-grounds;" conjoint symptoms, which, as Sir Gilbert Blane observes, will apply to no other epidemic whatever.*

How far the tanks or pools of water within the range of the febrile miasm, from whichever of the two sources produced, may become sufficiently impregnated to propagate the disease, has not been sufficiently determined. The Tamul, or native practitioners on the Coromandel coast, ascribe the epidemic that so often ravages their country to contaminated water as well as to contaminated air, and the able authors of the report on the Corimbatores fever incline to adopt this opinion.

In France, where, consistently with the popular doctrine of M. Broussais, the disease is supposed to be seated in the mucous texture of the stomach or intestines, and to be dependant on contagion alone,† as its means of propagation, a considerable degree of fancy has of late been indulged in, respecting the origin of this contagion; and the fancy has been varied according to the bent of the individual. Thus, M. Moreau de Jonnés has endeavoured to show, in a work of some learning, but more imagination (*Monographie Hist. et Méd. de la Fièvre Jaune des Antilles*, &c.), that the yellow fever, however at first produced, which has eluded his researches, has been perpetuated among Europeans, in the manner of plague, leprosy, and syphilis, by a specific poison that has existed immemorially among the Indians of St. Domingo, and was communicated by them to the Spanish fleet, under the command of Columbus, in December, 1493, and from this fleet to all the world in succession, in consequence of the close intercourse which took place between the individuals of the new settlement of Isabella, colonized out of the fleet, and the adjoining natives. In answer to which, however, it is sufficient to observe, after Dr. Chisholm, that the Spanish writers, Herrera and Oviedo, appealed to in proof of this fact, rather unite in showing, that the Spanish settlers received the disease, in the first instance, from marsh miasm, and then communicated it to the natives themselves: while M. Adouard traces the same contagious poison to an effusion or exhalation from the mucous membrane of the stomach of the indi-

* Future experience will decide, whether a fever, corresponding to that now adverted to, will ever arise in Ascension Island, except under circumstances similar to those stated by Sir Gilbert Blane. Fevers affecting the crew of a ship, however, may be looked upon as happening in a situation not the best adapted for ventilation, and where too many persons are congregated together; under these conditions, no doubt, any prevalent fever may become infectious. The state of the weather and atmosphere, and the localities, to whose influence the military were exposed in Ascension Island, about the period of their being taken ill, are particulars which should be studied in order to arrive at any very certain inference upon the subject.—Ed.

† This doctrine is on the decline in France, as already noticed in a previous page.—Ed.

vidual affected, produced by an engorged or congested state of its vessels, and which, in consequence of the gaseous elasticity of the material thus eliminated, escapes by eructation, and propagates itself by being swallowed, and thus communicated to the stomachs of others; on the mucous surface of which it commences a like action, and fructifies a like harvest of contagious matter; the black material which remains behind being, in his opinion, a mere caput mortuum, unendowed with any infectious or other mischievous property.—(*Relation Hist. et Méd. de la Fièvre Jaune, qui a régnée en 1821, à Barcelone*, 8vo., Paris, 1822.)

There is much truth in this last position, whatever becomes of all the rest. Black vomit has been by many physicians, and was at one time supposed by Dr. Rush, to be vitiated and discoloured bile; but it is now more generally conceived to be, as already stated, grumous or granular blood, let loose from the liver, stomach, or some other digestive organ, from the violent commotion of the disease.* Dr. Bancroft affirms that "it is always insipid;" and we have numerous instances of orderlies in sick rooms, who have had their hands and faces covered with black vomit suddenly ejected from the stomach, which they have taken little pains to wash off, while others have slept in sheets or blankets stained and inundated with its flow, and yet have escaped the complaint. It marks, indeed, the violence of the disease, and is hence, commonly, though not always, accompanied with the formation of contagious miasm, but in itself it is not a source of contagion. The following instance of disgusting hardihood, though it has been brought forward in proof, not only of the innocuousness of black vomit, but of the uncontagious nature of yellow fever from any source, falls rather within the limit of an exceptive idiosyncrasy, in the escape with which it was accompanied, than lays any foundation for a general rule. A. M. Guyon, of Fort Royal, Martinique, we are told in the *Revue Médicale*, had the bravery to wear, for twenty-four hours, the suit, drenched with sweat, of a soldier who had been labouring under this disease in its worst state; he suffered himself to be inoculated in both arms with the yellow matter issuing from suppurating blisters: he went into the bed of another patient, who had just died of the disease, while it was soiled with excrement; wore, at the same time, his shirt, soaked through with black sweat and still warm, and himself slept soundly, and sweated through a good part of six hours and a half, which he dedicated to this delectable trial; he exhibited several other feats of the same kind, and crowned the whole by drinking

about two ounces of the black vomit discharged from the dead man's stomach—and, nevertheless, entirely escaped the fever. Admitting the truth of this marvellous story, there is still no great difficulty in conceiving that a man, who was so totally torpid to all delicacy of mental feeling, might, at the same time, labour under a like torpitude of corporeal feeling, and be insensible to various irritants that would be sure to affect others.*

It is probably owing to an idiosyncrasy, producing something of the same kind of insusceptibility to the action of the contagion of yellow fever, that while the miasmatic poison for the most part takes place immediately, it sometimes continues dormant for an indeterminate period. Dr. Jackson has known it remain in this state for two months, and Dr. Bancroft for even nine or ten.

The individual who has passed through the disease, is rarely attacked a second time. In the opinion of some physicians, he obtains hereby an immunity at least equal to that afforded by the smallpox.—(*Report of the Army Medical Board on Dr. Pym's Observations*.) The examples, however, of recurrence are too numerous to justify such a comparison; though in most instances where the disease has returned, it has evinced a milder character. But this influence on the system, whatever it may amount to, seems to be lost by a short absence from tropical climates; so that those who return to Europe for a few months, are as open to all the effects of a febrile incursion, as though they had never been within the tropics before.

As the larger viscera suffer very differently in different cases of this malady, the appearances on dissection have generally kept pace with the previous indications: for, in some, the integuments of the brain, or even its vessels, its substance, and its cavities, have shown marks of inflammatory action, which have not been traced elsewhere; while in others, whose brain has appeared sound throughout, the stomach and its collateral organs have been found chiefly affected with congestion, rupture, or, still more frequently, an erythematous inflammation, which, in some instances, has spread from the pylorus through nearly the entire range of the intestinal canal. In various other examinations, the chest has exhibited the chief seat of disorganization; and in others again, the urinary organs.† The mucous membrane of the intestinal canal is by far the most frequently injured organ; and this has been laid hold of with no small degree of triumph by M. Broussais and his adherents, as affording a manifest proof of the truth of their

* The effusion of blood into the cavity of the stomach or intestines, it is thought, may occasionally depend upon certain states of that fluid itself, by which it is so modified, that it tends everywhere to escape from the vessels. According to Andral, this is what happens in some examples of poisoning by absorption, and in typhus, and is the cause of the black vomit in yellow fever.—See *Anat. Pathol.*, tom. ii., p. 151.—Ed.

* In the *Med. Chir. Trans.* of Edinb., vol. ii., Dr. Ralph has published the History of Yellow Fever, as it appeared in the queen's regiment in Barbadoes in 1816 and 1817. The facts mentioned by him, in proof of the disease not being communicable from one person to another, are remarkably strong; indeed, such as leave scarcely any doubt on the subject, as far as the particular fever described by him was concerned.—Ed.

† Bally, sur la Typhie Américaine ou Fièvre Jaune, Paris, 8vo.—Palloni, Obs. Méd. sur la Fièvre régnante à Livourne, &c.—Saverésy, de la Fièvre Jaune en général, &c.

favourite doctrine: and that yellow fever can be no other than *unc gastrite*, or, in still later language, *unc gastro-enterite*. But it should not be forgotten, that most of the gastric symptoms, and all the severest ones, only occur in the course of the disease, and rarely in a very early part of it; and that they are hence rather to be regarded as effects of overwhelming febrile action upon the delicate and irritable texture of the membrane so severely excited, than as a proximate cause of the fever itself: and the more so, as sometimes the biliary system, the lungs, or the brain are chiefly affected, and the intestinal canal exhibits fewer proofs of suffering than any of these organs.

Unfortunately, the practitioners in warm climates have differed as much in their therapia as in their etiology; for the latter, as might be expected, has greatly influenced the former. Dr. Lind, Dr. Clark, and Dr. Balfour, whose authorities were implicitly allowed and submitted to, some fifteen or twenty years since, alarmed at the debility which the system will have to encounter in the second stage of the disease, or as soon as it has run through its inflammatory career, shuddered at the thought of the lancet, and generally commenced with clearing the stomach and intestinal tube by gentle emetics or purgatives, or both, and immediately had recourse to the bark in as large doses as the patient's stomach could bear, paying little or no regard to the remissions or exacerbations of the fever: though the last of these physicians chose calomel as his cathartic, and alternated its exhibition with the bark till the disease was subdued, or had effected its own triumph; at the same time allowing a free use of opium to keep the bark on the stomach, as well as to allay pain and procure rest; to which were occasionally added wine and brandy in considerable abundance, three bottles of the latter having sometimes been given to a patient in less than twenty-four hours, and the same proportion continued for several days (*M'Cabe, in Edin. Med. and Surg. Journ.*, Oct., 1819): while recourse was only had to the lancet, where there was obvious proof of very violent local affection.

The times, however, have since changed, and by far the more popular plan of late years has consisted in active, profuse, and repeated venesections, large and quickly renewed doses of calomel, cold affusion, gestation in pure air, and, as advised by some, the bolder exercise and rapid motion of a cart, spring-wagon, or any other carriage.—(*Hist. and Cure of Fever, by R. Jackson, M. D.*, part i., chap. xi., pp. 267, 270.) It was in this manner that Dr. Rush, regarding the inflammatory impetus as the sole cause of danger, boldly resolved to lay prostrate if possible the morbid Hercules at its birth, by bleeding, according to the state of the pulse, two or three times a day during the first two days, and by following up the same plan as long as a single germe of an inflammatory diathesis should continue manifest. "I paid no regard," says he, "to the dissolved state of the blood, when it appeared on the first or second day of the disorder, but repeated the bleedings after-

ward, in every case, when the pulse continued to indicate it. It was common to see sily blood succeed that which was dissolved. The dissolved appearance of the blood I supposed to be the effect of a certain action of the bloodvessels upon it. The presence of petechiæ did not deter me from repeating bloodletting where the pulse retained its fullness or tension." And he affirms, that both petechiæ and vibices disappeared in various cases after bleeding. This plan he often pursued through the fifth and even the seventh day, in the course of which period, from a hundred to a hundred and twenty ounces of blood were frequently taken away by six or eight applications of the lancet.

His purgative plan was not less alert. Ten grains of calomel and fifteen of jalap, was the force with which he opened his remedial attack, and which he repeated every six hours, till the alvine canal was effectually evacuated. This mode of treatment, he tells us, he was led to by accident; and with it he became as successful as he had been unsuccessful under the tamer and more established method.

Under this plan of treatment, the venesection and the calomel were employed on a principle of depletion alone, and of diminishing a real or supposed increased action; and the former on the principle of a *gradual* depletion; Dr. Rush rarely venturing to withdraw more than sixteen ounces of blood at a time, though the venesection was as closely repeated as the patient's strength was conceived to be capable of bearing. Both these remedies have, however, still more lately been employed on different grounds, and under a different mode of management. Blood, instead of being taken away gradually and successively, has by many, and especially by Dr. Jackson, who seems to have introduced the practice, been drawn off, on the accession of the disease, to thirty or forty ounces at once, with a view of making a decisive impression upon the system; the same bold use of the lancet being repeated within three hours, if such impression be not effected: after which, "such powers are recommended as *stimulate* to a train of action, congenial to the action of health" (*Op. cit.*, pp. 267, 293): and calomel, instead of being employed as a purgative, has been enlisted as a powerful alterant and deobstruent, and persevered in, to salivation, by doses of from five to five-and-twenty or thirty grains every third or fourth hour, according to circumstances, till this point is obtained; which, however, is not regarded as important in itself, but as showing that the system is sufficiently under its influence. Dr. Chisholm seems fairly entitled to the honour of having first tried and recommended mercury with this intention.—(*Ibid.*) "It ought," says he, "to be a general rule of practice to consider *all* remittent fevers, within the tropics, as symptomatic of local congestion, and inflammation. It is a rule, the observation of which can never be injurious,—almost always positively beneficial,—and the neglect of which is always productive of harm. Under this view, the judicious practitioner will consider the *tendency* to congestion as the object of his main

attention, and direct his efforts to prevent it. Upon the whole, then, the treatment is reduced to one sentence:—bleeding to the extent necessary, plentiful alvine evacuation, MERCURIAL FRYALISM, and cold affusion" (*On the Clim. and Dis. of Trop. Countries*, pp. 46, 47); and he adds, in another part of the same volume, (p. 215) "let it never be forgotten, that, at whatever period of the disease salivation is excited, whether the supposed signs of putrefaction have appeared or not, the accession of it is the certain signal of cessation of disease, and of returning health."

This general plan of Dr. Chisholm has in the present day become highly, and perhaps chiefly popular; and is powerfully recommended from personal experience of its advantage by Dr. James Johnson (*Op. cit.*, pp. 50, 51, et passim), Sir William Burnett (*On the Bilious Remittent Fever of the Mediterranean*), Dr. Boyd (*De Febre Minoreæ*, &c., 1817), Dr. Denmark (*Medico-Chir. Trans.*, vol. vi.), and a long list of valuable authorities, who have practised in the one or the other of the Indies; all of whom, however, combine the use of calomel with copious bleeding; the former being regarded as the "sine qua non," or the "sheet-anchor," by some of them: and the latter being designated by the same terms, by others.

On a cursory glance, these diversified modes of treatment appear, in many respects, to be directly hostile to each other, and to establish an utter absence of any one therapeutic principle common to the whole; but a closer attention to the subject will show us, that there is not necessarily any opprobrium medicorum in the discrepancy, except what results from becoming so exclusively the champion of any one of these respective modes of treatment as to bend every case to its own limits, and thus convert it into a bed of Procrustes: for there seems abundant reason for believing, that, in different situations, or under different circumstances, each of these plans has proved equally judicious and successful; since we have seen, that the disease, under different incidents and coadjuvants, has exhibited every variety of violence, and inclined to almost every variety of febrile type. Where there is not much impetuosity in the onset, no great derangement or prognostic of inflammatory congestion in the larger viscera, where the remissions are regular, and the epidemy is pretty uniform in its character, large and repeated bleedings, as a general rule, must prove mischievous. They will not shorten the career of the disease, but they will convert the remittent into a continued fever: and we shall in the latter stage of its course stand woefully in need of that strength which we shall have squandered away at first, if we have commenced with profuse venesection.

This is more especially the case where the disease makes its attack slowly and insidiously, assuming in some degree a typhous guise, as in the Guzzerat form, described by Mr. Gibson of the Bombay Medical Department (*Edin. Med. and Surg. Journ.*, vol. xi.): in which he tells us, that the debility is so great and instantaneous, as well as the tendency to putridity, that

bleeding is never to be hazarded, except occasionally to the robust new-comer; and in which, even spontaneous hemorrhages, instead of proving critical, have always seemed to hasten death, and, indeed, without a single exception in his experience, to prove fatal. And it was probably from a survey composed largely of cases of this kind, though in the West Indies, that Dr. Hunter, in a tone still more generally proscriptive, and which will meet with few defenders at present, thought himself justified in affirming respecting venesection, that, even "in such cases as seemed most to require it—for example, where the patient was young, strong, of a full habit, and lately arrived from Europe—when the pulse was quick and full, the face flushed, with great heat and headache—and all these at the beginning of the fever—bleeding did no good."—(*On the Diseases of Jamaica*, p. 118, 3d edit.)

Dr. Pinckard, in his "Notes on the West Indies" (Vol. iii., letter xii., p. 134), has given a very interesting description of his own sufferings under this disease, and of the remedial process to which he had recourse. His attack commenced in the more common manner, slowly and insidiously, and demanded eight or nine days to reach its acme. His head, stomach, and at last his bowels, were severely affected, especially the first; but his intellect continued sound; and though the symptoms were vehement, there seems to have been little tendency to that violent visceral inflammation which in the stage of debility is so apt to produce gangrene; and consequently he had no black vomit. He lost twelve or fourteen ounces of blood at the commencement of the disease, and took a strong dose of calomel, which considerably relieved the pain in his head and eyes, and diminished the restlessness; but the thirst, heat, and dryness of the skin were still intense; and his weakness became extreme. Affusions of cold water, old hock, opium, and bark, were made use of in profusion, and each seemed to afford great relief. Yet, on the subsidence of the fever, he represents his feebleness as most deplorable. Here a freer use of the lancet could have been of no avail, and, had not the author most judiciously forbade its further employment, in all probability, he would never have been the historian of his own case.

On the contrary, if the disease make its incursion with great impetuosity; if the pulse be full and strong, or even if it be only hard, and there be great tendency to inflammatory congestion in any of the larger organs, as the head, the chest, or, as is far more common, the stomach, the spleen, and the liver, we cannot well be too bold both in bleeding and purging; and the plan laid down by Dr. Rush is by no means an exaggeration of what ought to be pursued. It may be, that eight-and-forty or even four-and-twenty hours are the whole we have to work in; and unless we can completely break down the inflammatory diathesis, the organs mostly affected will in all probability become gangrenous in a day or two, the oppressed bloodvessels will give way, and we shall have a chlo-

rotic or livid skin, cold extremities, black vomit, and all the other apparitors of death, before the tamer plan of aperients and diaphoretics could have time to produce the slightest impression on the system. Generally speaking, it will be best to bleed in an erect position, for the sensorial excitement, which is what we are chiefly to aim at, is best cut down by syncope, which an erect position will soonest induce; and we may hence save the expense of several subsequent bleedings.

Dr. Pym speaks with a very just discrimination upon this subject, in observing that, while the Bulam fever, or the disease in its most violent attack, is relieved by free venesection, the yellow fever, more properly so called from the brighter hue on the surface, or, in other words, that which is slighter in its incursion, will not often endure the lancet. Dr. Musgrave's statement seems to oppose this assertion, for he distinctly tells us, that "bloodletting in both forms is our sheet-anchor; the only pillar on which we can securely rest any hope of *extensive* success." The Antigua fever seems to have exhibited great severity in most instances, and hence called for a courageous course of practice with perhaps few exceptions. Yet the following paragraph proves that it did admit of exceptions, and softens down almost to unanimity a clash of opinion and practice which, after all, is more ostensible than real:—"We have repeatedly," says he, "with success, taken upwards of forty ounces of blood at one bleeding. With equal success we have in several cases renewed the bleeding up to the third, and even the fourth time; but generally speaking, those which require such reiterated evacuation evince an obstinacy NOT LIKELY TO ADMIT OF A FAVOURABLE RESULT UNDER ANY MODE OF TREATMENT. IT MUST ALSO BE REMEMBERED, THAT EVERY ONE WHO APPLIES FOR ASSISTANCE IS NOT ALIKE ABLE TO BEAR THIS LIBERAL DEPLETION." It only needs to be observed further, that the bowels were emptied, as they ought to be, by calomel or jalap, or some other active purgative; the head was shaven, and cold ablution preferred ordinarily to cold affusion, because of the fatigue endured under the latter. Bark was then instantly given, and, where the stomach would bear it, in the form of powder. Mercury, with a view of exciting salivation, was seldom tried, and not relied upon. In effect, in the milder cases it was not wanted for this purpose, and, in the more urgent, there was no time for its use.

There can be no doubt, however, of its being highly advantageous in a great multitude of cases, and of general benefit in various forms of this destructive epidemic. For, whether we contemplate the fever as local or unrestrained, as consisting in violent universal excitement, or, according to M. Broussais, in an inflammation of the mucous membrane of the stomach or duodenum irritating the bile-ducts, and the liver itself by sympathy; whether as threatening congestion to any of the larger organs, or actually accompanying congestion; there is no medicine which, *primâ facie*, affords a better prospect of relief than mercury, from its general ac-

tion on the excrement system, as well as its specific action on the intestinal canal and the salivary glands. It must, however, be admitted that it is only under a particular condition and tone of the vascular frame that it can at any time be employed with good effect; and hence, not only is a sound judgment constantly demanded in its application, but much important time is often lost in preparing the system for its remedial introduction. In the case of *ENTONIC* or strong vascular action, it is necessary, first of all, to lower, and, in the case of *ATONIC* or weak vascular action, to raise the living power to the proper standard before ptialism can be obtained, which is the grand test of its having taken effect; and hence, to accomplish the former, bleeding, purgatives, and cold affusion, must be first called upon to exercise their respective powers, and, in the latter case, tonics and cordials; upon which last ground, Swediaur (*Nov. Nosol. Meth.*, Syst. i., 28) tells us that the most efficacious plan of treatment consists in giving calomel and columbo, in doses of *thirty-five* grains each, five or six times a day. It is truly said, indeed, by the advocates for mercury, that such other remedies are all valuable adjuvants; and this is so far from being denied by those who are hostile to the use of mercury, that they affirm, on the contrary, that the benefit ascribed to this medicine, when it has once obtained a sway over the system, ought rather to be attributed to these adjuvants themselves, which would have proved still more beneficial had they been left to their own power and intention alone. Mr. Gibson, who is a strenuous advocate for the use of mercury upon the principle now adverted to, very candidly admits both these causes of impediment. "In hotter climates," says he, alluding to the debilitating province of Guzzerat, "the *PHLOGISTIC* state of the system is adverse to the introduction of mercury: but the prudent abstraction of blood happily reduces it to that standard which is most favourable for its action. In India, however, in fever, the disease in which this is *most speedily* to be desired, the same means would but in very few cases be admissible: for the *DEBILITY* is so GREAT and instantaneous, as well as the tendency to putridity, that only in the robust new-comer is it, if ever, to be hazarded. It would seem that *DEBILITY* AND THE *PLETHORIC SYSTEM* ARE EQUALLY INIMICAL TO THE SPECIFIC MERCURIAL ACTION. If the patient is fortunately invigorated sufficiently to give the mercury influence, and BEFORE ANY ORGAN ESSENTIAL TO LIFE IS INJURED, by the strictest nursing and attention afterward, the recovery is almost certain, all morbid action yielding from the moment ptialism is brought on."—(*Edin. Med. and Surg. Journ.*, vol. xi.)

Even in cases, however, in which the mercurial action is fortunately excited, the same intelligent writer tells us that he has frequently met with a very serious evil resulting from the mercury itself; for such, says he, is at times the profusion of the ptialism, when once induced, that the most disagreeable consequences succeed, and the convalescence is long and preca-

rious; on which account he laments that we have no criterion to determine how far we may proceed with the mercurial process, and when we ought to stop. Dr. Bancroft advances much further than this, and asserts that not only has the salivation retarded the convalescence, and produced very troublesome affections of the tongue, mouth, and throat, with other ill consequences thus acknowledged by its advocates, but that the salivators, even when they have been free from these evils, have not been more successful than other practitioners; and he particularly alludes to the admission of Dr. Rush, who was not unfriendly to the mercurial mode of treatment, that, "in the City Hospital (of Philadelphia), when bleeding was sparingly used, and the physicians depended chiefly upon salivation, MORE THAN ONE HALF DIED of all the patients who were admitted."—(*Essay on the Disease called Yellow Fever, &c.*, Philadelphia, 8vo., 1811.) For like reasons, Dr. Jackson speaks with as little satisfaction of the same practice, not only upon his own experience, but even upon that of Dr. Chisholm himself. Alluding to the high recommendation of mercury by the latter, he observes, "the detail of his testimonies does not warrant a conclusion so favourable; for the proportion of mortality in the detachment of Royal Artillery, upon whom this practice is supposed to have been first tried, has perhaps scarcely ever been exceeded in a tropical climate. Further, it is a common observation, that, where salivation actually takes place in continued fevers, it seldom shows itself till the violence of the symptoms has evidently abated: hence, a suggestion arises that the appearance of salivation is only an indication of the departure of the disease—no proof exists that the operation of the mercury is the cause of this departure. Such are the remarks which occurred in reviewing different modes of treatment in the hospitals of St. Domingo; to which it will not be superfluous to add an experiment made at the Mole in August, 1796, by Mr. Lind, Surgeon of Jamaica. Out of fifteen cases of fever put under the care of Mr. Lind, on the first day of the disease, and treated with the utmost attention, five died; in three of whom, salivation actually took place; five recovered, in whom no salivation took place; in the other five, who also recovered, salivation was evidently established; but, as is usual, not till the violence of the symptoms had begun to abate. Out of four who were put under his care on the second day of the disease, no one died; but one only was affected by the mercury; one, brought to the hospital on the third day of the illness, died: mercury was employed, but no salivation took place; one, on the fourth, likewise died, without marks of salivation; one, on the fifth—the salivation was established, but the disease proved fatal. In none of the above cases were less than ten drachms, and in most not less than two ounces of strong mercurial ointment rubbed into the legs and thighs, with the employment of all other means which seemed calculated to promote the expected effect."—(*History and Cure of Fever*, part i., ch. xi., pp. 293, 294.)

The question, therefore, to say the least of it, is still open; and, admitting all that can be said in favour of employing mercury as a sialogogue, the evils which flow from the uncertainty of its action, both in respect to time and degree, and its frequent inroads upon the constitution, even where it has been of use, are serious and important.

On the employment of EMETICS, there is now no longer any question. It is admitted, on all hands, that, in the irritability of the stomach and its collateral organs during this disease, they are generally improper, and almost constantly augment the morbid action; on which account, even the antimonial sudorifics are of very doubtful efficacy, and, whenever ventured upon, should be combined with opium. And, for the same reason, the use of carriage exercise, so strongly recommended by Dr. Jackson, and some of the most distinguished American practitioners, even "under the inconveniences of a scorching sun, of clouds of dust, and of a jolting cart" (*Ut* *suprà*, p. 287), has rarely been put to the test, except in the emergency of the sudden retreat of an army: and has hardly been allowed to enter into the catalogue of ordinary remedies.

The general treatment, indeed, may be summed up in few words. Copious bleeding, a free repetition of active purgatives, combined with opium where the ventricular irritation is considerable, in the commencement of the fever; frequent sponging, or affusion of cold water, with an interposition of the neutralized salts as diaphoretics, during its progress; and bark and other tonics, as soon as the febrile commotion begins to subside. The more powerful and violent remedies of repeated bleedings to faintness, mercurial salivation, or the stimulants of spirits, ether, and opium, being alone added to the list, according to the circumstances of the individual case.

Pure air, by a ventilation of the atmosphere, is, however, a more powerful remedial agent than all the rest put together; and to this position I apprehend every class of writers will accede, how much soever they may differ upon other points. The Army Medical Board is, therefore, peculiarly entitled to the gratitude of the country for the great pains it has taken to give improvement to this important object, by an establishment of open and wide-spreading encampments, instead of confined and unperforated barracks; and no man can hear of the desirable success with which this enlightened measure has been attended without exultation. The attempt, as I am permitted to state from the manuscript documents in the possession of the Board, has been made at Barbadoes, Tobago, and Antigua; not more than four individuals being allowed to occupy a single tent, instead of ten or twelve, which is the usual proportion at home: and the success developed in these islands has already become so considerable and decisive, that government has consented that a like trial should be made in all the islands around them. In the affected crew of the *Pyramus*, distributed by Dr. Hartley into an encampment

at Antigua, in the year 1822, not a single case of fever was found to travel from one individual to another. We cannot wonder, therefore, at beholding this able officer anxious, in his report for 1823, that the same plan should be extended to other places, and adopted in other diseases. "In cases of sickness," says he, "and especially in yellow fever, I feel convinced in my own mind, that nothing could prove so beneficial in checking the ravages of this disease, as separating the troops; and particularly by removing them to some distant dry field from the locality of the attack. Nothing could more immediately substantiate the advantages of removing and encamping a body of men, than the result in the Pyramus's crew."

In Barbadoes, where, as I have just observed, the same improvement has obtained a footing, the mortality for the last two years is almost incredibly abated. I have examined the tables subjoined to the annual reports in the office of the Army Medical Board, and have found that, from having been upon an average of seven years, about one in twenty-one of the sick list, in 1822, the mortality was only one in twenty-four; and, in 1823, only one in thirty-five. In this last year, however, it should be observed, that the hospital list was somewhat enlarged by the occurrence of an influenza unaccompanied with much danger; yet the aggregate of patients amounted to not more than about a hundred beyond those of the preceding year. I am ready to allow, that several other important regulations, for which we are equally indebted to the vigilance and judgment of the Army Medical Board, may have contributed to this salutary

change; but the greater part of it is still, perhaps, to be ascribed to the new plan of encamping. I cannot give a better description of the adjuvant regulations I am now referring to, than by adopting the words of Mr. Tegar, an enlightened inspector of hospitals at Barbadoes, who, in his manuscript report for 1823, thus enumerates them, and at the same time confirms the ameliorated health of the soldiers quartered in that station, and to which I have just referred. "The loss in that year," alluding to 1822, or the preceding, "was so comparatively small with former ones, that I hardly hoped to send so favourable a one again. This return, however, exceeds greatly any hopes I could have anticipated; being not one half the average amount of the preceding six years; and not a sixth part of the yearly loss sustained in the fourteen years antecedent to those. There are many reasons for this favourable change: the men are better clothed, better fed, and better looked after by their officers; there are many local improvements in the vicinity of the barracks, which formerly were not much attended to: such as draining swampy and marsh ground; clearing away brushwood and long grass, which harboured moisture, and emitted, at certain seasons, noxious exhalations, producing fever and other diseases, the treatment of which was very different from that of the present day. I believe most sincerely, that we are also indebted for the favourable comparison in the scale of mortality to the improved education of medical men, to the discoveries in the various branches of medical science, and to the rationale of medical practice."* The writer of this work cannot avoid adding his

* Under the head of *epanetus malignus*, Dr. Good has described several forms of fever, which by some clinical writers have been deemed to possess characteristics sufficiently dissimilar to justify a different classification. It is not the province of the editor, however, at any time to interfere with the material arrangement of the book, and more particularly in this instance, as the non-prevalence of *epanetus malignus flavus* in the northern and middle sections of the United States in latter years, has prevented him from observing its nature. He will therefore merely add a few remarks derived from the writings of American authors, who have had ample experience with yellow fever, and whose productions, if they had been within reach of Dr. Good, would doubtless have been mentioned in these pages.

Many American physicians richly deserve a noble reward for their efforts to alleviate public calamity, by their various expositions on the vexed subject of contagion and infection in febrile disorders, and particularly in relation to the malignant yellow fever, as it has occasionally appeared in different parts of our country.

Disclaiming to espouse with implicit confidence the theoretical views of any writers on the Bulam, the malignant, the pestilential, the yellow, or the bilious remittent fever, or to vouch for the accuracy of even our most ingenious native authors, the editor will only refer to some particular sources of information, which should be examined by those desirous of a more extensive and better knowledge of yellow fever than is to be found in the text.

For additional information in respect to the early appearance of yellow fever, besides the sources

already referred to, the reader may consult Hughes' Hist. of Barbadoes, and Towne on Yellow Fever. Dr. Moseley's work on Tropical Diseases contains an able article on the West India Ardent Fever, which he terms the *causus of Hippocrates*, in which opinion he is followed by some American authors. An excellent tract on the West India Disorder, is that by Dr. Fowle on the Ardent Fever, and the same is true of the treatise by Dr. Warren, on the Disease at Barbadoes. The well-known paper on Yellow Fever by Dr. Lining, of Charleston, S. C., in the *Edin. Lit. and Phil. Essays*, and the remarks on the same subject in the History of South Carolina, by the late American historian, Dr. Ramsay, should also command attention. Dr. Rush's several histories of the Yellow Fever, as it has prevailed in the United States, will be found replete with valuable information.—(See his *Med. Obs. and Inq.*, 4 vols., 8vo.) Dr. Samuel Brown published an essay on the Yellow Fever of Boston, in 1800. Dr. Colden's account of the Yellow Fever of New-York, in 1741-2; Dr. Bayley's remarks on the same disease, as it appeared in New-York in 1795; Dr. John Mitchell's description of the same in Virginia (see Francis and Hosack's *Amer. Med. and Phil. Register*), and the talented essays of the late Dr. Edward Miller (*Med. Writings*, New-York, 1814), may be consulted with profit. Professor Potter, of Baltimore, has traced the history of yellow fever from 1607 to 1822. But with the exception of Dr. Rush, no American has written so repeatedly and so largely on this pestilence as Dr. Hosack of New-York. He earnestly contends for its foreign origin, its specific character, and its contagious nature under

conscientious assent to the correctness of these views.*

There is another variety of malignant remittent, which has been known to medical prac-

certain circumstances.—(See his Medical Essays, 3 vols., 8vo., New-York, 1824.) Professor Caldwell, of the University of Transylvania, in his appendix to Alibert on Intermittents, has given an account of the yellow fever in Philadelphia, and many valuable articles on the same subject may be found in the Facts and Observations of the College of Physicians at Philadelphia, and in Additional Facts; also in the Philadelphia Medical Museum of Dr. Coxe, and the Philad. Medical Recorder. Papers on the yellow fever have been published also in the Med. and Phil. Register, edited by Drs. Hosack and Francis, in the New-York Med. Repository of Drs. Miller, Mitchell, and others, and the New-York Med. and Phys. Journal, edited by Drs. Francis, Beck, and Dyckman. The peculiarity of the immunity of the constitution from a second attack of yellow fever was first noticed by Dr. Pym, of London, in 1815, and in June, 1816, Dr. J. W. Francis called the attention of American practitioners to this fact, in a letter dated at London.—(See New-York Med. and Phys. Journal, vol. i.) The reappearance of the yellow fever in New-York in 1822, renewed with much ardour the controversy concerning its contagious character, and a volume of much research, maintaining its specific nature and contagiousness, was published by Dr. Townsend, New-York, 1822. The publications of Mr. Hardie should also be consulted. He has written distinct histories of the disease, as it invaded New-York in 1795–8, 1803–5, and 1822. Other papers on the disease, as it has appeared in the southern and southwestern states, may be found in the different volumes of the Am. Journ. of Med. Sci., in the Transylvania Journ., &c.

The pathology of yellow fever has been advanced by Dr. Physic's account of the results of post mortem examinations, made in 1793; from then, he concludes, that this disease is attended with a high degree of inflammation of the stomach. Dr. Cothrell's analysis of the black vomit may be found in the Trans. of the Am. Phil. Soc., vol. v.

Perhaps no writer has described the pathognomonic signs of yellow fever as distinct from bilious remittent fever, with more philosophical acuteness than Sir Gilbert Blane in his work on the Diseases of Seamen; and some of our ablest writers, who in their views of yellow fever have confounded diseases of different origins, might consult his work with singular profit.

It has justly been remarked, that some forms of bilious remittent fever occurring in the interior of our country, viz., those of great violence and of short duration, resemble the yellow fever very much; hence the unity of these two forms of disease has been maintained. A paper, pointing out the pernicious tendency of this too hasty generalization, drawn up by Dr. Norcom, of North Carolina, may be found in Hosack and Francis's Am. Med. and Phil. Reg., vol. i., p. 17; it throws light on an intricate subject, and is worthy of a close perusal.—D.

* Our author has not spoken of the proposal to cut short the disease by the administration of bark, arsenic, or other antiperiodic remedies, as in intermittent fever. Now, with reference to this suggestion, Dr. Joseph Brown very judiciously observes, that, in order for it to be tried with safety, the remission must be so perfect as to amount to an actual apyrexia, and the disease would then be identified with intermittent fever; and he has almost uniformly noticed, that the employment of

tioners from the time of the Greeks, though less frequent than the yellow fever, and which, by Hippocrates, has been denominated *causus*; as it has by later writers, who have only translated the Greek term, been called *FEBRIS ARDENS*, *ARDENT* OR *BURNING REMITTENT*. From its being usually accompanied with much disturbance of the stomach and intestines, it is called by Professor Frank, *febris gastrico-inflammatoria*, as the last variety is *febris gastrico-nervosa*. In Hippocrates, it is briefly described as a fever, characterized by extreme heat, violent thirst, a rough and black tongue, complexion inclined to yellowish, saliva bilious. There is commonly an acute aching in the head, nausea, great anxiety of the *præcordia*, with frequently a gnawing pain at the stomach. The bowels are unusually costive, particularly at the commencement of the disease. The tongue, mouth, nostrils, and, indeed, the whole surface of the body, are parched, and fiery-hot, whence, indeed, the Greek name for the disease; the pulse is full and strong; the voice hoarse; the breathing short and quick, with sometimes a slight cough, and occasionally delirium.

It chiefly attacks the young and the vigorous, who bear the attack better than old persons. The causes to which it was formerly ascribed are, long exposure to the heat of the sun, great fatigue from undue exercise or labour, or too heating a diet. It has of late, however, been supposed, and with much plausibility, from its frequent occurrence towards the autumnal equinox, and especially from its resemblance to the yellow fever, that, like the latter, its ordinary remote cause is the miasm of swamps and marshes. And if so, it affords us a proof that, under certain modifications, febrile miasm issuing from this source may, as I have already suggested, produce a caumatic or inflammatory, as well as a synochous or typhous tendency, in constitutions predisposed to this character of fever; * for the *causus* is, in fact, whatever be its cause, a vehement inflammatory remittent. It is on this account, that Dr. Mosely conceived the *causus* of the ancients, and the yellow fever of the present day, to be one and the same disease; whence he applies to the latter the Greek name of *causus*. This, however, is not quite correct: for in the real *causus*, the burning heat is more intense, the thirst more intolerable; while the stomach is generally less irritable, and will bear vomiting with advantage: and, in the second stage, the chilliness which, in the yellow fever, is merely accompanied with horripilation, and is a mischievous symptom, in the *causus* is accompanied with a smart rigour, which often terminates in a copious and salutary sweat. The process, moreover, in the *causus*, generally lasts only four days, and is

any antiperiodic in truly remittent fevers not only failed, but invested the disease with a more continued and dangerous character.—Cyclop. of Pract. Med., art. *FEVER*.—Ed.

* Devèze, *Traité de la Fièvre Jaune*, 8vo., Paris, 1820. Saverésy, *De la Fièvre Jaune en générale, et particulièrement de celle qui a régné à la Martinique en l'an 1803–4*.

terminated, when left to itself, by a critical diaphoresis, vomiting, diarrhoea, or nasal hemorrhage; but if the fever be not carried off in this way, it commonly becomes fatal.

We have, nevertheless, satisfactory proofs, that though the *causæ* and yellow fever be not the same disease, both often issue from the same febrile miasm, and sometimes run their race conjointly; the difference depending chiefly upon the idiosyncrasy, or the peculiar condition of the constitution at the time of attack.

Thus, in that most formidable assault of yellow fever which took place at the Mole in St. Domingo, in the autumn of 1796, Dr. Jackson tells us, that "the symptoms of the disease, among a set of men vigorous by nature, and often transgressing the rules of temperance, were *ardent and violent*, with much vascular excitement in the early periods, often subsiding on the third day, and terminating rapidly in black vomiting, and a formidable train of horrors."—(Op. cit., p. 66.) And he has since met with the same form in Spain, which, in effect, constitutes his first division of the Andalusian fever.—(*Remarks on the Epidemic Yellow Fever on the South Coast of Spain*, London, 8vo., 1821.) And, hence, Dr. Chisholm informs us, that "the diseases which originally proceed from marsh exhalations, may be so impressed with the action of irregular temperature as to render them *highly inflammatory*, although the character and nature of the original are so manifest, as to make a mode of treatment suitable to the two diatheses, or rather the mixed diathesis, prevailing in the system, necessary." And, in proof of his remark, he has quoted several instances from the Report of the Army Medical Board, of which that which occurred in the year 1812, at Brimstone Hill, St. Christopher's, is probably most worthy of notice, on account of the topography and general healthiness of the spot, which is described as follows:—

"Situation, N. Lat. 17°—soil light and dry—composition, rock and sand—elevation, six hundred feet—distance from the sea, a quarter of a mile. Barracks exposed to currents of air and strong winds, directed on them by ravines. No swamps in the neighbourhood. Change of temperature sudden, from 70° to 80° and 90° in the course of a few hours. RAIN ABUNDANT. Probable cause, previous hot dry weather, ill-ventilated and ill-constructed barracks, some of them bomb-proof. Epidemic cause unknown; and prevalence of the disease cannot be accounted for."

The cause, however, is not difficult to assign; and, in truth, we have already adverted to it in describing the occasional origin of yellow fever: for, however dry and elevated the situation may be, yet, on the descent of copious and continued rains, such as are here set down, a temporary swamp is very soon produced, and of sufficient power, in hot climates, to generate, even "on a light and dry soil, and a sandy rock," febrile miasm enough for the severest epidemic; and especially where such miasm receives the collateral aid of ill-ventilated barracks, and currents of cold air blowing down long ravines di-

rectly upon the troops while in a state of perspiration; and producing a sudden abstraction of animal heat, more mischievous, perhaps, within the tropics, than on the banks of the Copper-mine river during the snows of the winter season, where, as Captain Franklin informs us, the Chippewayan Indians find them the most detrimental and destructive to life of all the numerous and heavy evils to which they are exposed.—(*Nar. of a Journey to the Shores of the Polar Sea, &c.*, p. 249, Lond., 4to., 1833.)

The fever continued through the winter, evidently in this case kept up by its having become contagious. It was at first confined to one of the barracks occupied by a company of the 25th regiment; and its symptoms are thus briefly but forcibly described:—"Type continued:—thirty-four admissions from this company alone: symptoms, in all, of a most unfavourable character from the first attack; great headache, sickness, and vomiting; pulse full and hard; eyes inflamed; face flushed; ardent heat of the skin; in many cases yellowness of the whole body on the second day of the disease. The entire number of cases was four hundred and twenty-two: of which not fewer than one hundred and eighteen died, affording a mortality that treads close upon the heels of that in the plague."

In the treatment of this variety, the advocates for copious bleeding and for free doses of calomel may shake hands; for both may be allowed with liberality. The calomel, however, is found most successful when combined with antimonials or Dover's powder. Free purging is also to be strongly recommended; the means, in effect, whatever they are, must be vigorous to be of any avail: for the disease itself is of great vigour and rapidity; and, unless prostrated at the onset, will soon prostrate the patient. In conjunction with this process, we may also adopt that of Hippocrates, who, in the burning remittent of his own day, employed cold applications in every way: the coldest possible drinks; and the coldest possible clysters, and ablutum with cold water applied to every part of the body.—(*Περὶ Πυλῶν*, p. 518, lib. 48, 51, p. 419, lib. 37.) Under proper regulations, there is no doubt of the advantage of such a treatment; and the medical process of the continent, as well as that of our own country, throngs with cases in which it has been found serviceable. Marquet recommends (*Observations sur la Guérison de plusieurs Maladies*) the application of cold air as well as of cold water; and gives an instance of a rapid cure in one who, in a state of delirium, exposed himself naked to the cold of the atmosphere out of doors. And on this account Schäffer advises (*Versuche*, i., p. 164), that the patient, in any acute fever accompanied with dry burning heat, should be carried forth from his chamber on a mattress, and thoroughly ventilated abroad. Dr. Jackson would indeed have him ventilated in any way, even on a cart or wagon, if there be no easier conveyance.

In the preceding varieties, the malignant remittent has shown a tendency to an inflammatory or a synchous career. Under particular circumstances, however, it evinces a like incli-

nation to a deep nervous depression, sensorial debility, or a TYPHOUS CHARACTER from the first. And this, whether the febrile miasm originate from a decomposition of marsh or of human effluvium; for the records of medicine furnish us with innumerable instances of both. In the two cases, however, there are a few slight variations in the range and mode of its action, the laws of which I have already endeavoured to lay down as far as we are acquainted with them (p. 343); and hence M. Bally, confounding this variety with proper yellow fever, calls the latter the *American typhus*, and makes two divisions of it, a contagious and an uncontagious, according to its degree of violence.—(*Sur le Typhus d'Amérique, ou Fièvre Jaune, &c.*, Paris, 8vo.) This modification of the disease, therefore, is best distinguished by the name of ASTHENIC REMITTENT.

The epidemics of this kind, accompanied with most mortality, are those which arise from a decomposition of human effluvium in the midst of filth, poverty, or famine, great heat and moisture, crowded multitudes, and a stagnant atmosphere: for here we have almost all the auxiliaries of febrile miasm operating for its production. The remittent epidemics of Cadiz and Malaga seem chiefly to have been of this kind; and they are the common pestilences of dispirited armies, maintaining their ground with difficulty in the midst of great carnage, surrounded by the dead and the dying, reduced to short provisions, and worn out by the fatigues of the campaign. The writings of Sir John Pringle are full of examples of this kind: and Professor de Haen has given a striking description of the same in his account of the contagious epidemic that committed such tremendous havoc throughout the Prussian army, at Breslaw and its vicinity, in the middle of the last century, constituting the disease to which M. de Sauvages has given the name of *Tritæophya Vratislaviensis*. It was peculiarly distinguished by irregular action, great debility, and overwhelming dejection of mind. The lypiria, or coldness of the surface, with which the disease opened, rarely yielded to any general reaction, for the extremities seldom became warm, and were often rigid and convulsive; at the same time that the interior parts burned like a fire; the head and stomach suffered with acute pain; there was great anxiety about the præcordia; and so exquisite a soreness over the entire surface, that the patient had the greatest dread of being exposed to the contact of the external air, a mere change of the temperature being intolerable. De Haen himself at length became a prey to the infection, and his attack commenced as thus far stated. On the fourth day, he tells us, all his symptoms were worse, his feet quite chilled, but his hands red, and agitated with convulsive motions; he had occasional vomitings, and was terrified with the image of impending death. On the eighth day the pulse was convulsive, and he was continually crying out from his pains. On the ninth, delirium, and a rejection of grinous blood from the stomach. On the eleventh, perspiration and a

tranquil pulse, but the voice was broken, the speech was interrupted, and the teeth grated. On the twelfth, the jaw was convulsed, there was a sardonic laugh and deafness. On the fourteenth, an icy coldness covered the whole body, accompanied with a cold sweat, but a frequent use of ablutions afforded relief. On the eighteenth, he had a vivid delirium, but fainted on being taken out of bed; which was succeeded by hunger, copious sweats, and profound sleep, with an intolerance of noise. At this time, every thing appeared new and extraordinary; a feeling described by many sufferers as soon as the violence of the disease begins to abate, and which Dr. Pinckard has very strikingly noticed in his own case. The symptoms varied considerably from this period, and he had still many dangers to contend with. He recovered, however, though very slowly, and with numerous drawbacks; for, on the thirty-sixth day, he had a cholera, and on the forty-eighth, his skin scaled off and he lost his nails.

Towards the close of the disease, the skin was covered with a scabid or ichorous eruption, rather than petechiæ; evidently from debility of the capillaries: a fact that has often occurred even in the slighter attacks of this variety of remittent in our own country, when it has occasionally broken out, as in 1765, among the troops stationed in the vicinity of Portsmouth, and is particularly noticed by Dr. Lind. In this last case, it was often suspected to be the itch, to which it had a very near resemblance: and it is highly probable that, in many instances, it was so, and that the *acarus scabiei* found, in the sores, a convenient nidus for the deposit of its eggs.

There are situations, however, in which the febrile miasm, producing this low variety of remittent, is generated by a decomposition of the stagnant matter of humid marsh-lands; such chiefly are the regions about Cape Coast, in Africa, especially when visited by the foul and smouldering harmattan, and about Gombrow, or, as Sir John Chardin calls it, Bander-Abassi, on the Gulf of Persia (*Voyage du Chevalier Chardin, &c.*, tom. ix., p. 511-518): in which last place the mortality is so severe between the months of April and September, that the deaths are ordinarily calculated at nine out of ten of the inhabitants, and this notwithstanding that most of them retire during such period towards the mountains, and all mercantile concerns are relinquished; so that, says the chevalier, "la moisson est fermée, comme un parle." The diseased are commonly removed higher up the country as soon as they sicken; but, whether removed or not, they usually die in four or five days.

There can be no doubt, that, in both these places, the danger of the disease may be augmented by the dense and stinking vapour that is perpetually blowing upon them during the pestilential season, the "puantes vapeurs de la mer," as Sir John expresses himself, "qui font bondir le cœur la première fois qu'on les sent." These, on the African coast, are innegated from the impenetrable mangrove swamps of the

interior of Guinea, and on the Persian, from the saline and sulphurous exhalations of the several adjoining islands, which the winds of the season pass over in their periodical sweep; and the copious disengagement of hydrogen, whose presence the intolerable stench seems to indicate, will account in no small degree for the deficiency of living power, which so peculiarly distinguishes the malignant remittent in these quarters. In the latter region, indeed, some such debilitating influence seems to operate habitually: for the ingenious author thus quoted adds, that "the nations carry in their complexion and constitution the proofs of their malignant atmosphere, being yellow and ghastly from the age of twenty-one, and decrepit at thirty." Of the destructive power of such vapours, we have sufficient proof from what occurs on the coast of Batavia, and the islands that immediately surround it: for if, by judicious treatment, a patient in this quarter should become convalescent from an attack of yellow fever, he is still almost certain of falling a prey to the disinvigorating and deliquescent influence of the noisome exhalation by which he is surrounded, and especially between sunset and sunrise, unless timely removed to a more salubrious quarter.

We may hence readily conceive how yellow fever may, under certain circumstances, have a strong tendency to the same asthenic character, and run rapidly into a typhous form, or be combined with its symptoms from the first.

This is, in truth, the hybrid disease of Sir Gilbert Blane, Dr. Lemprière, and Dr. Dickson. "In certain seasons," says Dr. Jackson (*Op. cit.*, 277), "in certain situations, and in certain periods of the year, the character of the ENDEMIC is insidious and malignant. The disease under those circumstances often begins regularly as a single tertian; and two, and sometimes three revolutions pass over without giving any alarm to ordinary observers: but at one or other of the above periods, a paroxysm commences with coma, stupor, and suspension of functions, threatening immediate destruction: or, as often happens, the energy of action becomes less and less distinct in every succeeding paroxysm; the skin becomes dry, or damp and greasy, the powers of life are overwhelmed, the pulse contracts itself, or becomes apparently weaker and weaker under the use of bark, wine, and the strongest stimulants of the materia medica." His second form of the Andalusian fever of 1820, is precisely to the same effect.—(*Remarks on the Epidemic, &c., on the South Coasts of Spain*, 1821.)

It is to this variety of the endemic of inter-tropical regions, that Dr. Chisholm has given the name of *malignant pestilential fever*. "It must be kept in mind," says he (*Op. cit.*, p. 167), "that this, the most tremendous of all the tropical diseases, wherever it appears, is the typhus of Europe, grafted on the yellow remittent fever of the torrid zone, or of countries whose climate, during part of summer and autumn, possesses the temperature of the torrid zone."—"It is evident," says he in another place (p. 43), "that typhous infection does

exist, perhaps does originate, within the tropics. How fraught with mischief, therefore, is that theoretical notion, that such infection cannot exist, cannot originate, and cannot be propagated in hot climates. Let the young and unexperienced practitioner guard himself against it, and be prepared for it when he meets it."

Dr. Chisholm offers a variety of examples in proof of this assertion, to several of which he had been an eyewitness, especially to that which is so well known to have broken out in the unfortunate attempt to colonize the Island of Bulam, in the spring of 1793, and which gave rise to the fever of this name, so strikingly characterized by its asthenic signs. He has noticed others also, of nearly equal demonstration, extracted from the reports communicated to the Army Medical Board of our own country. But, perhaps, none offer more striking proofs of this peculiar type than the Edam remittent of 1800, described by Mr. Shields, and that of Trinidad of 1819, described by Dr. McCabe.—(*Edin. Med. and Surg. Journ.*, Oct., 1819.) In the former of these, the marks of an extreme debility were often peculiarly impressive from the first. The patient, with little previous notice, was seized with giddiness and cold chills, great sense of weakness, pain over the orbits and in the epigastrium, together with vomiting. He frequently fell down and was insensible during the paroxysm, his body covered with a cold clammy sweat, except the pit of the stomach, which always felt hot to the palm of the hand; the pulse was small and quick; great torpor in the intestinal canal; the pupil dilated and incontractile; great despondency at first, then low delirium or insensibility to danger. The patients, while on the island, were carried off in eighteen, twenty-four, thirty, or forty hours: though often, when removed, not till after as many days. So malignant, indeed, was this pestilence, that "almost every one who slept on the island a single night died." The organs chiefly affected were first the brain, and in succession the stomach and liver. In the Trinidad remittent, so reduced was the vital energy, that it was found necessary, in various instances, to give the patient three bottles of brandy in less than twenty-four hours, and to continue this proportion for several days.

The treatment has here varied as much as in yellow fever; in truth, it ought to vary—not, indeed, according to preconceived and general hypotheses, whose only variance consists in fighting general rules against general rules, but in modifying the plan, whatever it may consist in, to the peculiar case.

Bleeding, however, must never form a part of the general practice, how necessary soever it may be in particular instances where atonic congestion may oppress the head or any other large organ. And even in such instances, it will generally be found more expedient to employ calomel in large and repeated doses, than the lancet, unless we see the patient at the very opening of the disease. Under either practice, the bowels must be opened, and kept open by active purgatives; since, from this

general disturbance of the functionary balance, there is violent action in the abdominal viscera, while the vessels on the surface are entirely torpid. To restore this balance should be our uniform effort: and hence, in conjunction with the above, nothing bids fairer, or has in fact been found more successful, than the use of warm diaphoretics with opium. Cold water as a beverage, or in the form of injection, has also proved a highly refreshing tonic; frequent potations of old hock still more so. The bark is a doubtful remedy, for it often sits uneasy on the stomach, and is rejected. It has hence fallen into undeserved disrepute. When, however, it harmonizes with the stomach, and is retained without oppression, it is entitled to all the praise that has been bestowed on it by former writers, and cannot be given too freely. The best preparation of it for the present purpose is undoubtedly the sulphate of quinine. Ablution with cold water has been tried very generally during the malignant remittents of most climates, and always with very great advantage.—(*Epidemia verna quæ Wratislaviæ, anno 1737, afflixit. Vide Act. Nat. Curios., tom. x.*)

SPECIES III.

EPANETUS HECTICA.

HECTIC FEVER.

PULSE WEAK; STAGES OF CHILLINESS, HEAT AND SWEAT VARIOUSLY INTERMIXED, AND SOMETIMES SINGLE; COLD STAGE EXHAUSTING; EXACERBATION CHIEFLY IN THE EVENING.

THE symptoms of this species, except in its sweating stages, are far less violent, and consequently its duration is far longer, than that of either of the preceding. Nothing, however, can more fully prove its complexity and irregularity, than the different characters given of it, and the different places allotted to it by different authors. Sauvages and Sagar introduce it into the list of continued fevers: Linnæus, Crichton, and Parr, into the present division, or that of remitting and exacerbating fevers: Boerhaave regards it as of a mixed nature, a continued intermittent. "Febris hectica," says he, "est referenda ad febres continuatas intermittentes." Vogel and Cullen degrade it into a mere symptomatic affection. "As I have never," says the latter, "observed a fever of this kind except when symptomatic, I could not consent to admit it into the list of idiopathic fevers, which alone ought to be enumerated."

Those who have adopted Dr. Cullen's opinion, have usually contemplated it as a mere effect of absorbed pus. Dr. Heberden seems to think it dependant upon a local cause, but that irritability in any diseased organ, which cannot be brought into a healthy state, will excite it as effectually as pus introduced into the system.*

* The late Dr. Thomas Young, when a boy, had every symptom of tubercles in the lungs, accompanied by hectic fever; but they never attained the stage of suppuration.—See his *Practical and Historical Treatise on Consumptive Diseases*, de-

On the contrary, Galen, Mr. John Hunter, and Dr. Willan contend, that hectic may be, and often is, a strictly idiopathic affection. The second of these valuable writers regards hectic fever as of two sorts, symptomatic and idiopathic.—(*On Blood*, part ii., chap. ix., sect. 1.) The first he ascribes entirely to local irritability, and opposes the idea that it is ever produced by absorbed pus. His argument is, that if absorbed pus be capable of producing it in one instance, it ought in every instance: but this we know is not the case; for we have had large buboes and even empyemas removed by absorption suddenly, and yet no hectic has taken place. He does not think that more pus is absorbed during the existence of hectic fever, than when no such fever is present: but, admitting that this should be the case, he would rather ascribe the increased absorption to the hectic constitution operating upon the abscess or sore, than to the abscess or sore operating upon the constitution; in which case the hectic diathesis is the cause, and the increased absorption is only the effect. So that, even here, he regards the hectic as a primary or constitutional disease.

As a symptomatic affection, however, he refers it to a general irritability of the constitution, produced by sympathy, in consequence of "some incurable local disease of a vital part, or of a common part when of some magnitude;"* and which becomes incurable from two causes; firstly, because, though the local irritation is small, the constitution is bad, and does not dispose the parts to a healing state: and, secondly, because, though the constitution is good, the local irritation is so considerable, that it cannot muster up a sufficiency of remedial energy to subdue it; and hence, while sympathizing in the irritable action, falls a prey to its own efforts.

Yet, says he, it is possible for hectic fever to be an original disease of the constitution; for the constitution may fall into the same mode of action without any local cause whatever, at least that we know of. And in this manner he accounts for its existence as an idiopathic affection. And, in effect, nothing is more common than for hectic fever to exist in patients in

duced from Original Observations, and collected from Authors of all Ages, 8vo., 1815.—Ed.

* The period at which the commencement of hectic fever takes place from local irritation or disease, and also the severity of it, are influenced very much by the seat of the original affection, as well as by its nature and extent. "The system will much more readily sympathize with an abscess, or other disease of a vital organ, such as the lungs, heart, liver, stomach, intestines, mesenteric glands, or kidneys, than with a similar disorder, existing in the muscular or cellular tissue, near the surface of the body." Diseased lungs will more quickly bring on hectic symptoms than diseased joints; though, the power of joints to repair some of their injuries and morbid changes, being very inferior to those of many other parts, their diseases are often tedious, and frequently incurable, so that we cannot be surprised to find them often associated with hectic disturbance of the system.—Ed.

whom we can trace no local cause whatever : and, in all such cases, we must either indulge in a gratuitous hypothesis, and throw our suspicions at random upon the lungs, or the liver, or the kidneys, or the heart, or the mesenteric glands, or whatever other organ a few casual symptoms may suggest to the fancy : or we must at least act upon the principle of its being an idiopathic affection, even though we should refuse, in terms, to admit that it is so.

"I willingly subscribe," says Dr. Percival of Dublin, in his manuscript comment upon the author's Nosology, "to idiopathic hectic, and have known it to last three months without any pulmonary affection, and then to break out in the lungs."*

There seems, indeed, great reason for admitting, with Dr. Stoll (*Praelect.*, p. 19), a *habitus phthisicorum*, a hectic diathesis or temperament, the features of which are, for the most part, strongly marked, and are to be found in a fair skin, blue eyes, yellow hair, lax fibre, and sanguine disposition. And, wherever this exists, it is probable that most of the causes of other fevers, operating upon it, will produce a hectic.† And we can hence readily account for the examples cited by different authors of its being produced by diseased actions or affections of the heart, stomach, mesentery, liver, pancreas, lungs, or brain ; by a suppression of various exanthems, or other eruptions, or of various habitual discharges, natural or morbid ; by other fevers ; by chronic inflammations or abscesses. It is well known to be a common sequel to the measles, occasionally so to the

smallpox, and, in a few instances, to rosalia, or scarlet fever. It may, hence, be a result of dyspepsy ; and one case is said to have been produced by eating bacon, which remained undigested in the stomach for a term of eighteen months, when it was disorged by sickness, and the hectic symptoms disappeared.—(*Arnold, Diss. de Hecticâ Stomachâ*, 1743.) And it is hence possible that hectic fever may occasionally spring, like other remittents, from febrile miasm.*

The character of the disease is well given by Mr. John Hunter in the following words :—"Hectic may be said to be a slow mode of dissolution ; the general symptoms are those of a low or slow fever, attended with weakness, but more with the action of weakness than real weakness ; for, upon the removal of the hectic cause, the action of strength is immediately produced, as well as every natural function, however much it was decreased before. The particular symptoms are, debility ; a small, quick, and sharp pulse ; the blood forsaking the skin ; loss of appetite ; often rejection of all aliment by the stomach ; wasting ; a great readiness to be thrown into sweats ; sweating spontaneously when in bed ; frequently a constitutional purging."—To which he adds, "the water clear." There is, in reality, much difference of opinion upon this last point. Dr. Heberden has observed, that the same irregularity which accompanies most other symptoms of the disease, attends this also ; that the urine is equally clear or turbid in the exacerbations and the intervals ; sometimes clear in the first and turbid in the second ; and sometimes turbid in the first and clear in the second ; while Dr. Duncan, from long and assiduous attention, asserts, that the urine is peculiarly distinguished by a natural furfaceous separation. Such is the character it has usually exhibited in my own practice ; though, where authorities thus clash, it is not a symptom to be depended upon as a pathognomonic.

From the frequent approaches which the hectic makes towards a perfect pyrexia, it is sometimes apt to be confounded with an intermittent ; but there is rarely any remission in which the pulse is not at least ten strokes in a minute quicker than it ought to be ; and by this it is sufficiently distinguishable, as it is also by the greater irregularity of its different stages, and, indeed, of all its symptoms.

It is owing to this last feature that, sometimes, the exacerbation commences with a chilly fit, and sometimes without ; and that, where there is a chilly fit, sometimes it is immediately succeeded by heat, but sometimes by perspiration, without any intervening hot fit ; while occasionally the cold fit only leads to heat, or even terminates singly without either heat or perspiration. Hence the exacerbations must vary in duration : but even where every stage is pres-

* With regard to this case, the editor fully coincides with the remark made on it by Dr. Joseph Brown. "From the extreme difficulty of detecting the presence of tubercles in their unsoftened state, even with the improved method of diagnosis now employed, is it not reasonable to conclude, that these bodies had existed in the lungs undetected, and produced the fever ; since we find this affection, which of all is most frequently attended with hectic, ultimately displaying itself by manifest signs ?" Some years ago Dr. Brown saw a case of apparently idiopathic hectic, which proved fatal : on examination of the body, small abscesses were found in the muscular substance of the heart.—*Cyclop. of Pract. Med.*, art. FEVER, p. 246.—ED.

† These are the commonly described emblems of a scrofulous habit in which tubercles, and other forms of local disease, are frequent. Instead of adopting the author's hypothesis, and that of idiopathic hectic, it would be more correct to regard hectic fever as a protracted constitutional disturbance, excited and kept up by some local irritation or disease, which is either not immediately curable, or totally incapable of relief. Mr. Hunter considered hectic fever as the remote consequence of a local injury or disease, contrasting it with sympathetic inflammatory fever, which he sets down as the immediate or earlier effect on the system. He also divides hectic fever into two kinds ; one depending upon a disease which would be curable, if the constitution had strength enough to bear the struggle ; the other arising from a disease that is absolutely incurable. When Mr. Hunter speaks of spontaneous hectic fever, he seems to mean really nothing more, than that the cause of it is not apparent.—ED.

* Hectic fever may follow visceral disease, brought on by other fevers, but certainly it cannot be correctly stated to be in any instance directly brought on by febrile miasm.—ED.

ent, and succeeds in regular order, the duration of the entire exacerbation is almost equally uncertain, inasmuch that it is seldom that three exacerbations of equal length recur in succession. The remissions will sometimes extend to ten or twelve days, without a single intervening pyretic symptom: and sometimes the cold or the hot fit, or the sweating, will be renewed several times in the same day. Yet, let the perspiration appear whenever it may, the patient is never relieved by it, but is as anxious and restless during its continuance as in the heat or chill.

Dr. Heberden (*Trans. of the College*, vol. ii., art. i., p. 6) has sometimes seen a hectic attack persons who seemed in tolerable health, in a sudden and violent manner, like a common inflammatory fever: and, like that, in a little time bring them into imminent danger of their lives; after which it has abated, and afforded hopes of recovery. But the hopes have been deceitful; for, the hectic has still been fed by some lurking mischief; some concealed local disease; and, resisting the power of medicine, has gradually undermined the patient's health and destroyed him.

More commonly, however, hectic fever commences slowly and insidiously, and is not suspected for some months: and the only symptoms noticeable are, lassitude upon slight exercise, loss of appetite, and a wasting of the flesh. But, if these symptoms be connected with a general increase of pulse, so that the artery beats from ninety to a hundred or a hundred and twenty strokes in a minute, there will be real ground for apprehension.

This is one of many diseases, in which the art of medicine has hitherto laboured in vain to strike into any direct track of cure. The real cause is commonly involved in great and impenetrable obscurity, and we can do little more than attack single symptoms as they make their appearance.

Where the disease is evidently symptomatic, the case must depend upon curing, or, if incurable, upon removing, when this can be accomplished, the part affected. When idiopathic, we must combat, as far as we are able, the irritable diathesis; and, above all things, endeavour to strengthen, without increasing, the action of the machine. The best sedatives as well as tonics are acids, and of these the vegetable will usually be found preferable to the mineral, since, on account of their corrosive property, the latter can only be taken in small quantities. They abate the febrile heat, diminish the restlessness, and frequently succeed in checking the night-sweats. And if, as is often the case, the patient be tormented with pains in the limbs or joints, resembling rheumatism, and preventing him from sleeping, we may combine the acids with opium. The bowels must be kept regular by gentle laxatives, and the neutral salts seem to answer this purpose better than most others. It will, however, be convenient to vary them occasionally, and sometimes to exchange them for the senna confection, or some other aperient.

Stimulants rarely answer any good purpose; and, in many instances, evidently heighten and accelerate the exacerbation. The Peruvian balsam has been given advantageously with nitre; but myrrh is a medicine of fairer promise; and beyond these, we can scarcely ever venture to proceed.

The lighter bitters are certainly serviceable in many cases, and may conveniently be employed in combination with the acids; but bark, though tried in numerous instances, and with great perseverance, has not been found successful. Dr. Heberden, however, says, that he never saw it do any harm in the hectic fever, and his opinion is confirmed by that of Sir Edward Hulse, after having prescribed it for forty years. Yet neither of them ever obtained proofs of any beneficial result.*

A light and regular diet, regular hours, and gentle exercise, are coadjutants of great importance. When the disease is dependant upon some local affection, the Bath waters have often afforded a palliative degree of relief; but in idiopathic cases, they usually augment the fever, aggravate the patient's sufferings, and hasten his death.

GENUS IV.

ENEZIA.

CONTINUED FEVER.

ONE SERIES OF INCREASE AND DECREASE; WITH A TENDENCY TO EXACERBATION AND REMISSION, FOR THE MOST PART APPEARING TWICE EVERY TWENTY-FOUR HOURS.

WE now enter upon the important genus of continued fevers, or those which run their course, not indeed without any change or relaxation whatever, as many of them were supposed to do formerly, and were distinguished by the term *continentes*, but with occasional and slight fluxes and refluxes, which bear the same proportions to the exacerbations and remissions of the epanetus, as these do to the paroxysms and intervals of the anetus, or intermittent. When there are two tides or fluxes within the twenty-four hours, the one occurs in the morning, and the other in the evening. The last is always the most distinct; and takes place usually between five and six o'clock, which is somewhat later than the latest of the paroxysms of genuine intermitting fevers; that of the quartan, which is the latest of the whole, usually occurring before five o'clock. It should also be farther observed, that, where continued fever discovers but one augmentation in the twenty-four hours, it is always that of the evening. Dr. Fordyce attempts to show that, even in a state of the firmest health, we constantly discover some tendency to a little febrile affection every evening; this he calls the natural evening paroxysm of fever; and to this habit

* The lighter preparations of bark, as the sulphate of quinine, and the infusum cinchonæ, are often found to be eligible tonics in hectic cases; yet they cannot be expected to accomplish much good, if the cause of the constitutional disturbance continue undiminished, or unremoved.—ED.

he ascribes the existence of an evening increase of continued fever.

The genus thus defined and characterized, includes the three following species:—

1. *Enecia Cauma.* Inflammatory Fever.
2. ——— *Typhus.* Typhus Fever.
3. ——— *Synochus.* Synochal Fever.

Sauvages draws a line of distinction between these three from their respective duration, as well as from their more essential symptoms, affirming that the *cauma* terminates in a week at the farthest; the *typhus* in two, though sometimes protracted to three weeks; while the *synochus* reaches beyond the second, and often beyond the third week. As a general rule, this remark is worth keeping in mind; but, the deviations from it, in all the species, are too frequent to enable us to lay hold of it in assigning their specific character.

SPECIES I.

ENECIA CAUMA.

INFLAMMATORY FEVER.

HEAT GREATLY INCREASED; PULSE QUICK, HARD, AND STRONG; URINE RED; DISTURBANCE OF THE MIND SLIGHT.

This species has been distinguished by a variety of names by different nosologists and other medical writers; the chief of which are, *imputrid synochus*, which is that of Galen; *imputrid continued fever*, which is that of Boerhaave; *imputrid continens*, which is that of Lommius; *sanguineous continued fever*, which is that of Hoffmann; and *synocha*, which is that of Sauvages, Linnæus, Cullen, and most writers of the present day. Of these, *Synocha*, for reasons stated in the comment to the Nosological Synopsis, is the worst; it has no clear or correct etymological meaning; it has been used in different senses by different writers, and approaches so nearly to *synochus*, used as extensively by most of the same writers, as to create a perpetual confusion in the minds of young students; and the more so, as the disease before us is expressly denominated *synochus* by Vogel, while most writers employ this term to import a different species of fever. On all which accounts, I have judged it right to exchange *synocha* for *cauma*, a term already employed for the same purpose by Dr. Young, and which, derived from, *καίω*, “uro,” is etymologically significant of the character of the disease it designates. The common English term, *inflammatory fever*, is excellent; and is, in truth, a direct translation of the Greek term *cauma*. Dr. Fordyce denominates it *general inflammation*: by which he clearly intimates, that this species of fever bears a near resemblance to the symptomatic fever produced by the local affections called phlegmasiæ, or phlogica, which constitute the next order of the present class, to which the term *inflammations* is now commonly limited; but which Dr. Fordyce would distinguish by the term “*local inflammations*.”

In effect, inflammatory fever and the fever

of inflammations bear the same relations to each other, as the idiopathic and symptomatic hectic: in both, there may be a general or a local remote cause; but, the influence upon the constitution will be the same, whatever be the source of excitement. It has been doubted, however, whether *cauma* or inflammatory fever ever exists without a local cause; and Dr. Cullen, who does not allow that hectic fever is ever found without a local cause, distinctly affirms, that he has never seen inflammatory fever existing under the same circumstances; whence Dr. Clarke, of Newcastle-upon-Tyne, who has too much generalized the subject, has struck inflammatory fever entirely out of the list of diseases, contending, that even the term inflammatory ought never to be applied to fever, excepting when fever itself only exists as a concomitant of some local affection: * while Dr. Clutterbuck, as we have already observed, has contended, that this local cause is at all times, and under every variety of fever, an inflammation of the brain. If, however, a cause of this kind be ever fairly made out, a variety of facts, of late detection, will be far more likely to fix it in an inflammation of the arteries, the ARTERITIS of the French writers, who have recently examined the subject at considerable length, especially MM. Portal (*Cours d'Anatom. Médic.*, tom. iii., p. 127, 1804), Dalbanc, and Vaidy (*Dict. des Sciences Médicales: Journ. Complément.*, vi., Août, 1819); and to which Dr. Frank has, indeed, already ascribed inflammatory fever in one of its forms.—(*De Cur. Hom. Morb. Epit.*, lib. i., § 118, 8vo., Manheim, 1791.) But the subject is still involved in great obscurity, as it is doubtful whether the change of arterial structure, which has been found after death in many cases of supposed arteritis, has been really an effect of inflammatory action. In acute rheumatism, it is probably a frequent cause or concomitant; but this is a question we shall have occasion to return to under that disease. How far either hectic or inflammatory fever may, under particular circumstances of human or atmospherical constitutions, occasionally originate from marsh or contagious miasm, it is difficult to determine; but as Dr. Cullen was peculiarly desirous of reducing all fevers to these two sources; and as, to say the least, they are not obvious sources of either of the diseases in question, his mind appears to have received some bias from this fact in rejecting them from the list of idiopathic fevers. And as it has already been shown that this decision has laid a foundation for much of that “tug of war” in which many

* Observations on Fevers, &c., 8vo., London, 1779. Though Dr. Tweedie does not distinctly represent this fever as being essentially connected with local inflammation, as a cause, he observes, that “it is necessary to bear in mind the local inflammations which almost invariably arise in the course of these acute fevers, and the effect of such complications on the febrile symptoms.”—See Dr. Tweedie's Treatise on Continued Fever and its Modifications, p. 49, 12mo., Lond., 1832.—EDITOR.

distinguished members of the profession have of late years been engaged, respecting the nature and treatment of particular species of fever, it is highly probable, also, that several of the more recent hypotheses, concerning its proximate cause, have originated from the same spring.

Inflammatory fever, as it has often occurred in the author's own practice, and in that of others who have described it, usually commences with the symptoms of an acute ephamera, and may in fact be contemplated as the same disease running on from four or five to about eleven days, without intermission, or a renewal of the cold fit. It commences with a sense of languor and inaptitude for exertion, with a disrelish for food, which continues for a day, or perhaps two. There is then chilliness and soreness over the surface, with nausea and headache, succeeded in the evening by a great increase of heat, and at night by perspiration, with great thirst, restlessness, and sometimes delirium; sometimes, in young persons, convulsions, with a stupid drowsiness. The bowels are usually costive, the urine high-coloured, and the pulse quick and hard.

With Dr. Fordyce, the grand pathognomonic symptom of cauma is hardness of the pulse. This accompanies it from first to last, in its simplest and in its severest state. When the disease is mild, it is hard alone; when more violent, it is at the same time full, strong, and frequent. The obstructed pulse is often confounded with the hard, and it is not easy to distinguish them without considerable practice. There is rigidity of resistance to the finger in each, but of a different kind. In the hard pulse, it is much firmer and tenser; and is supposed by Dr. Fordyce to result from such an increase of arterial contraction as to overbalance its correspondent dilatation. It indicates, in his opinion, a very high degree of living power, and is peculiarly characterized by a tardy coagulation of the blood when drawn freely into a hemispheric basin, in consequence of which the red particles have time to subside, and leave the surface colourless, or with a buffy appearance. In the obstructed pulse, on the contrary, the blood coagulates at once; and, the red particles not having time to separate, the surface is of the same hue as the cake below.

The disease sometimes terminates abruptly with a critical sweat, or some other evacuation, on the fourth or fifth day; but more usually increases in violence, though with occasional declinations, for a week longer; during which time the pulse rises to a hundred, or a hundred and ten strokes in a minute, but continues regular; the nausea subsides, and the patient will take and retain whatever is offered to him of simple nutriment or medicine; the thirst is less violent, but the tongue is deeply furred, and the lips are parched.

The disease is not often dangerous; and about the eleventh day gradually subsides, or yields to some critical discharge, which is usually that of a free and alleviating perspiration.

The pulse soon sinks to eighty, and the chief symptom is weakness.

During the course of the fever, every organ suffers from its morbid and increasing impetus; but they do not all suffer alike: for in some parts there is, occasionally, a greater resistance to the flow of the circulating fluid than in others, whence that acute pain, which is often complained of in the head or the side: in the latter case, sometimes amounting to pleuralgia. And, not unfrequently, the vessels of one part will give way more readily than those of another, and there will be a sense of heaviness and oppression in the head, the heart, or the lungs; as though some effusion had taken place, which, in some instances, is perhaps actually the case. If the head be much affected, delirium is a frequent result, with ravings and violence, rather than the low muttering incoherence of asthenic fevers.

From the history already given of the malignant causus, or ardent malignant remittent, it appears probable, that inflammatory fever may sometimes be produced from febrile miasm, though it is commonly derived from other sources. Of these, the stimulus of violent passions is, perhaps, one of the most common; and especially upon a vigorous and plethoric habit, which is the usual temperament in which inflammatory fever makes its appearance. Undue muscular exercise, heating foods, or excesses of any kind in the same habit, are also frequent causes; while another may be found in the suppression of any accustomed discharge, as that of menstruation, epistaxis, or periodical bloodletting. Suddenly suppressed perspiration is, in like manner, a frequent, perhaps the most frequent cause of any; especially when the body is very hot, and the change is effected by exposure to a temperature of great cold, applied externally or internally, as that of a current of cold air, a large draught of cold water, or plunging into a river.

Some writers, as Sennert and Crichton, have supposed inflammatory fever to be occasionally produced by an absorption of bile into the bloodvessels under the excitement of a tropical sun, or of a torrid summer in milder regions; and they suppose that the bile is, in this case, possessed of a more than ordinary degree of acrimony, and that the symptoms are varied by a more pungent heat and more intolerable thirst, with a more scanty secretion of urine, preternaturally acid and high-coloured.

That bile of this description is often forced back into the system under the circumstances here supposed, is unquestionable; as it is also that inflammatory fever is a frequent accompaniment of this morbid change. But, notwithstanding the above authorities, such fever seems less attributable to the reflux of bile into the blood, than to the insolation or solar excitement; which, by unduly stimulating the liver, has been the cause of an overflow of bilious secretion. How far a more irritant or exalted acrimony may be communicated to bile thus operated upon, or what may be its effect upon the system, admitting it to take place, it is dif-

ficult to determine ; but there is much reason to doubt whether genuine bile in the sanguiferous system is ever a cause of fever, or stimulates the heart or arteries to increased action. For if this were the case, jaundice would always be accompanied with inflammatory fever. Instead of which, however, we find it accompanied with atony instead of entony, or diminished instead of increased power.*

Sauvages gives a case, in which inflammatory fever was produced by a mechanical irritation of the meninges of the brain, by a lodgment of vermicles in the frontal sinus, of which seventy-two were discharged during a fit of vomiting and sneezing, from which time the patient began to recover.

These vermicles were most probably the larvae of some species of the cestrus, or gadfly, which had crept up into the frontal sinus, after being hatched in the nostrils, in which the parent insect had deposited her minute eggs. This is a very common affection in grazing quadrupeds, and especially in sheep, which are often peculiarly tormented, and sometimes driven almost mad, by the violence of the irritation.

Stoll gives a case in which the brain, on examination after death, was found deluged with serum—*diluvium serosum*.—(*Mat. Med.*, iii., p. 294.) But such an appearance is rather to be regarded as an effect, than a cause of the disease ; as an instance of *cephalitis profunda*, in consequence of the brain having suffered more than any other organ from the inflammatory impetus.

Hence the following varieties are noticeable under the present species :

- | | | |
|---|---|---|
| a | Plethoricum.
Plethoric inflammatory fever. | Produced in a plethoric habit by great mental or muscular excitement, or heating foods ; or by a sudden suppression of perspiration, or of other accustomed discharges. |
| β | Biliosum.
Bilious inflammatory fever. | Accompanied with an excessive secretion of bile, absorbed into the sanguineous system. |
| γ | Pleuriticum.
Pleuritic inflammatory fever. | Accompanied with a violent stitch or pain in the side. |
| δ | Cephalalgicum.
Cephalalgic inflammatory fever. | Accompanied with acute pain in the head. |

As an inflammatory diathesis constitutes the essence of this fever, the cure must depend altogether upon a reduction of the vascular, and especially of the arterial entony : always bearing in mind the possibility, that the disease may suddenly lose its inflammatory character, and rapidly pass into that of a typhus. Regulated by this view, we should generally commence with bleeding and cooling purgatives. There are a few cases, indeed, in which bleeding may

be dispensed with, as when the habit is by no means plethoric, and the pulse is obstructed rather than hard ; but these are cases that rarely occur. Diaphoretics, or relaxants, as they are denominated by Dr. Fordyce, may then be employed with advantage. Of these, the tartarized antimony, the antimonial powder, or James's powder, are chiefly to be relied upon ; and may be given alone, or, which is often better, in saline draughts ; and particularly those formed of the acetate of ammonia. And it may not be amiss to observe here, that the acetate of ammonia is sometimes prepared in the form of crystals, and sits more easily on the stomach in this than in any other shape. When given as a liquid, it is of importance that the solution should retain the carbonic acid gas of ammonia as largely as possible ; and, for this purpose, the union should take place in a strong close vessel. According to Bergman, nearly half the weight of ammonia depends upon the quantity of this gas which it contains : so that in a pint of the solution of the acetate of ammonia, comprising four drachms of the latter, there will be extricated, if made in the manner here recommended, little less than a hundred and sixty cubic inches of air.

As the stomach is for the most part but little affected, emetics, if used at all, can only be employed for the purpose of determining to the surface ; but, as we can do this by the antimonial and other diaphoretics just referred to, as also by diluent drinks, it is hardly worth while to irritate the stomach in order to accomplish the same purpose. Perfect rest of body and mind, a reclined position, and a light liquid diet, destitute of all stimulants, are also indispensable towards recovery. The air should by all means be kept pure by being constantly renewed, though without a sensible current ; the temperature cool ; the clothing light, and as often changed as may be necessary to maintain cleanliness ; and the beverage, toast-water, lemonade, or cool tea.*

* Our author has here omitted all notice of cold affusion, the advantages of which, in the acute or inflammatory forms of fever, have been acknowledged by almost every writer. The effect of it is to diminish the heat of the body, to lower the pulse, and to bring on perspiration and sleep. As a general rule, the sooner the affusion is applied after the irregular chills of the first stage are over, the better, provided the heat of the skin is steadily above the natural standard. Dr. Currie deems the safest time for it to be that when the exacerbation is at its height, or immediately after the commencement of its declination. At this period the heat rises one or two degrees in the central parts of the body, and still more in the limbs. Dr. Currie, therefore, generally directed affusion to be employed between six and nine o'clock in the evening. It is never to be resorted to when any considerable sense of chilliness exists, notwithstanding the thermometer may indicate an augmented temperature of the body. Neither ought it to be adopted when the heat, measured by the thermometer, is less than, or only equal to, the natural heat ; nor when the patient is perspiring profusely. Dr. Tweedie informs us, that he has never seen a single case in which cold affusion succeeded in cutting short the fever, though all

* Inflammatory fever in the United States is not unfrequently caused by the action of solar heat, and the influence of sudden vicissitudes in the temperature.—D.

After all, however, it is not often that examples of pure inflammatory fever are to be met with in the present day; and it is contended by very high authorities, and seems to be established by the medical records of earlier times, compared with those of our own, that it is a disease far less common now than it was formerly; and that it is seldom, to adopt the words of Mr. J. Hunter, "that physicians are obliged to have recourse to the lancet,* at least to that excess which is described by authors in former times. They are now more obliged," continues the same writer, "to have recourse to cordials, than evacuations; and, indeed, the diseases called the putrid fever, and putrid sore throat, are but of late date. I remember when the last was called Fothergill's sore throat, because he first published upon it, and altered the mode of practice. I remember when practitioners uniformly bled in putrid fevers; but signs of debility and want of success made them alter their practice. Whether the same difference takes place in inflammation, I do not know, but I suspect that it does in some degree; for I am inclined to believe that fever and inflammation are very nearly allied, and that we have much less occasion for evacuations in inflammation than formerly; the lancet, therefore, in inflammation, and also purgatives, are much more laid aside."—(*On Blood*, &c., part ii., p. 227.)

It is not easy to account for this change in the national temperament. It is common, indeed, to ascribe it to an alteration in our mode of life, which is asserted to be much fuller than that of our forefathers. "We may be said," says Mr. Hunter, "to live above par. At the full stretch of living, therefore, when disease attacks us, our powers cannot be excited further, and we sink so as to require being supported and kept up to that mode of life to which we have been accustomed."

If this be a correct view of the times in Mr. Hunter's day, they have greatly altered and improved within less than half a century; for there

the patients so treated felt afterward greatly relieved. He sets down the practice as best adapted to inflammatory fever (synocha), and more especially to the fevers of hot climates, which are accompanied by much greater excitement than those of temperate countries. He advises the practitioner, however, to ascertain, in every case, before such a powerful remedy is administered, that there is no visceral inflammation; "were such a powerful shock given to the system under these circumstances, dangerous and even fatal consequences might ensue." On account of these reasons, and the manner in which most patients object to cold affusions, Dr. Tweedie prefers sponging the surface of the body with cold water, or vinegar and water. In winter the fluid used may be tepid, if more agreeable to the patient.—See Dr. Tweedie's *Treatise on Continued Fever and its Modifications*, p. 187, et seq.; also, Dr. James Currie's *Med. Reports on the Effects of Water, cold and warm, as a Remedy in Fever*, 8vo., Liverpool, 1798.—Ed.

* These remarks cannot certainly apply to this type of disease, as it occurs in the United States.—See Miner and Tully's *Essays on Fevers*, Middletown, 8vo., 1823.—D.

has never been a period, since wines and fermented liquors have been introduced among us, so temperate and sober as the present. Drunkenness, which was formerly common in our streets, is now rarely met with; suppers are almost entirely relinquished; and, instead of its being disgraceful, as was the case in "the olden time," for the master of the house to let his guests leave him either sad or sober, nothing is now so disgraceful as intoxication. It is true, we are got back again to a very free use of the lancet in many instances; which would seem to show, that we had completed a revolution in our general temperament, as well as our general temperance; but it is not a little singular, that, while the lancet is still used with comparative caution in inflammatory fever, it is chiefly employed, and often unsparingly, in typhus or putrid fever. And hence, there is more reason, I fear, for suspecting a revolution in the professional fashion, than in national temperament; and that the bold and the timid plans have been alternately introduced and alternately dropped, not so much from any radical change in the constitution, as from their being found to fail, because employed as popular means, or under the influence of some favourite hypothesis, on all occasions, without a due degree of clinical discrimination, or attention to the habits or symptoms of individuals at their bedside.

SPECIES II.

ENECIA TYPHUS.*

TYPHUS FEVER.

PULSE SMALL, WEAK, AND UNEQUAL; USUALLY FREQUENT; HEAT NEARLY NATURAL; GREAT SENSORIAL DEBILITY, AND DISTURBANCE OF THE MENTAL POWERS.

THE term is derived from Hippocrates, who uses it, however, in a sense not exactly parallel with its application in modern times, but rather in reference to that low, muttering, and stupid delirium, which so frequently accompanies the disease. It is, nevertheless, admirably expressive of the general nature of the fever to which it was applied at first, and which it designates at present; which burns, not with open violence as the cauma, but with a sort of concealed and smothered flame; for the Greek term *τίφω* signifies "to smoulder," or "to burn and smoke without vent."†

Any of the ordinary causes of fever may be a cause of typhus; for the typhoid form is often dependant upon the character of the constitution into which it is received, as evincing a great deficiency of sensorial power: and hence cold,

* A peculiar form or type of fever, characterized by the more early and severe affection of the brain and nervous system; by the more constant changes which the mucous membranes undergo; by affection of the cutaneous and glandular systems; and, in the advanced stage, by great prostration and symptoms denoting putrescence."—Dr. Tweedie on Continued Fever, p. 76.

† The name of this fever is sometimes believed to be derived from the Greek word *τυφος*, signifying *stupor*.—Ed.

mental agitation, excess of muscular labour, and even intemperance, which, in a high entonic habit, might generate synocha or inflammatory fever, will often, in a debilitated constitution, and especially when the debility depends primarily upon the state of the nervous system, and the nervous influence is recruited with difficulty, give a typhous complexion to the disease from the first.

But though all the causes of fever may in this way give rise to typhus, its common cause, as we had occasion to notice when treating of the remote causes of fever (Cl. I., Ord. I.), is febrile miasm, issuing from the decomposition of human effluvium, under the influence of the ordinary auxiliaries of a close and stagnant atmosphere; still farther corrupted by a load of foreign exhalations from dirt or filth of any kind, and of that degree of warmth and moisture which must always exist where society exists, and especially where it exists in too crowded a state. Under these general circumstances, a very low degree of warmth and moisture is sufficient, though there must be some proportion of both. And, provided there be an adequacy of warmth, the lower the temperature, the more certainly an individual becomes affected; not from a more abundant generation of febrile miasm, or from its being more volatile,—for, on the contrary, it is here perhaps less abundant, and even less volatile,—but from the more depressed state of the living power, and the less resistance it is capable of offering to any morbid influence whatever.

I have just remarked, that, under a depressed state of the living power, whatever be its cause, whether a want of cheerful warmth, cheerful passions, cheerful food, or cheerful and regular habits, typhus is often more likely to take place than any other species of fever. But when febrile miasm, produced by a decomposition of effluvium from the living body, exists in co-operation with these, it is almost impossible for an individual to escape; as the miasm thus generated has a specific power—a power beyond all other febrile causes whatever—of lowering still farther the vital energy as soon as it is received into the system, and thus of confirming the previous tendency to this peculiar type.

All this, indeed, has been observed already, though it is necessary to revert to it on the present occasion: it has also been farther observed, that, when a typhus has, in this or any other manner, once arisen, the effluvium from the living body during its action is loaded with miasm of the same kind, completely elaborated as it passes off, and standing in no need of the decomposition of the effluvium for its formation. In many cases, indeed, all the secretions are alike contaminated; and hence, febrile miasm is often absorbed in dissection, by an accidental wound on the hand, and excites its specific influence on the body of the anatomist; for in this way, also, typhus has been produced.

Hence, typhus becomes infectious; but as the miasm it generates, though more suppressive or exhaustive of sensorial energy, is less volatile than that of marsh-lands or dead or-

ganized matter, its infectious power is confined to a much more limited atmosphere than that of fevers arising from this latter source. And, on this account, fevers originating in jails, or other confined and crowded scenes, are less extensively communicable than the yellow fever, or that of hot climates and exhaling swamps.

It may be also necessary to remind the reader of another remark already made, that, in a pure atmosphere, the miasmatic materials, from whatever source derived, become dissolved or decomposed; but this happens slowly and with great difficulty, perhaps not at all, in a vitiated atmosphere, already saturated with foreign corpuscles. In a state thus crowded, moreover, they less readily disperse or ascend beyond their proper periphery of action; and where they are less volatile, as when issuing from human effluvium, they perhaps adhere by a peculiar tenacity to bodies more ponderous than themselves, and thus loiter for a still longer period within the stratum of human intercourse. And hence, the fouler as well as the more stagnant the atmosphere, the more general, and, from the former cause, the more malignant the disease; for, as nothing is so contributory to the preservation of sound health as pure air, so nothing tends so much as foul air to prolong or aggravate diseases of every kind. And hence, again, we have an obvious and sufficient reason, why typhus should become more severe in proportion as it spreads and impregnates a given space with its specific miasm and accompanying colluvies.

To what extent febrile miasm, issuing from the source before us, may spread in a free influx of pure air without becoming dissolved, or, in other words, so as to retain its contagious power, has never been very accurately ascertained. We know, however, that its range is very circumscribed, and reaches to but a very small distance from the patient, or the nidus of foul clothes or utensils in which it may be lodged; and never infects a person in an adjoining street, or house, or room in the same house; nor even, as Dr. Haygarth has observed, in the patient's own chamber, if large, airy, and kept clean: a remark that has since been confirmed by Dr. Baillie. "With respect," says he, "to the contagious nature of these fevers, I am convinced, that it is in general not considerable. I do not recollect an instance in which a patient in that hospital (St. George's) communicated the infection to a patient lying in the next bed. When patients are crowded together, and the apartments are ill-ventilated, I entertain no doubt of this species of fever being capable of being communicated from one individual to another."—(*Lect. and Obs. on Medicine*, 1825, unpub.) [Dr. Alison, in his description of the epidemic fever of Edinburgh, in 1827, likewise particularly mentions, that, in the men's ward of the hospital, there was no instance of any patient, admitted on account of other complaints, taking fever in the house, notwithstanding its continued presence on the opposite side of the ward. In the women's ward, however, two or three patients, admitted

on account of other complaints, took fever. Notwithstanding what happened in the men's ward, this intelligent physician adduces many convincing facts in support of the doctrine, that fever spreads, not from malaria, but from contagion communicated by intercourse between the healthy and the sick.—(*Alison, in Ed. Med. and Surg. Journ.*, No. xciii., p. 234, et seq.)]*

It is also of great importance to know, that typhous miasm, like the specific miasms of exanthems, does not render clean clothes of any kind contagious; or, in other words, does not adhere to, or harbour in them. When, however, they are not clean, they may unquestionably be rendered contagious; and hence, it is probable, that the animal filth with which they are impregnated, while it is a source of additional miasm, becomes a fomes of that already formed, and separated from the patient's body.

A susceptibility, however, to diseases of every kind, varies considerably in different individuals; and hence many persons, upon an equal exposure to typhous contagion with others, receive it far less readily, and, in some cases, seem to be almost favoured with a natural immunity. As we have already remarked, that a peculiar state of body gives a peculiar tendency both to generate and receive typhus, we can easily conceive that, where the body is in an opposite state, it must be much less susceptible of its influence; and we are thus put in possession of a general cause of escape. But there seems to be something beyond this, dependant, indeed, not upon the incidents of more vigorous health, or higher animal spirits, but upon the nature of the idiosyncrasy itself.

Dr. Haygarth has endeavoured to determine, from very ingenious and plausible data, the average proportion of those who in this manner remain exempt from contagion, while spreading on every side around them. And he limits the immunity to one in twenty-three; for he tells us that, when one hundred and eighty-eight men, women, and children, were exposed fully to the typhous contagion for days and nights together, in small, close, and dirty rooms, all of them, except eight, were infected with this fever.—(*Letter to Dr. Percival*, p. 31.) And he has farther endeavoured to show, that the miasmatic poison, when received into the body, continues in a latent state for seven days from the time of exposure to the contagion, before the fever commences; and may continue in the same state for seventy-two days, beyond which we have no instance of its producing any effect. And this deduction is in pretty close unison with the experience of Dr. Bancroft (*Essay on Yellow and Typhus Fevers*, p. 515), who, in ninety-nine cases of orderlies and nurses that attended the English army, on its arrival at Plymouth from Corunna, in 1809, observed that

they were rarely attacked with fever earlier than the thirteenth, and in no instance later than the sixty-eighth day. [In numerous instances, however, brought forward by Dr. Marsh,* the latent period of typhus, or the interval between the receipt of the contagion and the beginning of the symptoms, was a very short period; and the infection taken so instantaneously, as it were, that doubts arose, whether the contagion had had time to operate through the medium of the absorbents.]

* See Marsh on the Origin of Fever; Dublin Hospital Reports, vol. iv., p. 456, &c. Dr. Elliotson never saw an instance in which typhus fever showed a contagious character (*Med. Gaz.*, 1832, p. 146); nor has the editor of this work ever noticed the occurrence even in the great prisons which he has now attended more than seven years. No doubt, however, where many cases of severe fever are brought together, and the effluvia from the patients concentrated, the disorder will sometimes assume a very infectious nature. The records of the Fever Hospital seem to leave no doubt of typhus being contagious under certain conditions; for every medical officer, every servant there, and every person employed in washing the linen of that institution, have all had typhus. Some have had it more than once, and others have died. Yet, nothing of this kind has happened at the Smallpox Hospital, which is on the very same spot. And, as Dr. Elliotson remarks, this fact is very important, as clearing up the point, whether all these persons have had it through the emanations of the patients in the Fever Hospital, or through the situation. The following passage from Dr. Elliotson's lectures is highly instructive:—"You will find an argument against the contagion of typhus fever adduced from this circumstance, that it will sometimes disappear during an extreme temperature, and it will sometimes disappear altogether, without any obvious reason; whereas, if it were contagious, it is argued, it would spread from one to another, till all, or the greater part, had suffered from it. It is said, that it is only a disease which depends upon a particular state of the atmosphere, and not upon an emanation from a diseased person; and that, therefore, it is suspended by the extremes of temperature, or will suddenly cease, without any obvious reason. It is, indeed, true, that non-contagious yellow fever, and intermittent and remittent fevers, and other diseases decidedly not contagious, will be aggravated or repressed by extremes of temperature, and by causes not discoverable. But this is exactly the case, not only with typhus fever, but with diseases which all people of common sense allow to be contagious. Epidemic smallpox is frequently checked by extreme cold. The plague, which, I believe, almost everybody allows to be a contagious disease, in the strict sense of the word,—*not infectious*, but *contagious*,—is also stopped by extreme heat or cold. Smallpox is frequently so stopped, and likewise by the wind called *harmattan*, which also arrests the plague; and, what is curious, this wind will prevent persons from taking the smallpox, even if they be inoculated. Hooping-cough and measles, which most persons allow to be contagious, are generally checked at the height of summer; and Sydenham says, that scarlatina is most prevalent when the summer is over." If such, and some other irregularities, will occur in the case of diseases known to be contagious, there is no reason at all to doubt that typhus fever is contagious, merely because it will suddenly cease in a dis-

* On the subject of the communicability of typhus by one person to others, Dr. N. Smith remarks (*A Practical Essay on Typhus Fever*, New-York, 1824), "it is impossible for me not to believe this fever contagious, though it may not perhaps be so certainly and readily communicated as some other contagious disorders."—D.

Man is so much the creature of habit, that his constitution is, in a thousand instances, brought by degrees to endure poisons of the most fatal power. This we see daily in the use of opium and ardent spirits; and we shall in due time have to notice something of the same kind, even in plague. This adaptation of the constitution, however, to the circumstances by which it is surrounded, is in nothing more conspicuous than in the fever before us. Not, indeed, in all persons,—for all do not possess the same pliability of constitution,—but in those who are endowed with it. And hence, one reason why nurses, and perhaps hospital-surgeons, escape so often without injury, and especially why prisoners, brought into a court for trial, remain themselves occasionally in perfect health, while their clothes are so impregnated with the contagious miasm as to infect a whole court, and communicate the disease to the judge or others who are at the greatest distance from them; of which we are furnished with melancholy examples in the Oxford assizes of 1577, those at Exeter and Taunton in 1586, those of the Old Bailey in 1736 and 1750; besides similar instances in various hospitals and ships of war.*

There are other persons again, as Sir John Pringle has well observed, whose constitutions, forming a middle line between those who readily receive and who powerfully resist the contagious aura, are affected only in a modified degree. They bend to the assault, but are not cut down by it. They become feeble and irritable; the sleep is disturbed; the tongue white in the morning; the appetite impaired; the smallest exertion fatigues them, and accelerates the pulse; and, in this state, they remain for weeks together, and at length recover without any formal attack of fever.

We have seen that the same influence of habit exists under yellow fever; during which

the natives of those climates where its remote causes are in almost perpetual operation, suffer far less when it attacks them, and are far less susceptible of its attack.

But, though febrile miasm, issuing from a decomposition of human effluvium, has a peculiar tendency to generate typhus, we have seen that the same miasm, issuing from a marsh effluvium, or a decomposition of dead organized matter, under a peculiar state of modification, has produced remittents with a typhous character, and sometimes specific typhus itself.—(*Epanctus malignus asthenicus*, *suprà*, Cl. III., Ord. I., Gen. III., Species 2, *δ*.) And as, in this case, the miasm is apt to spread more widely, typhus has, by many writers, been said to be occasionally epidemic. When, however, the disease issues from this source, it is far more generally in temperatures too low than too high and heated; since, as already observed, cold, and especially cold and moisture, have a peculiar tendency to depress the living power; and hence this disease is said to be almost stationary at Carlsrone, or at least to have lingered there for four or five years on some occasions.—(*Foxe, Neuen Schwed. Abhandl.*, band. viii.)

[The opinion that the type of fever has not an exclusive connexion with its cause, and that it depends much upon atmospheric influence or constitutional diathesis, is supported by Dr. Marsh (*Dublin Hospital Reports*, vol. iv., p. 519, et seq.), who cites several cases in which exposure to typhoid contagion was believed to have occasioned intermittent and remittent fever; and to puerperal infection, typhus.]

Typhus, therefore, originating from different causes, and all these causes modified in their action by collateral circumstances, may readily be supposed to be accompanied with very different symptoms, and to appear under very different degrees of severity. The chief varieties, however, are the two following:

strict, without our knowing why, or because it is apparently arrested by atmospheric change.—See Elliotson's Lectures, delivered at the Lond. University, published in *Med. Gaz.*, 1832, p. 147.—Ed.

* Many facts connected with the progress of contagious or infectious disorders as they have prevailed under different circumstances in the U. States, might be here adduced in corroboration of the views in the above paragraph. Some striking instances of exemption from the influence of febrile infection have been presented by intemperate persons, who, in seasons when yellow fever prevailed extensively, have passed unmolested by it, though exposed to the disorder in every possible manner; while temperate individuals, coming from the pure air of the country, and unassimilated to the peculiar atmosphere of an infected city, have sickened and died soon after their arrival. The same remark will hold good in regard to the effects of febrile infection on individuals unaccustomed to its influence, when from accidental causes they have been brought within its power, by imprisonment in jails, or by confinement in hospitals and almshouses. We think that the medical reports of our hospitals would furnish many proofs of this law of infection, as it applies to typhus fever. We shall here mention only one instance recorded by Dr. Francis, which occurred in the city prison or

Bridewell of New-York. "About the 16th of July, 1814," says Dr. Francis, "several cases of the *typhus carcerum* appeared in the Bridewell of New-York. The disease was first observed to exist in an apartment of the prison commonly called the eastern wing, a room about fifty feet long and twenty-five broad. In a very few days after, the complaint became general; and out of eighty-five individuals at that time confined in this part of the building, nearly forty were taken ill with symptoms characteristic of typhoid fever. The disease was produced from the local circumstances of the place, the crowded condition of the ward, the want of cleanliness about the persons and in the clothing of the prisoners, and the neglect of free ventilation. The increased impurities of the atmosphere seemed to give additional activity to the virulence of the disease; of the persons thus affected, a large majority were those who had come from a pure atmosphere, and were but recently subjected to the noxious air of the place, several not more than thirty or forty hours, and many not more than three or four days. The infection was more readily communicated to those, too, who were naturally possessed of vigorous and robust constitutions, and its effects were in most cases more violent upon persons of this description than on others."—See Hosack's *Med. Essays*, vol. i., p. 355.—D.

a Mitior. Nervous fever.
 γ Gravior. Putrid fever.

THE FIRST VARIETY, OF MILD TYPHUS, was called by Dr. Huxham *febris lenta nervosa*, and has hence been commonly distinguished by the name of low or slow NERVOUS FEVER, from the great languor and dejection of mental or sensorial power with which it is always accompanied, and, on this account, it has sometimes been denominated *hysterical fever*.* It is particularly characterized by slight shiverings; heavy vertiginous headache; oppression at the præcordia; nausea; sighing; despondency; coma, or quiet delirium; whey-like urine.

When the disease appears sporadically, it is usually under this form. There is nothing alarming to the patient's friends on its accession. The first symptoms are slight, the tongue exhibits little change, and the pulse is only a little quickened and somewhat smaller than usual; at the same time, however, there is great anxiety and depression of mind; so that the symptoms do not much differ from a mild and comparatively insignificant fever of any kind, operating upon a nervous temperament. But, as the disease advances, all the symptoms of sensorial debility become severer; the skin, which has hitherto been mostly dry, will, about the third day, be covered with profuse, clammy, debilitating sweats, while the heat is still inconsiderable, and the countenance pale and sunk. The sweat is often offensive to the smell, frequently acid, and sometimes, according to Stoll (*Rat. Med.*, iii., p. 79), as sour as the sharpest vinegar. About the tenth day, the weakness greatly increases; all the limbs tremble; and the tremours soon become convulsive, with a despondency and alienation of mind, at first observable only in the night, but soon continuing with little intermission: the delirium is of the mild or quiet sort, and rarely amounts to phrensy.

The disease often runs on to the twenty-first day, and, occasionally, to a much longer period. It is seldom marked by that sudden change which can be called a crisis; but gradually becomes more aggravated in its symptoms, till it reaches a fatal termination; or slowly advances to convalescence, by evincing a disposition to natural sleep; more steadiness and firmness of pulse; a more favourable countenance; a tongue more florid at the edges; a firmer and more collected mind, and a returning desire for food, often, indeed, capricious, but without nausea or sickness.†

* Manningham on the Symptoms, Nature, and Cure of the Fibricula, commonly called the Nervous or Hysterical Fever. Lond., 1776.

† The following are some of Dr. Tweedie's observations on this fever:—"In typhus mitior the febrile symptoms are mild, though it is evident, from the intellectual disorder and prostration, that the nervous system is much affected. Probably, at the commencement, there is no inflammatory action in the brain, the whole of the phenomena, viz., great languor, feeling of debility, muscular prostration, soft, feeble pulse, giddiness, intellectual dulness, and transient delirium, being the result of the peculiar operation of the febrile causes on the nervous system. Sub-acute inflam-

In an anomalous and very singular case related by Dr. Satterley (*Med. Trans.*, vol. v., art. xxii.), the desire for food, which at first was greatly loathed in whatever form offered, reappeared about the fifth day, with an enormous craving, which it was impossible to satisfy. Animal food was preferred, but food of any kind was swallowed voraciously; and, when food was not allowed, various indigestible substances were devoured in its stead. This desire returned with every returning ingravescence of the fever, which adhered to no regular period, and it continued as long as the ingravescence lasted, which was usually ten or twelve hours. The disease extended with numerous variations to upwards of thirty days, when the fever unequivocally subsided, and the patient gradually recovered.*

Of the treatment we shall speak, after considering it in its severer forms.

The heavier, severer, or PUTRID TYPHUS, chiefly differs from the mild in the violence and rapidity of its march, and the marked and undisguised character it assumes from the first. While the mild, therefore, commences insidiously with only slight shiverings, the heat scarcely above the natural temperature, and the pulse small, and only a little quickened, the heavy typhus opens with sensible and alternate rigour and heat, succeeded by little or no perspiration; the pulse is tense and hard, usually quick, but fluttering; with pain over the forehead and crown; urine alternating from limpid to turbid; delirium succeeded by stupor; purple dots or patches, and other early signs of putrescence.

From the last feature, the disease has derived its common name, of PUTRID FEVER; as it possesses the additional names of JAIL, CAMP, and HOSPITAL FEVER, from its appearing so frequently in these situations: while, from the purple or flea-bite spots, which last are often called petechiæ, or, as it should rather be written, petechiæ, this variety has been very generally treated of at home, under the name of SPOTTED FEVER, and on the continent under that of *febris petechialis*, or *petechizans*; sometimes, as by Follini (*Orat. de Med. Feb. Peticularis*. Colon., 1722, 8vo.) and Matarasius (*De Feb.*

mation of the brain often supervenes on this condition of the nervous system; and, when this takes place, the more prominent symptoms of cerebral inflammation are recognised; and to the difference in the intensity of the cerebral affection, may be traced the infinite variety of nervous symptoms, which individual cases present."—See Tweedie on Continued Fever, p. 80.—Ed.

* Dr. N. Smith states a curious instance of the effects of this disease on the moral principle—"a patient in particular who had been extremely sick with this disease, after his recovery, had a strong propensity to steal, and did in effect take some articles of clothing from a young man to whom he was under great obligations for the care he had taken of him during his sickness. He at length stole a horse and some money, and was detected and punished. I took some pains to inquire into the young man's former character, and found it good, and that his family were respectable."—Essay on Typhus, p. 32.—D.

petie. malign. contagiosis, &c., Mezarini, 1722, 8vo.), under that of *febris peticularis*; sometimes, as by Jacobi and Morelli (*De Feb. purp. epid.*, Lion., 1641, 8vo.), that of *febris purpurata*; while by A. Castro it is termed *febris punctularis* (*Febris maligna punctularis aphorismus delineata*, Tub., 1693); and by De Cernona, *febris cum punctulis*.—(*Tract. de Peste et febr. cum punct.*, Sevilla, 1581, 8vo.) By the Spaniards, it was hence vulgarly denominated *tavardillo* or *tabardillo*, from *tavardo*, a spotted cloak formerly in common use. It is a termination very common in various parts of America. These punctæ or vibices, however, are nothing more than symptoms of putrescence; and are common to other fevers, and even to diseases without fever, as land or sea scurvy (*porphyra hæmorrhagica* and *p. nautica*) as well; and hence are no ground whatever for establishing a distinct species, and still less a distinct genus, though they might perhaps form a variety. By most writers therefore of eminence, from Cullen to Swediaur, they are arranged and treated of as different forms of the same disease.

During the first twenty-four hours, the alternate heat and cold are considerable; the fever increases every evening, and, in the second week, the delirium usually commences; the stupor following five, six, or seven days afterwards. From the first, there is a heavy and vertiginous headache and vomiting: the pain over the forehead shoots through the eyes to the bottom of the orbits; the eyes themselves are full, heavy, and slightly inflamed; the countenance is bloated; the tongue white rather than furred; the temporal arteries throb, while the pulse at the wrist is small and oppressed; the ears tingle; and the mind, antecedently to the delirium, is fearfully dejected. There is also occasionally, from the weak degree of action on the surface, a livid but interrupted turgescence over the whole of the body, as well as the face, not unlike the mottled appearance on the skin of a healthy person when exposed to a slight degree of cold. Dr. Hildenbrand has regarded this symptom as constant and pathognomonic; and has hence introduced contagious typhus into the list of exanthems, specifically distinguished by this spotted efflorescence (*Ueber der ansteckenden Typhus, von J. V. Edler von Hildenbrand, &c.*, Wien, 1815), which he seems further to believe is loaded with its peculiar miasm. So far, however, as the present author has seen, it is an occasional, rather than a necessary accompaniment, and appears to be a natural result of the cause just stated. It subsides in a few days.

The balance of the sanguiferous system is generally much disturbed from a greater degree of sensorial debility in some organs than in others; and hence the blood is determined irregularly, and accumulation, effusion, and inflammation, are frequent effects. These show themselves chiefly in the head, the lungs, and the liver; but there is no organ in which they may not occur; and they never can occur without danger. All the external senses evince great hebetude, and especially the hearing, so

as often to amount to absolute deafness; the stupor is increased, and the speech muddled, while the patient appears to dream without being asleep, and talks deliriously; thus evincing the typhomania of the ancients; being often unconquerably riveted to a single idea or train of ideas. And as the nervous exhaustion increases, he is indifferent to every thing, feels little or nothing, and if he answer at all to an inquiry how he is, says he is very well.

[Typhus fever affords a striking example of the vast change produced in the secretions by disease. The fact is particularly noticed by Dr. Armstrong in his description of the state of the tongue. In typhus fever, he observes, as the lips and cheeks become dusky during its perfect development, a peculiar secretion is besmeared over the tongue and fauces, almost as if the fibrine and albumen had been dissolved, so as nearly to resemble in its adhesive property common melted glue; the tongue itself, from the evaporation of the thinner portions of this secretion, becomes dry, presenting a varnished appearance, like that of a walking-stick; and at a still more advanced stage, it becomes brown, and ultimately black, from an apparently carbonaceous deposit. In some fully developed cases, where the tongue is glazed, dry, and brown, and the lips and cheeks of a dusky or purple hue, the blood drawn from the temporal artery has a venous colour. The circulation of such blood within the arteries is connected with many of the most conspicuous and curious phenomena of the advanced stage of typhus. *The cause of this remarkable change can be shown by dissection to depend upon a specific bronchitis*, the mucous texture of the bronchial tubes being loaded with dark blood, and besmeared with a copious and tenacious secretion.*]

About the thirteenth or fourteenth day, sometimes preceded by an augmented exacerbation, and sometimes without any, the fever suddenly abates, a relieving dew appears on the parched skin, and all the excretories evince the same freedom from spasmodic constriction: the tongue loses its dryness; the nostrils are moistened with mucus, and occasionally discharge blood; the lungs pour forth a free exspuition, which softens the harsh glottis and the fauces; the bowels, if not loose, feel more refreshed after evacuations; and the urine is more copious,

* See Armstrong's *Morbid Anatomy of the Bowels, Liver, &c.*, pp. 8, 14, &c., 4to., Lond., 1828. According to Dr. Burne, the blood flows slowly from divided vessels, is blacker than usual, coagulates less firmly, rarely shows the buffy coat, and in the dead body, is found black and fluid. On Typhus, or Adynamic Fever, 8vo., Lond., 1828. Dr. Clanny's observations lead to the conclusion, that the watery part of the blood increases in proportion during the progress of the fever; while the quantity of all the animal principles and salts of that fluid is lessened; and that, when the crisis has taken place, the opposite change begins, so that the blood returns to its natural condition. Supposing this statement to be correct, we must not fancy, with Dr. Clanny, that fever depends upon the derangement of sanguification, but only that the latter is one of its attendant changes.—Ed.

with an abundant deposit: and, to close the whole, in the elegant language of Professor Frank, “*increscent pulsus, mollesque unda arteriam aequali rhythmo attollit: sequuntur somni placidiores, reficientes, et oblatum ægrotus cibum minùs abhorret.*”—(*De Cur. Morb. Hom. Epit.*, tom. i., p. 107.)

If, however, no critical change take place about the fourteenth day, leading distinctly to an amended state, the symptoms of putridity increase both in number and degree. There is great faintness; difficulty of respiration, intermixed with deep sobs; the breath is hot and offensive; acute pains in the loins and limbs; a heat upon the skin, biting and pungent rather than burning; leaving a smarting sensation on the fingers for several minutes after touching it, and which, from this very peculiar effect, has been called *calor mordicans*. The tongue, whitish at first, is now dry, dark, livid, black, or of a pomegranate colour. The lips are furred with a black tenacious sordes; the urine becomes brown or blackish, with a most offensive smell; a blackish or bilious matter is occasionally thrown up from the stomach; the skin is more or less discoloured, as just observed, with flea-bite-shaped or broad purple spots; the stools are blackish and highly fetid. Cold, clammy, colliquative sweats and convulsions, sometimes accompanied with hemorrhage from one or more organs, soon afterward usher in death; the period of which is extremely uncertain, and ranges from the fifth to the eighteenth day, according to the malignity of the attack, the strength of the patient, or other contingent circumstances.

I have said that the milder variety or nervous fever usually shows itself sporadically, originating from some other cause than febrile miasm in an irritable and atonic habit. Malignant typhus sometimes commences in the same way, but usually by a decomposition of human effluvia accumulated in a camp, a ship, or even a large single family, where the space is too small for the number, the habits uncleanly, and the atmosphere stagnant and unventilated. The cause is one, and the fever the same, varied alone by accidental circumstances or symptoms, that depend altogether upon its less or greater degree of violence.

In this metropolis, therefore, malignant typhus is almost exclusively to be met with among the poor; and the more wretched and destitute they are, the more readily they become its prey. I cannot better illustrate its rise and progress than by the following simple picture as furnished by Dr. J. Hunter: it is drawn from life, and will be easily recognised by every practitioner.

“A poor family, consisting of the husband, the wife, and one or more children, were lodged in a small apartment, not exceeding twelve or fourteen feet in length, and as much in breadth. The support of them depended on the industry and daily labour of the husband, who, with difficulty, could earn enough to purchase food necessary for their existence, without being able to provide sufficient clothing or fuel against the

Vol. I.—C c

inclemencies of the season. In order, therefore, to defend themselves against the cold of the winter, their small apartment was closely shut up, and the air excluded by every possible means. They did not remain long in this situation before the air became so vitiated as to affect their health, and produce a fever in some one of the miserable family. The fever was not violent at first, but generally crept on gradually; and the sickness of one of the family became an additional reason for still more effectually excluding the fresh air; and was also a means of keeping a greater proportion of the family in the apartment during the daytime; for the sick person was necessarily confined, and another as a nurse. Soon after the first, a second was seized with the fever; and, in a few days more, the whole family perhaps were attacked, one after another, with the same distemper. I have oftener than once seen four of a family ill at one time, and sometimes all lying on the same bed. The fever appeared sooner or later, as the winter was more or less inclement; as the family was greater or smaller; as they were worse or better provided with clothes for their persons and beds, and with fuel; and as their apartment was more or less confined.”—(*Med. Trans.*, vol. iii., art. xxii.)

There are a few auxiliary causes not noticed in the above faithful delineation, which seldom fail of being present, and have always a very considerable degree of influence: these are, the anxiety and dejection of mind so sure to accompany such a scene of misery, and the increasing carelessness, and consequently uncleanness of person, which are equally sure to follow. And we may hence see why typhus should so frequently make its appearance in the poorest and most miserable streets of a metropolis, and be generally confined to such streets; why it should rage most extensively and most violently in times of the severest public pressure and distress; and hence, again, why it should be more common in Ireland than in England, in Dublin than in London. We also see the inestimable advantage of such establishments as Fever Houses or Infirmarys in all populous towns, when built upon the sound principles, and governed by the judicious regulations, and, I may add, superintended by the active humanity and established talents, which are so conspicuous in the Fever Hospital of this metropolis.

To describe the typhus of jails, ships, camps, and other large bodies of men, we have only to multiply the single family we have just beheld into fifties or hundreds; ever remembering, that the virulence of the febrile poison increases in power, not in a numerical, but in a sort of geometrical proportion, to the numbers by which it is fed. So that if five patients produce a given ratio of pestilence, ten will produce, not as much again, but nearly a hundred times as much. And hence we may readily account for the fearful and deadly ravage which this cruel scourge is well known to inflict upon a people when closely pressed together, and incapable of flying from its pestilential aura, as in crowded encampments, or a besieged and pent-up town: and

especially where, as is often the case, there is considerable carnage from the casualties of war, and a deadly calm prevails for weeks together in the atmosphere. This last concomitant, indeed, gives completion to the whole, and is a heavier calamity than it is generally conceived to be; for the most fatal pestilences of which we have any account, seem to have been preceded by a stagnant atmosphere. Thus Maitland, in his *History of London*, observes, "that for several weeks before the plague broke out in this metropolis, in 1665, there was an uninterrupted calm, without sufficient-motion in the air to turn a vane." The assertion is confirmed by Baynard, a contemporary physician; and a like harbinger, as is observed by Diemerbroeck, preceded the plague at Nimeguen.

In both varieties, the prognosis must be collected from the vehemence of the symptoms, and the character of the idiosyncrasy; and the cure must depend upon the means we may possess of supporting the vital power, and restoring its lost energy.

The peculiar properties by which typhous miasm is distinguished from miasms of every other kind, are the rapid and direct debility with which it affects the nervous system; the activity of its leaven, by which it assimilates all the fluids of the body to its own nature; and the urgent putrefactive tendency it gives to every part.

The last of these properties may, in some degree, be dependant upon the first; but it does not appear to be entirely so; since we often find the sensorial power reduced to a much lower ebb, as in asphyxy from hanging or drowning, suffocating exhalations or lightning, catalepsy, and deliquium from loss of blood, while there is an almost infinitely less degree of tendency to putrefaction. And, in like manner, although the miasms of many of the exanthems, as rosalia or scarlet fever, smallpox, and plague, are also capable of tainting the secretions of the body, none of them appear to do it so completely and universally as that of typhus when in its most malignant state; in which the breath, all the egesta, and all the fluids are loaded with contagion. It has been propagated by the excrement (*Riedlin, Lin. Med.*, 1695, p. 402), by the odour of flowers employed to decorate the dead body (*Eph. Nat. Cur. Dec.*, ann. vii., viii., obs. 193); by washing the bandages employed in typhous gangrene (*Hennen's Principles of Military Surgery*, p. 218), and, in innumerable instances, by the communication of a minute drop of any of the fluids of the dead body to a punctured finger during dissection.

In forming our prognosis, and attempting a cure, these properties should always be prominent in the mind; for they will best enable us to calculate the nature and result of symptoms that are present, and will guide us to the most rational and satisfactory mode of practice.

From the debility that prevails, even from the first, the pulse is feeble and tremulous, the extreme vessels torpid, or nearly so, and the circulatory balance greatly disturbed. Hence, we have reason to expect, that effusion and congestion, or an irregular determination of the

blood, will, in many cases, be an early attendant; and, if there be energy enough remaining in the organs thus affected to produce any degree of reaction, that local reaction will follow, and perhaps lead on to inflammation terminating in suppuration or gangrene; of which Sir John Pringle has given numerous examples. And hence there is some ground for contemplating typhus, as Dr. Armstrong has done, under the three varieties of a simple, congestive, and inflammatory affection; this last being sometimes seated in one organ, and sometimes in another: most frequently, perhaps, in the brain, where Marcus supposes it to exist in every case whatever; and occasionally, perhaps, in some of the secreting membranes, through all of which, it is conceived in every instance to extend by Hildenbrand, the rete Malpighi, the membrane that lines the cavity of the nose, of the mouth and throat, the tunica arachnoidea, and the mucous membranes of the stomach, intestines, and organs of urine and generation.—(*Ueber der ansteckenden Typhus*, &c., Wien, 1815.) [It is a fact now perfectly established, that, in certain forms of fever, the mucous coat of the intestines is often found in an inflamed, ulcerated, or even gangrenous state. The writings of Broussais, Andral (*Clinique Médicale*, iv. tomes, 8vo., 1823–1827), Ribes (*Anat. Pathol.*, tom. i., 8vo., 1828), and others in France, leave no doubt on this point, which has received still further illustration from the publication of Dr. Bright (*Reports*, &c., p. 178), as was noticed in the consideration of remittent fever. Besides the affection of the head and nervous system, which seems to be connected with the first impression of fever, Dr. Bright is convinced that there is a secondary state of cerebral irritation, which depends upon the mischief going on in the intestines; and this often shows itself after the fever has continued for several days, increasing with the increase of the abdominal affection, and going on till it produces that general nervous agitation with injected conjunctiva and constant delirium, which often closes the scene of life. These observations remind the editor of a fact, which, according to Dr. Ribes, has been completely established by M. Scoutteten by numerous dissections; namely, that the connexion between the intestinal canal and the pia mater is so intimate, that, when the former is affected with either acute or chronic inflammation, the latter always participates equally in the affection, with this particularity, that it only happens when the mucous membrane of the bowels is concerned, and not when the serous one alone is disordered.* An observation made

* The modern French pathologists seem to have demonstrated, by numerous examples, this important principle, that an affection of the pia mater and of the arachnoid membrane is often the consequence of an inflammation of the mucous membrane of the stomach or intestines. Dr. J. W. Francis assures us, that he has noticed the same fact in the post mortem examinations of subjects who have died from drinking cold water in the heat of summer; and particularly in those who were intemperate. A majority of the bodies dis-

by Dr. Alison rather corroborates the foregoing statement; as he notices, that, in the worst cases of remittent fever of children, the mucous membrane of the bowels is inflamed and ulcerated, and that one mode in which the case proves fatal, is by sudden conversion into an affection of the head.—(*Alison, in Edin. Med. Chir. Trans.*, vol. i., p. 433.) The researches of Dr. Bright agree with those of the French pathologists in fixing upon the mucous membrane of the ileum, cæcum, and beginning of the colon, as the principal seat of morbid alteration, though occasionally the same membrane has been inflamed and irritated throughout the whole extent of the intestinal canal. "The appearances (says Dr. Bright) which are most marked in the mucous membrane of the intestines, are those of increased action, vascularity sometimes occurring in patches of greater or less extent, without any obvious dependance on inflammation of the mucous glands, and occasionally extending, under some form or other, through the whole track from the pylorus to the rectum; but this vascularity is more generally connected with inflammation of the mucous glands, which often appear like the smallpox on the second or third day of the eruption, elevated and almost transparent, with minute vessels which dip into them from the lining membrane of the intestines. They scarcely seem to go into a state of true suppuration, but become distended with a yellow cheesy matter, and slough off; or sometimes ulceration takes place upon their points externally, without any collection of yellow matter being perceptible. The same process, or nearly so, takes place both in the solitary and in the congregate glands; except that, in the latter, the appearance becomes much more formidable, and the mischief more extensive. The masses or clusters of congregate glands, are chiefly placed along that part of the intestine which is farthest from the insertion of the mesentery; and, when the parts are irritated from disease, three, four, or five considerable branches of vessels are seen passing on the mucous membrane, from the mesentery on each side, towards the cluster of congregate glands." The glands themselves enlarge, and, after some time, form a thick, flat mass, of a lighter colour than the surrounding intestine. This sometimes increases to the thickness of a half-crown piece, and occasionally even spreads on the top, so that the surface overhangs the base nearly the sixth part of an inch. Sometimes a dark-coloured matter, like grumous blood, is deposited among the glands; so that the whole mass, instead of being lighter than the intestine, is of a brown colour, elevated evenly above the surface; but, in either case, the mucous membrane is at first only raised, and not broken. In a little time fissures are formed, and the whole mass ulcerates. When the inflammation subsides, the depth of the ulcer diminishes; and the greater

sected by Dr. F. during the last fifteen years, after death from this cause, have presented this pathological connexion between the stomach and the brain.—D.

part of the glandular structure being apparently removed by ulceration and sloughing, the edges fall down, and the ulcer becomes shallow, sometimes leaving the muscular fibres nicely displayed, or often exposing the internal surface of the peritoneal coat to the extent of a quarter or half of an inch square. This excavation is filled up by the process of granulation, which, Dr. Bright says, may be seen very beautifully by suspending the intestine, cut open, before a lamp or the bright sunshine, and examining it with a common lens. When the whole is healed, a scar remains visible for some time, and appears to be covered by a true mucous membrane. These ulcerations are stated to be quite analogous to those painful and irritating sores which frequently occur on the lips or lining of the cheeks. The space occupied by the ulcers in the intestines, is usually about two feet at the lower end of the ileum, and frequently the valve of the colon, on the side towards the ileum, is the part where the disease is most advanced. A few ulcers are likewise often found in the cæcum, and some are occasionally dispersed along the colon. The peritoneal coat at the back of the ulcers is generally discoloured and vascular, though seldom actually inflamed; which, however, it is sometimes, when the tenderness of the abdomen becomes more marked, and, after death, a sero-purulent effusion is found, and the convolutions glued together with threads of coagulating lymph. In a few rare cases, the ulceration extends completely through the peritoneum, the contents of the bowel becoming effused in the abdomen, followed by general inflammation of that cavity and death. Together with the foregoing changes, the mesenteric glands are usually found enlarged and vascular, particularly those which are situated opposite the intestinal ulcers, and which occasionally suppurate. In the remittent fever of scrofulous children, Dr. Alison represents the mesenteric glands next to the ulcerations of the mucous coat as being much swelled, and of a dark red colour, both externally and internally. Dr. Bright's investigations confirm the remark of the generality of modern pathologists, as Andral, Percival, Macartney, and others, that, in addition to the preceding morbid appearances of the intestinal canal in subjects destroyed by fever, other organs frequently suffer as much as the bowels, and even more, especially the brain and its membranes, in which marks of congestion are very manifest. Nor, says he, is it at all unusual to find the lungs altered, as in pneumonia, and it is even more common to find them loaded with an extraordinary quantity of blood.*

* See Bright's Reports of Medical Cases, p. 180, et seq., 4to., Lond., 1827. After noticing the tendency to an inflammatory affection of the brain, Dr. Tweedie remarks, "that of the lesions in other organs, which arise in the more severe cases of typhus fever, congestion, or inflammation of the mucous membranes, bronchial and intestinal, and inflammation of the parenchyma of organs, are the most important. The congested state of the capillaries of the mucous membranes, the blood being at the same time in a state which favours its transudation, occasionally gives rise to hemor-

Many of the cases in which the above morbid appearances in the bowels were observed by Dr. Bright, seem to have been of the remittent type; though others were probably typhoid, as far as can be judged from the particulars recorded. The discharge from the bowels is very often dark-coloured in typhus, but not always; and hence the circumstance of the morbid changes, pointed out by Dr. Bright, being denoted by the watery ochre-coloured appearance of the feces, must not be taken as a complete proof that none of his cases were typhoid. It merits notice, that similar alterations of the mucous membrane are particularly described by the French pathologists as occurring in typhus. This doctrine has even been carried to such a degree, that, in France, the question has been entertained, whether the ileum and the valve of the cœcum are the real seat of the disorder, characterized by symptoms usually termed putrid and typhoid? A question to which, as Dr. Ribes properly observes, a negative answer must be decidedly returned; because some facts prove that typhus fever may be quite unattended with any of the foregoing morbid appearances in the ileum and valve of the cœcum, and the symptoms be connected with traces of organic disease in the stomach.* We have seen also, that inflammation and ulceration of the mucous coat of the bowels prevail in remittent and other fevers, which are quite different from typhus.]

It should never be forgotten, that typhus in every stage and variety is one and the same, a disease of sensorial debility; and that our only hope of cure depends on economizing the nervous power that remains, supporting it as far as we are able without farther loss, and opposing the natural tendency of the disease by such tonics as the system will best bear.

On this account, whatever tends to weaken the animal frame generally, or any one of its functions particularly, must, as a common rule, be carefully abstained from; and hence severe evacuations, by bleeding† or purging, are among the foremost objects of prohibition.

rhage from different parts, more frequently, however, from the bowels than from either the nose, lungs, or any other cavity; and, when the hemorrhage is excessive, the already exhausted powers of the patient are often irrecoverably sunk. A similar hemorrhagic action is not unfrequently manifested in the skin, in the form of small red spots (*petechiæ*), or more extensive patches, termed *vibices*. In cases of still greater malignity, carbuncles, gangrenous inflammation of the skin, painful swellings of the lymphatic glands, and, in some seasons, especially in hospitals, erysipelas may arise."—See Tweedie on Continued Fever, p. 80.—Ed.

* *Anatomie Pathologique considérée dans ses vrais rapports avec la Science des Maladies*, p. 102, tom. i., 8vo., Paris, 1829. A further refutation of this doctrine is contained in the writings of Laennec, and in Burne's Practical Treatise on Typhus, 8vo., Lond., 1828.

† This doctrine should be qualified. "In the milder cases of typhus fever, bloodletting is seldom necessary, and may in general be dispensed with, unless some special circumstance arise to render

The bowels, indeed, ought by all means to be moved by a gentle aperient; but beyond this we ought not to proceed, as we shall add to the debility, without obtaining any correspondent advantage. The grateful acids of tamarinds, cream of tartar, or prunes, are preferable, if found sufficiently powerful; but, if not, they should be combined with rhubarb or senna.* And, as the stomach is less irritable than in yellow fever, an emetic may be given whenever indicated; but, unless there be a troublesome nausea, even this had better be avoided. Ipecacuanha will answer better than antimonial preparations, and the evacuation should be followed with a cordial draught.

[On this part of the subject, the following observations, delivered by Dr. Bateman, seem judicious. The first object is to arrest the febrile affection, if possible, in its very commencement, by means capable of exciting a kind of shock in the system. The two most efficacious remedies of this nature are emetics and the affusion of cold water on the skin. The first has this advantage, that it may be employed in the very onset of the fever, during the presence of the rigours; while the second, although perhaps more powerful, is inadmissible until the hot stage be completely formed. If an active emetic be given during the chills, and a free vomiting be excited, the cold fit is often speedily terminated, and a general glow, accompanied with a degree of perspiration, is produced. Or, if the emetic be delayed until the hot fit has commenced, its operation is frequently followed by it expedient; such as severe pain, or sense of weight in the head, flushing, intolerance of light, hot skin, and other symptoms, denoting a more intense form of fever. With such symptoms, the abstraction of a moderate quantity of blood, especially if the patient be young, or of a full habit, will be proper. If, however, the pulse, though rapid, be soft and compressible, the tongue begin early to assume a brown taint, and there be considerable prostration, the loss of blood cannot be sustained."—See Tweedie on Continued Fever, p. 210.—Ed.

* On account of the greater tendency to inflammation of the mucous membrane and follicles of the intestines in typhus, Dr. Tweedie thinks that every source of irritation, and, consequently, the stimulus of cathartics, should, as much as possible, be avoided. "If these precautions as to bleeding and purging are necessary in the early stage, they are more especially so in the advanced; at which period such aperients as remove unhealthy secretions without producing watery stools are to be employed, viz., rhubarb, magnesia, or castor-oil, with occasional doses of mercurials. It is necessary to examine daily the evacuations from the bowels in typhus fever. Bloody diarrhoea is always a most alarming symptom in fever, showing a malignant form of the disease. It depends on a loaded state of the capillaries of the mucous membrane. The congestion of the mucous membrane, and consequent hemorrhage, may take place without ulceration; but, when there is ulceration, the blood does not proceed from the open surface, but by capillary exudation. This symptom is best managed by suspending all irritating medicines, and administering occasional doses of superacetate of lead and opium."—See Tweedie on Continued Fever, p. 213.—Ed.

a free perspiration, as well as a relief of every symptom.*]

But congestion, as already observed, may take place, and this too in the larger and more important organs of the animal frame, as the head, the lungs, or the liver.† If in the first, there will be a sense of oppression in the brain, most commonly combined with stupor, or low muttering delirium; if in the second, a laborious weight on the chest and a difficulty of respiration; if in the third, the bowels will usually be found costive, the motions pale and argillaceous, and sometimes the skin and the urine chlorotic, or of a greenish yellow, from a regurgitation of morbid bile into the sanguineous system. Hence the fever will be aggravated from local irritation, and the affected organ will be in danger of inflammation, if not of gangrene.

Is the general rule in this case to be departed from? is blood to be taken from the system? and if so, is it to be drawn locally or generally? and to what amount?‡

We have here only left to us a choice of difficulties. Nothing, as Dr. Fordyce has justly observed, is more dangerous in any fever, than its affecting one part more than another; but in typhus the danger is extreme, and must be combated boldly and rapidly by whatever plan has a chance of taking it off, and however hazardous in itself, provided the hazard be less than that of the disease. And hence in this case, bleeding must be had recourse to, for there is nothing we can so well depend upon. If we

* Bateman, in Rees's Cyclopædia, art. FEVER. Although Dr. Elliotson approves of giving an emetic in the beginning, yet, if there were tenderness of the epigastrium, or tenderness on making pressure on any part of the abdomen, he would not have recourse to such measure. Also, if there were violent determination of blood to the head, he would not recommend it. If this symptom existed, together with a full pulse, he would first bleed the patient.—Lectures at Lond. Univ., pub. in Med. Gaz., 1832, p. 183.—Ed.

† For further information respecting the state of these organs, see Dr. E. Percival on the Epidemic Fevers of Dublin in 1813, 1814, and 1815; in Dublin Hospital Reports, vol. i., p. 304, &c. Also, Dissections by Dr. Macartney, recorded by Dr. Barker, in Trans. of King's and Queen's College of Physicians, vol. ii., p. 574, et seq.—Ed.

‡ As Professor Elliotson observes, "it is necessary, in every case of fever, to be constantly on the look-out for local inflammation; every day to ascertain what is the state of the affection of the head, of the affection of the chest, and of the affection of the abdomen. You should always ask if the patient complains of headache; you should look at his eyes, and see whether they be red or not; ascertain if his pulse be full, and inquire whether there be any throbbing of the head. So, with respect to the chest, you should observe whether there is difficulty of breathing, and if there be, it is well to apply the stethoscope, and ascertain what rattling there is. The abdomen ought to be carefully felt every day, to see whether the stomach, intestines, liver, peritoneum, or other parts, are inflamed. When we find a sufficient degree of inflammatory disturbance of these parts, then it is right to take away blood locally."—Lectures at the London University, pub. in Med. Gaz., 1832, p. 210.

have reason to believe that the overloaded organ is without inflammation, the blood should be drawn locally and till relief is afforded; if there be good ground for suspecting that inflammation has commenced, and especially if the organ affected be large and important, it will be better to employ the lancet; and it cannot be employed too soon, nor ought it to be relinquished till it has attained its object.—(J. P. Frank, *De Cur. Hom. Morb. Epi.*, tom. i., p. 136.) There is a risk in the practice; but there is death without it. Fainting may perhaps take place in the midst of the operation; but this is rather to be wished for than guarded against; for the exhaustion of sensorial power produced by deliquium, bears no comparison to that produced by the influence of the typhous miasm.

The following remarks of Dr. Baillie upon this subject, as indeed upon most others, are peculiarly important; and the more so from the modesty with which they are given, and the striking proof of the candour which so particularly distinguished this great and experienced man. It is thus he writes, towards the close of his active and honourable career:—"During the greater part of the time in which I have practised medicine, physicians in general, and myself among that number, have, I believe, been too sparing in taking away blood in typhus fever. It was hardly ever directed to be taken away from the arm, and not often locally, except by the application of leeches to the head. Of late years many physicians have gone into the opposite extreme, and have taken away blood too profusely. In the course of a few years, this remedy, like every other, will find its proper level."*

In the above state of the disease, namely, that combined with visceral congestions also, instead of merely keeping the bowels open, we should employ purgatives that will maintain a stimulating effect upon the whole of the intestinal canal, so that three, or even four evacuations may be obtained daily; and calomel will be commonly the best medicine for this purpose. [When the symptoms indicate irritation and ulceration of the mucous membrane of the bowels, Dr. Bright prescribes the hydrargyrum cum cretâ, and the compound chalk powder, with or without ipecacuanha; and if the alvine evacuations are too scanty, he gives castor-oil with a few drops of laudanum. This, with fomentations, leeches, and cupping of the abdomen, according to circumstances, is the practice from which he has seen the greatest benefit result, where fevers are attended with the complication of diseased mucous membrane of the bowels.†]

* Lectures and Observations on Medicine, by the late Matthew Baillie, M. D., 8vo., 1825, unpublished; printed by Taylor.

† See Bright's Reports of Medical Cases, p. 184, 4to., Lond., 1827. The following is the advice delivered by Professor Elliotson:—"If there be vomiting, or tenderness at the epigastrium without it, you should apply leeches there, which are the best remedy for it; because, when there

Such are the exceptions, and the only ones we should allow to the general rule of opposing the disease, by economizing, supporting, and restoring the depressed tone of the nervous system. But there are pathologists, and of considerable authority, who recommend bleeding, and even full bleeding, in almost every instance of the disease, as the first step to be pursued: thus inverting the mode of practice here laid down, and taking the exceptions for the rule, and the rule for the exceptions.

The theory of this recommendation is but of little importance, provided it be justified by its result. At the same time, I cannot avoid observing, that its chief advocates have not been able to bring themselves to any thing like a common theory, or to support their recommendation upon common principles; than which nothing can be more unfavourable to the reception of a doctrine, or more hostile to its scientific pretensions. Typhus is, by Dr. Clutterbuck, regarded, like every other kind of fever, as the result of an inflammation of the brain; and bloodletting is here grounded upon the principle of attacking the cerebral inflammation, and *debilitating* the action of the living fibre. The visceral and other local congestions and inflammations that so often occur, are, by Dr. Armstrong (*Practical Illustrations of Typhus*, &c., 8vo.), regarded as precursive and generative of the sensorial debility, while the disease itself is no more derived from the brain than from any other organ. And bloodletting, under this view of the subject, is recommended as the means of *preventing* debility in the living fibre, instead of *adding* to it. "We may perhaps find," says he, "sufficient data for concluding that the nervous appearances, even from the very first attack, are only secondary of vascular disorder." Now, these hypotheses, discrepant as they are from each other, may be both founded upon a mistake of the effect for the cause.—(*Appendix to his Remarks on the Constitution of the Medical Department*, &c.) And such, indeed, seems to be the general opinion of pathologists upon the subject; and hence, even admitting the benefit of bloodletting as an invariable or common rule, we have yet to search for *some other reason* by which such benefit is to be explained. Dr. Jackson thought he had found this reason in the *stimulant* effect of venesection upon the system at large, which, by exciting new motions, suspends or changes morbid motions, and affords room for the *vires medicatrices* nature to act

is tenderness or vomiting, it generally arises from inflammation of the mucous membrane, and leeches will remove it by removing the causes of inflammation. So, with regard to the abdomen at large, when that is tender, there is generally more or less diarrhoea; the intestines are acting too violently, and leeches, freely applied, are the best mode of restraining it. After they have been applied, you may employ a blister; but you should always remember that a blister will not answer as a substitute for local bleeding, if the inflammation be considerable."—Lectures delivered at Lond. Univ., and published in *Med. Gazette*, 1832, p. 211.—Ed.

with a more salutary power; while, by its mechanical effect in diminishing the circulating fluid, it adapts the moles movenda to the vis movens. Venesection, therefore, upon Dr. Jackson's hypothesis, acts not by debilitating, or even preventing debility, but directly by *invigorating* the living fibre; and in this view he employed it in fevers of every kind, entonic and atonic, inflammatory and putrid, and, in his own belief, with nearly equal success.

But this is to regard the blood as an encumbrance, a dead and foreign body in its own vessels, instead of as a living and nutrient principle; the removal of which affords ease and freedom to every part of the animal frame, and clears it for the contest in which it is about to engage. A violent and general commotion, produced in the system from severe bleeding, or any other cause, cannot fail of exciting a very deep impression upon every part; and has often suspended or changed the actual train of motions, and introduced a new train in its stead; and, in various instances, the change has unquestionably been beneficial, and even salutary. This is particularly the case in sudden and overwhelming excitements of mental emotion, which have, sometimes, abruptly cut short the career of fevers as well as of various other complaints; of which the Baron Van Swieten gives a striking instance in a man, who, while labouring under a continued fever, with delirium, was so alarmed at the terrific aspect of a person that burst suddenly into the sick room, vociferating that the house was on fire, which in this case was the fact, that he rose without help from his bed, ran out of the house with all speed, and was well from that moment. To this principle of salutary change of action, excited by a violent and general commotion throughout the system, it is probable, that we are to ascribe the occasional benefit that has followed upon draining the vessels of blood in diabetes, and even in lyssa, or canine madness. And it is possible, therefore, that copious venesection may, also, in many instances, have cut short the attack of typhus, and thus proved a rapid and effectual remedy. But, if this be the ground upon which it acts, few practitioners would be disposed to recommend it; while, if it be not, we have no other ground that will furnish us with a satisfactory explanation.

In the commotion which takes place from copious venesection, it should moreover be observed, that there are often local determinations of other kinds or to other organs; for, the more we lessen the general strength, the more we make an inroad upon the instinctive power of preserving a balance in the circulating system; and as these new determinations are almost uniformly accompanied with an apparent, though a deceptive, increase of force, as well as of fulness in the pulse, and other symptoms of great violence of action, the friend to phlebotomy is too often stimulated to an exercise of his lancet through several times in succession, still wondering at the perversity of an action, whose mischievous, and, it may be, fatal

perseverance, is only maintained by his own exertions. The following remark of Dr. Pring is, upon this subject, of great value, as well as perfectly correct:—"It is commonly, and in my own experience it has been invariably, the case, that those who have sustained great losses of blood, suffer more or less from what is called determination to the head. The symptoms most commonly are, intense pain and throbbing in the forehead or back part of the head, with a pulse seldom under 90. I have known these symptoms to proceed on, with a pulse from 120 to 140, to delirium, apoplexy, and death."—(*Principles of Pathology, &c.*, by Daniel Pring, M. D., 8vo., 1823.)

But the author has observed, that the theory is of little importance, provided the practice has justified itself by the event. How then stands the sum of general opinion upon this subject, even apart from such occasional fatalities? The practice is by no means new, though ordinarily supposed to be of recent origin; for it has alternately lived and died away, been revived and again sunk into disrepute, for considerably upwards of three centuries; and its advocates have, in various times, been as numerous and as confident, and have maintained as warm a contest, as we are called upon to witness at present: of which any one may convince himself who will turn to the books referred to in proof of this assertion, at the foot of the page;* of which the first three were published in the sixteenth century, the ensuing two in the seventeenth, and the last two in the middle of the eighteenth. Professor De Büchner, of Halle, was strenuously opposed in his recommendation of venesection, at Paris, by Chambon de Montaux, and at Rome, by Sinibaldi. Yet, as in the present day, the supporters of the depleting system had also not a few controversies among themselves, though they were not precisely of the same description as those in our own time; the chief point of dispute being the part of the body from which blood could be drawn with most advantage; some practitioners performing on the arm, and others on the leg or foot; a point, however, that gradually lost its importance, as the doctrine of the circulation of the blood became more generally adopted and understood. It is not a little singular, nevertheless, that Dr. Marcus, who is entitled to the distinction, if not of reviving the plan of sanguineous evacuation in the present day, at least of carrying it to a more daring extreme than any other practitioner, and of stamping its general use with all the weight of his authority, was, only a few years before the publication of his "*Special Therapeutics*," in which the

advantages of bold depletion were first triumphantly promulgated, one of the most ardent disciples of Dr. Brown of Edinburgh, and consequently one of the warmest advocates for the opposite system of cordials and stimulation.

Judging, therefore, of the expediency of blood-letting, from the history of the practice before us, when enforced as a general rule in typhus, the sum of medical opinion upon a trial of three centuries is against it. The practice has occasionally started into popularity; but it has never been able to establish itself. In the peculiar states of the disease I have already adverted to, it may be useful, and ought not indeed to be neglected: but every case must speak for itself, and the rule must not be confounded with the exceptions. And such, in effect, was the opinion of Dr. Gilchrist, as expressed in his treatise on Nervous Fevers, published seventy years ago, in which he tells us that, at that period, "the ordinary evacuations in the beginning were bleeding and vomiting," and that it was sometimes "necessary to bleed once and again, by which the symptoms were considerably lessened."—(*Edin. Med. Essays*, vol. iv., p. 281.) But he had too much good sense to enforce this practice indiscriminately, and felt the necessity of yielding to contingencies; for, in many instances, he adds, "though we bleed, the symptoms are not always much abated by it; and if we bleed freely, being deceived by an appearance of plethora, we do harm: indeed, in general," continues he, "I imagine bleeding seldom did much good; and if great caution were not used, I suspect it was hurtful: but as I was not often called in the beginning, I am unwilling to pronounce positively about it." The passage is well worthy of attention, as containing the free opinion of an able, candid, and distinguished writer upon an extensive examination of the subject in his own day: and an opinion, too, which is very considerably in accordance with the opinion and practice of Sir John Pringle and Dr. Huxham, and still more lately of Professor Hildenbrand who is well known to be one of the most extensive practitioners in the disease before us, as well as one of the most able writers upon it in the present day.

The fact is, that action has too generally been mistaken for energy, than which, a more fatal error can never be committed. The immediate effect of profuse or repeated bleeding is exhaustion; but this effect shows itself in very different ways in different constitutions or idiosyncrasies, the principle of which the reader will find explained under the subject of syncope. While this exhaustion continues, there is a diminution of action of every kind, morbid as well as natural, and hence an imposing appearance of relief to the symptoms of the disease; but it no sooner takes place than an instinctive effort is made, the vis medicatrix naturæ, to remedy the evil hereby produced, and to restore the system to its former balance of power. This effort is called a rallying or reaction of the living principle. The arteries contract, to adapt themselves to the measure of blood that remains; the sensorial organ is roused to the secretion of a

* Bernardi Caxanes, De Ratione mittendi sanguinem in Febris putridis, Barcelon., 1592; Sylvaticus, De secundâ in putridis Febris venâ quam Salvatellam dicunt, 1583; Turini, An in omni Febre putridâ compatiatur phlebotomia? Rem., 1545; Nigrisoli, Progymnasma de venâ in Febre malignâ secundâ? an superiori an inferiori? Guastalla, 1665; Suavalla, Ergo malignæ febris venesection? Paris, 1694; De Büchner, Diss. de Venesectione in febris acutis malignis, Halle, 1757; Gilchrist, Edin. Med. Essays, vol. iv., art. xxiii.

larger proportion of nervous power to supply the inordinate drain that takes place during the general commotion, all is in a state of temporary hurry and urgency, and for the most part irregularity of action, while the instinctive effort is proceeding. And hence, no sooner is the immediate effect of prostration, exhaustion, or syncope overcome, than the heart palpitates, the pulse beats forcibly with a jerking bound, the head throbs, the eyes flash fire, and the ears ring with unusual sounds. Now, it often happens, that these concurrent signs are mistaken for proofs of latent or increased vigour, instead of being merely proofs of increased action; and action too, that adds as, largely to the exhaustion as the depletion that produced it: and the unhappy patient is bled a second, a third, or even a fourth time, till no such reaction follows; at which time it is strangely supposed that the entony, plethora, or inflammatory diathesis, is subdued and lulled into a calm, because the patient has been so far and so fatally drained of his living principle that there is no longer any rallying or reactive power remaining; and gives up the ghost, in a few hours, to the treatment, instead of to the disease.

There is a valuable paper upon this subject from the pen of Dr. Marshall Hall, in a late volume of the Transactions of the Medico-Chirurgical Society (vol. xiii., part i., p. 140), which should be read by every one before he ventures to employ his lancet in the case before us. "The symptoms of exhaustion," says he, "with reaction, have, I am persuaded, frequently been mistaken for those of INFLAMMATION, or other DISEASE OF THE HEAD OR HEART. Under this impression, recourse has frequently been had to the further detraction of blood by the lancet; and the effect of this practice is such as greatly to impose upon the inexperienced, for all the symptoms are perhaps fully relieved. It was some time before I could fully comprehend the nature of this fact. I had satisfied myself that, in certain cases, the symptoms were those of loss of blood, and yet it appeared to me no less certain that those very symptoms were relieved by the lancet. At length I discovered, by careful observation, that the symptoms which were relieved were those of reaction, and the mode of relief the substance of syncope; that the relief endured as long as this state of faintness continued, but returned as this state gave way to the rallying and reaction of the vital powers.

It should never be forgotten, however, that the expediency of bleeding must depend, not only on the diathesis of the individual, but very considerably on the state of the atmosphere. This remark I wish to enforce very strongly on the attention of practitioners, as it is derived from experience, and is of more importance than it may at first appear to be. As inflammatory fever has sometimes a tendency, from peculiarity of constitution or accidental circumstances, to run rapidly into typhus, typhus, in like manner, occasionally meets with incidents that suddenly reverse its character, and incline it to an inflammatory type. A very stimulant plan of treat-

ment has sometimes done this; but far more frequently, a sudden change in the atmosphere, from hot, hazy, and relaxing weather, with scarcely a breath of air stirring abroad, to a dry, cool, and refreshing east or northeast breeze: and I have often found a like tonic effect produced upon a patient labouring under typhus in a low, damp, filthy, and suffocating lodging, upon his being removed into a large, cool, pure, and well-ventilated chamber, such as is now generally found in our fever institutions. In this case, bleeding, which I had not dared to risk, notwithstanding some symptoms of oppression, before the removal, has been practicable without any risk afterward, and has laid the foundation of a speedy and effectual cure; and I am inclined to think, that some part of the clash of opinion which prevails upon this subject in the present day, proceeds from a want of due attention to the different states in which different, or even the same patients, are placed by this difference in the purity and temperature of the surrounding atmosphere; and that many hospital physicians, who are the warmest advocates for sanguineous depletion in their own fresh, cool, airy wards, would hesitate upon its expediency if they were to attend their patients throughout in their own close, heated, and miserable habitations.

[This accords with Dr. Alison's experience, who remarks, that "there is probably less typhoid tendency in the earlier stages, and more demand for evacuations in the hospitals, than in the houses of the poor."—(*Edin. Med. Journ.*, No. xciii., p. 250.) The ill effects, however, which this able physician imputes to the removal of patients in the second week of the disease into a pure cool air, seem to the editor more justly ascribable to the disturbance of such removal than to the altered quality of the air itself. That great and decided benefit does result from the timely removal of the patient out of a bad atmosphere, is proved by the valuable testimony of Dr. Bateman, who "frequently experienced the great and obvious benefit of a cool and well-ventilated room, independently of medicine. He has visited patients who had applied for admission into the House of Recovery, in their own close and suffocating apartments, and found them in a state of delirium, with dry, black tongue, great heat, and other bad symptoms. Having directed them to be removed to the house, he has found them cool and perfectly collected, with other symptoms of equal amendment, on the following morning, from the mere influence of a cool bed and an airy apartment."—(*Art. Fever; Rees's Cyclopaedia.*) No doubt, however, Dr. Alison's opinion on the disadvantage of removing the patient in a late stage is perfectly well founded, as the editor has had many opportunities of learning from experience.]

Upon the subject of bleeding, there is a passage in Dr. Hennen's Military Surgery so strikingly in point, that I cannot avoid quoting it. After the famous battle of Vittoria, in July, 1813, the sick and wounded of the British and Portuguese army were chiefly removed to a temporary hospital established at Bilbao; where,

typhous miasm having soon been produced by its ordinary causes, viz., a foul and stagnant atmosphere, crowded wards, and depressed spirits, the sick were soon affected, and, whatever was the nature of the individual constitution, the wounds of all of them ran rapidly into a typhous gangrene; "exhibiting," says Dr. Hennen, "one of the most subtle and destructive poisons that ever infested an hospital, attacking equally the most robust and the most debilitated, and, if unchecked by medical aid, proceeding invariably to a fatal termination."—(*Principles of Military Surgery*, p. 19.) "The atmosphere was, at this time, sultry and relaxing, and greatly contributed to the general debility. 'I need scarcely say,' continues Dr. Hennen (p. 223), 'that a remedy so strongly recommended as venesection had early occupied our attention; but, previous to the month of October, the obviously typhoid type of the disease made us extremely averse from employing it. At that period, however, a change in the weather from sultry to cold, and even frost (at night) took place, marked by a corresponding change in the thermometer, which, at its medium range, was 20° lower than in the preceding month. But what more than all convinced us of the change of type, and pressed on our consideration the propriety of bloodletting, was, that the spontaneous hemorrhages, which formerly sunk the patient's strength, were now accompanied with obvious relief.' And he proceeds to state, that, from this time, the practice of venesection, on the appearance of inflammatory symptoms in a wound or newly-healed stump, became general, and was the only remedy had recourse to, whether as a cure or a preventive.

Of such importance is it for us to be guided by particular and general circumstances in the treatment, not merely of typhus, but of all diseases whatever: to let the rule have its exceptions, but not to mistake the exceptions for the rule. "The art of physic," says Sir George Baker (*Med. Trans.*, vol. iii., 417), "rarely admits of any perpetual precepts; and the best medicine may do harm, if not adapted to the patient as well as to the disease."

There is another remedy of very extensive use in the cure of typhus, far less disputable, and which is founded altogether upon the indication of equalizing, supporting, and restoring the sensorial power, and that is, the free application of cold water, and especially externally.

This valuable medicament has been employed in some form or other almost immemorially. Hippocrates recommends it in malignant fevers, generally in the form of epithems, or napkins wetted with cold water, and applied repeatedly to the head, or any other viscus, as the cloths become warm.—(*Περὶ Νοσῶν*, ii., p. 484, 50.) Among the later Greeks however, it does not appear to have been in very general use; and, though it is highly prized by Celsus, in various debilities, and especially sensorial debility affecting the head, and combined with fever, in which, says he (*Medicina*, lib. iii., sect. xx.), "existat validissimè repente aqua frigida infusa," yet it does not seem to have constituted a fixed, or

even a frequent practice in his day. In our own country, it was successfully employed by Dr. Willis in various fevers, and especially those accompanied with delirium; and was hence strongly recommended by Sir J. Floyer and Dr. Baynard: and was used on the continent not merely in the form of epithems (*Mur-smna über Ruhr und Faulfieber*; Loeffler, *Beyträge*, &c.) and affusions, but occasionally in that of immersion, or cold bathing in a river adjoining the patient.—(*Eph. Nat. Cur. Dec.*, iii., ann. iii., obs. 48, and ann. v., vi., app., p. 128.)

On the continent, indeed, it seems to have been employed at a much earlier period than in our own country, as we learn from Milot's Dissertation, "*Ergo febris frigidis et humidis expugnenda?*" printed at Paris in 1594; and Hernault's, on the same subject, "*Ergo propria febrium medela refrigeratio!*" printed in the same place in 1630. It was also used internally as well as externally, both in our own country as well as on the continent, especially in Spain and Naples, as is obvious from Dr. Hancock's *Febrifugum magnum*,* and Dr. Cy-rillo's paper on the subject in the Philosophical Transactions. Even snow, or snow water, under the name of aqua nivata, or aqua nive refrigerata, was also occasionally employed (*Nouvelles Annales de Médecine*, iv.), and, in the ardent fever, recommended by Paullini, both externally and internally.† Professor Hildenbrand, of Vienna, during the extensive range of practice which the Austrian army afforded him in the late war, employed sometimes the cold bath, sometimes affusion of cold water, and sometimes a general friction of the surface with snow itself in the commencement of the fever.

—(*Ueber den ansteckenden Typhus*, &c., ut supra, Wien, 1815.) And, to prove how torpid to common impressions the body is under nervous fevers generally, and how little disposed to be injured by such applications, it is only necessary to advert to the case of a patient at Lucca, given by Dr. J. Benevuti, in another part of the Transactions just referred to. On the ninth and tenth day from the incursion of a malignant fever, he was thought to be in great danger. On the eleventh, he expressed a wish to go to sleep, and desired the attendants to withdraw. On their return, he was found to have left his bed; and, three days afterward, was discovered in a hut in a vineyard, about two miles from the house, having but just recovered his senses, and as much wondering how he came there as those who had traced him out. It appeared, on farther inquiry, that he had descended from his chamber by the window, in his shirt

* *Febrifugum magnum*; or common Water the best Cure for Fevers. Lond., 1752. The editor saw many fevers in the Military Hospital at Canterbury, in 1813, treated entirely by sponging the body with cold water, and making the patient drink copiously of the same cheap article. The success of the plan was considerable.—Ed.

† Cent. i., obs. 66. See also Nehemias (Abrah.) De tempore aquæ frigidæ in febribus ardentibus ad satietatem exhibendæ, 8vo., Venet., 1591; Planchon, Journ. de Méd., tom. xxx., p. 127; Lamarque, id., tom. lxvi., p. 460, lxvii., p. 68

alone, and in a great perspiration; had walked all the way in the snow with which the ground was then covered, and had swallowed a large quantity of it to quench his thirst. Yet neither the cold air, nor cold beverage, affected him otherwise than beneficially. He continued well from this time.—(*Phil. Trans.*, vol. viii., 1768.)

The use of cold water, however, as well external as internal, appears on many occasions to have been employed with too little caution; and hence one reason of its falling into frequent disrepute. Even as early as 1581, Masini thought it right to guard the profession against its abuse, by a work expressly devoted to this subject (*De Gelidi Potūs abusu.*, 4to., Cesen.); and numerous others occurred in succession through the ensuing century.

In our own day, Dr. Wright, of Jamaica, is perhaps the first physician who revived the practice; but it is chiefly to the judgment and experience, the writings and recommendation of Dr. Currie, of Liverpool, that cold water, as an external application, is indebted for the high and deserved degree of popularity it again possesses, and especially in typhus.

It is now equally used in the form of sponging, ablution, and affusion, the last of which is the *κατάδουσις* of the Greek writers, though this term sometimes also imported immersion. All these are of essential use; yet the most sudden and decisive benefit has been observed to result from affusion; for which purpose the patient is to be supported on a stool in a low wide tub, and to have a small bucket of water, containing about two gallons, poured briskly on his head, and repeated four or five times in the course of the twenty-four hours, when the surface of the body is hot and without perspiration. In many cases, this plan alone has proved successful, and the fever has been cut short in a day or two from its commencement. But the method is too violent and exhausting to be employed after the first three or four days of attack; after which it will generally be most useful to restrain ourselves to epithems about or all over the head, the hair being removed for this purpose, or to sponge the body generally; and if the sensorial debility be extreme, we should prefer tepid to cold water, or mix with the cold water a little brandy or other spirit. When this method succeeds, the usual salutary effects are, a considerable diminution in the number of the pulse; diminution of heat and headache; natural sleep, and a breathing perspiration.

It does not appear to me that the principle has yet been fully explained, by which the external application of cold water becomes thus unequivocally beneficial. This is generally referred to its tonic power in exciting a reaction as the result of its chill. But though affusion often produces not only a chill, but even horripilation, sponging the body with tepid or even with cold water produces no chill of any kind; and there are many cases of extreme debility in which, if a chill were to take place, it would be most mischievous, and certainly would not be succeeded by any heat or reaction whatever.

Independently of which, the refreshment takes place too speedily for such an effect, and is of a different and more tranquilizing kind, than the excitement which follows upon the chill of cold bathing in a state of health.

Upon internal medicines we can place but little dependence, except where they have pretensions to a tonic power, are moderately cardiac, or tend to equalize the nervous influence or circulating fluid.

The chief tonics in use among the Boerhaavians, were the serpentaria and contrayerva, on account of their systematic objection to the bark. The tonic power of these, however, is but feeble; by their stimulant property, they sometimes prove diaphoretic: but even as cardiacs their place is better supplied by other medicines; and in proportion as the bark has established itself, they have gradually fallen into disrepute. Yet even this last seems to be following the same track in the opinion of some practitioners of the present day, who have withdrawn all confidence in it, and undertake to affirm that it has done more mischief than good. But this is strangely to set aside the wisdom of former times, and to misconstrue the train of phenomena before them. Bark, like every other medicine, is necessarily injurious when injudiciously made use of; but there are few if any medicines of more importance, even in typhus, when there is a fit opportunity for employing it. Where the stomach is irritable, and will not retain it, or so feeble in its secret power as not to digest it, and particularly where there is a tendency to local accumulations, it ought unquestionably to be avoided, till these symptoms are subdued by other means. But, where there are no such objections, it cannot be begun too soon, though it should not be pressed in such large doses as in the more rapid course of yellow fever. And where the bark cannot be made to sit easy on the stomach, its place may be well supplied with columba, either in powder or infusion. I need not add, that the sulphate of quinine is its best form.*

* Dr. Cullen lays it down as a rule, that whenever bloodletting is proper in continued fever, bark is prejudicial. Dr. Bateman, in the early part of his practice, used to prescribe cinchona on the first appearance of languor and debility; and he followed this method till he was convinced that it had pernicious effects, rendering the tongue dry and brown, the pulse harder and quicker, the skin hotter and more parched, &c. Hence, he nearly abandoned bark altogether. Dr. Tweedie also deems this medicine hurtful in the early stage of epidemic fever, and, when the symptoms of fever have completely subsided, he considers no tonic or stimulating treatment necessary, unless the patient be much enfeebled, and the recovery of the strength slow. But he holds its exhibition in the early stages of fever, under any circumstances, improper, as tending to keep up or increase the febrile action; and, when there is local complication, he sets it down as still more improper. "When the fever is of the typhoid form, and the symptoms, as the disease advances, denote failure of the powers, more particularly if the pulse become soft and compressible, the skin covered with petechiæ, and there be tendency to

If the skin be greatly heated and dry, either of these medicines may be combined with nitrate of potash, or a solution of the acetate of ammonia; and if the prostration of strength be considerable, we may employ camphire or wine in conjunction with tonics.

Camphire has, indeed, been united with medicines of very different powers; as with large doses of nitrate of potash, or nitrate of potash and calomel, which was at one time a favourite practice in Germany (*Abhandl. von der Wirkungen des Camphors und Calomels in anhaltenden Fiebern*); or, which is far better, with cinchona, a combination peculiarly recommended by Lasonne as increasing the energy of each, in which opinion he is joined by Dr. Cullen. Camphire, however, is in itself a highly valuable medicine on the present occasion, and cannot well be given too soon. It calms the low delirium, produces a genial glow on the surface, and seems to act as a steady permanent cordial. It was chiefly trusted to by Professor Hildenbrand during the late war, though he often united it with arnica; and, believing that no practice whatever could shorten the natural course of the disease, endeavoured to sustain the system by these remedies almost exclusively.

Acids, indeed, of all kinds, and acidulous drinks, are of great benefit in typhus. They allay the heat, tranquillize the restlessness, support the strength, and oppose the tendency to putrescence. The muriatic was preferred by Sir William Fordyce, but the sulphuric appears to be equally efficacious, and is much pleasanter.

The best cordial is wine, and it must be given in proportion as the living power flags. We must be cautious, however, in first administering it; for its very stimulus produces exhaustion, and, consequently, increased torpidity: and we should invariably recollect, that, when we have once commenced with its use, we can never leave it off; and should hence begin with such doses only as may be safely persevered in, or even increased if necessary.

Under the influence of Dr. Brown's name, both wine and spirits were lately given in enormous quantities; and it is possible, that, in a few instances, the practice may have been successful; but the risk is great and empirical; yet the practice is by no means of so late an origin as Dr. Brown's name would incline us to believe: for Borelli, Chambon de Montaux, and Reidlin, gave it quite as largely, and at least with as much success. Borelli prescribed it in injections (*Cent. i.*, obs. 55); Reidlin assures us, that he cured a patient by administering a large dose of spirit of wine (*Linn. Med.*, 1695, p. 220), upon which Brown does not appear to have ventured; and we are told by another writer, long before Dr. Brown's time, that he completely succeeded in conquer-

ing a typhus by making his patient drink wine to ebriety on a critical day.*

Opium appears to be of less service in typhus, than in many other species of fever, and by no means entitled to the unmeasured eulogy bestowed upon it by Dr. Home, who contended, that, in every case of typhus, it was the most useful medicine; that it procures rest without any inconvenience; and that it is more to be depended upon than camphire, castor, the sedative salt of Homberg, or any other medicine of the same class.—(*Clinical Experiments, Histories, and Dissections*, 8vo., Edin., 1780.) It is best given in combination with camphire; and there is ground for the assertion of Lasonne and Hall, that, thus united, it produces less confusion of the head and disturbance in the dreams: and, so far as I have seen, it agrees better with the young than with those of middle life. Hildenbrand reserves it in every instance against distress from dysentery or diarrhoea.†

* Eph. Nat. Cur. Dec., i., ann. iii., obs. 145. With respect to wine, as a remedial agent in typhus, Dr. Wilson Philip offers two general remarks; the first is, that more or less wine is beneficial in all severe cases of typhus; and that there are few, in which large quantities are not injurious. The exhibition of wine in typhus must be as much regulated by circumstances, as blood-letting in synocha. "Wine is seldom necessary in the early stages, nor, as a general rule, at any period of the acute forms, unless, as occasionally happens, unexpected exhaustion comes on, or, towards the decline of the disease, the powers give way. Under these circumstances, a few ounces of wine, if the skin be cool, the pulse soft, and the tongue moist, will frequently improve the condition of the patient."—(Tweedie on Continued Fever, p. 216.) According to the experience of the same physician, the propriety of administering wine in fever will sometimes depend upon the type of epidemic fever. In 1829, as the records of the London Fever Hospital prove, fever required a most decided antiphlogistic treatment; in 1830 and 1831, the symptoms assuming a low typhoid form, a more stimulant plan became necessary. We have seen, that local inflammations not unfrequently arise in feeble habits, or in the advanced stage of low fever, requiring general or local bleeding. The treatment necessary to subdue the local disease, lowers the general strength; the patient does not rally, and perhaps loses ground. In such cases, Dr. Tweedie finds a moderate quantity of wine, provided the pulse be soft, and the skin cool, is followed by excellent effects. When the fever assumes the petechial character, he also approves of wine. Dr. Tweedie offers much valuable advice on this part of the subject; and, perhaps, what he has stated, joined with the remarks of Dr. Wilson Philip and Dr. Marshall Hall on the same topic, will give the best general views of the doctrines which should regulate the practice of venesection in fever.—Ep.

† From the stimulant effects of opium, it is generally regarded as an improper medicine in the acute forms of fever, especially when local inflammation exists. According to Dr. Tweedie, the delirium and wakefulness of sub-acute inflammation of the brain are best overcome by topical bleeding, and the application of cold lotions to the scalp; and, when the morbid condition of the

gangrene, bark, in addition to nourishment, wine, and other stimulants, may be given with the best effects. The sulphate of quinine, combined with sulphuric acid, is the best mode of administration."—Tweedie on Continued Fever, p. 225.

Antimonials are a doubtful remedy: they tend to throw the action towards the surface; but, as relaxants, they tend at the same time to diminish the tone of the muscular fibre. It is not often that they can be employed with advantage. In many instances, blisters, judiciously interposed, will be found useful auxiliaries, and especially where the head is much affected; but the body should not be covered with them, as is often the case, from head to foot, so as to be highly distressing to the patient, and to exhaust the little irritability he has left. Cataplasms, or bottles of hot water applied to the feet, when the circulation is unequal, will often be a better practice.

During the entire course of the fever, from the time the bowels have been sufficiently evacuated, the patient may be allowed animal broths and jellies in alternation with the farinacea: he should be lightly covered with bed-clothes; his chamber should be freed from all unnecessary furniture; his sheets and body-linen be frequently changed, and be instantly taken out of the room; as should also the egestions of every kind.

Above all things, the chamber should be freely ventilated, which is infinitely the best way of purifying the air, and dissolving the febrile miasm as it issues from the body: upon which subject we have already touched. Where the ward or chamber is large, or the sick are remote from each other, simple ventilation by opening the opposite windows, or the windows and door, will be sufficient. But where the wards are small, or may not admit of sufficient ventilation, or the patients are numerous, fumigation with nitric or muriatic acid should not be neglected. At present, we have no reason for a preference, except that the vapour of the former appears to be rather more volatile and penetrating. Of late years there have been attempts to decry the use of fumigations, and especially by M. Von Mons and Dr. Trotter, who conceive that they rather increase than diminish the septic matter of the atmosphere. On which account, they advise the room to be frequently sprinkled with water, and a good fire to be maintained,—believing that febrile contagion is much better destroyed by pure aqueous vapour than by any other means.

But this conception is founded upon a double

brain, on which the want of sleep depends, is removed, the patient generally enjoys intervals of refreshing sleep. In other cases, a state of distressing restlessness, with obstinate wakefulness, remains. If, with these symptoms, the pulse, though soft, be rapid, the skin cool, the face pale, the tongue moist, and there be no effusion of the eyes, Dr. Tweedie approves of opium. If, however, its exhibition be followed by increase of delirium, thirst, and heat of skin, or if the tongue become dry and the bowels confined, he recommends it to be discontinued. The preparations of opium preferred by this excellent physician are the muriate and acetate of morphia in half-grain doses. He has also found 15 grains, or ʒj, of camphire, joined with a quarter of a grain of the acetate of morphia, a valuable formula.—On Fever, page 227-229.

hypothesis, and an hypothesis apparently mistaken upon both points: first, that febrile miasm and septon, or the elementary matter of putrescence, are the same thing; and next, that this common principle is nitrous oxide, or oxide of azote, agreeably to the conjecture of Dr. Mitchell. Of septon, however, we know but little; yet, from the established power of hydrogen in exhausting or destroying animal irritability, it is more probable that M. Morveau's conjecture of its being a combination of hydrogen with azote, rather than of oxygen with the same, is the real fact. But be this as it may, we have no more reason for believing that febrile miasm consists of either of these, than that it consists of animalcules of a peculiar kind, as was once contended for by Dr. Chandler.

Febrile miasm, we have reason to believe, is a peculiar and specific production; the chief properties of which I have already endeavoured to point out. Pure air unquestionably dissolves it; and hence there may be other gases capable of dissolving it also, and even more readily; or which, combined with pure air, may render the latter a speedier and more powerful solvent. And it is probable that the vapours of the mineral acids act in this manner. In this respect they may be useful; but, if ever employed to supersede ventilation, the opinion of Dr. Trotter, that they do more mischief than good, will be completely established. The aromas of volatile plants are of no benefit whatever; and if the fumes of tobacco were ever serviceable in the plague, it was most probably, as Dr. Cullen conjectures, from their exhilarating the spirits, like wine or opium, and diminishing the irritability.*

* Our author and his editor have spoken so amply of the nature and treatment of the several forms of typhus, that we have room only for a passing remark. Typhus is of rare occurrence in this country, when compared with Great Britain; and American physicians are most frequently called on to treat that type of it which Armstrong terms the congestive. Typhus is occasionally the sequel of our inflammatory and our remittent fevers; and this fact may be witnessed in the sporadic cases of typhus occurring in the pure air of the country, as well as in those instances of it which are seen in hospitals and almshouses. The observation of Dr. Dewees, however, will have its full weight with the careful physician: "We have," says he, "in several places (Practice of Physic), borne testimony against confounding a certain condition of the system in the yellow, the continued, and the remittent fever with typhus; because they bear no analogy to it, as they all want the power of propagating themselves by contagion." As to treatment, the practice of blood-letting, though not to be enforced with the earnestness of Armstrong, will in some instances be found a remedy of great consideration. Dr. Drake remarks, (West. Med. and Phys. Journ., Jan., 1828), "that it often saves the life of the patient, although it may not cure the disease;" the judicious practitioner, however, must cautiously weigh the peculiar features of each case. Where the signs of increased action, fulness of the pulse, and energy of system demand it, moderate bloodletting may be of service, and may perhaps be repeated, the better to relieve the oppressed heart and ar-

[A few years ago, M. Labarraque discovered that the chloride of lime, now generally employed instead of chlorine for bleaching, likewise possesses the power belonging to that gas of destroying putrescent effluvia. It is also suspected to have considerable power in destroying the effluvia of infectious disorders. Hence, its use is ordered by the French government in all hospitals and lazarettoes. The powder should be dissolved in forty or forty-five parts of water.* Such a lotion would undoubtedly have more effect against contagious effluvia than simple water; the skin, when hot and dry, might be freely sponged with it; and the room sprinkled with it. Indeed, the preparation called the hydrochloruret of lime is recommended by Dr. Reid as an internal remedy, in certain stages of fever and dysentery.—(*Clinical Obs. on the Efficacy of the Hydrochloruret of Lime, &c.*, Dub., 1827.) It has also been given by Dr. Cloquet in doses of from 20 to 30 minims, in examples of gangrene, as well as applied to the part.—(*Alcock's Essay on the Chlorurets of Oxyde of Sodium and Lime*, 1827.) The chloruret of soda has also similar powers.]

teries. But we are to guard against a too great waste of the natural powers of the system. Local congestions will sometimes require dry cupping. As emetics remove sources of irritation from the stomach, and act on the skin, they are not to be overlooked; and mild purgatives, if prescribed with care, are among our best modes of relief. Americans differ as to mercurial remedies; while some approve of them, they are condemned by others. Drs. Tully and Miner, however (see Essays), recommend small doses of calomel, from one to two grains, every three or four hours, until its specific influence on the salivary glands is manifested. The late Dr. Warren, of Boston, bears testimony to the good effects of mercury in typhus fever.—(See his *Mercurial Practice*.)

We have authority for stating, that the practice by affusions of cold water has never been attended in this country with the favourable results obtained by Currie and others in England; probably from the want of a proper discrimination as to the time when this agent should be applied. To secure a salutary reaction, it is necessary that the tonic powers of the system should not have been too much impaired by disease or by medical treatment. The best form of administering opium, when necessary, is probably in the combination termed Dover's powder. We should always bear in mind the medical axiom of Younge, that where bloodletting is indicated, opium is inexpedient.—D.

* See Professor Marc's Official Report; also, Kopp's *Reise in Deutschland und Frankreich*, p. 198; and *Edin. Med. and Surg. Journ.*, No. lxxxix, p. 447.

† "In the cure of fever, we must aim, in the first place, at having free ventilation, and the most perfect cleanliness; plenty of washing, plenty of clean linen, and plenty of fresh air. With fresh air and fresh water, we may go on very well; but if there be any smell which ventilation and washing will not remove, the chlorides, I need not say, are excellent things, sprinkled upon the bed, or the floor, &c. A solution of the chloride of lime ought to be put into the utensils which the patient employs, that no unpleasant smell may arise in the room—no contamination. When you first see a patient, if he be dirty, before prescribing any thing else, it is right to prescribe soap and water."—Professor

SPECIES III.

ENECIA SYNOCHUS.

SYNOCHAL FEVER.

COMPOUNDED OF CAUMA AND TYPHUS: IN ITS COMMENCEMENT RESEMBLING THE FORMER; IN ITS PROGRESS, THE LATTER.

It is not necessary, after our copious histories of the two preceding species, to follow up the present, which is a mixture of both, through a detailed description of its course. It is certainly the most common form under which continued fever makes its appearance in our own country; for it is but rarely that cases of fever occur which preserve a strictly inflammatory character from the beginning to the end. It is in fact an inflammatory fever bent out of its proper career, often, perhaps, by the temperament upon which it has to act; but still more frequently, as Dr. Brocklesby has well observed, by confined and vitiated air, and hence dropping its inflammatory pretensions in the middle of its course. Its causes are therefore the same as those that produce inflammatory fever. Dr. Cullen has entered it into his catalogue of genera after Sauvages and Linnæus; but with a doubt whether he is correct in so doing. "Since many fevers," says he, "are neither altogether inflammatory nor altogether nervous, they cannot be referred either to the synocha (cauma) or the typhus: and I have hence inserted the genus synochus, whose type is frequently seen in this country. Yet, between the typhus and synocha, I cannot place any accurate limits; and I doubt whether they should in fact be deemed genera, or have a different place allotted them." And in his *First Lines* he observes, "I am disposed to believe that the synochus arises from the same cause as the typhus, and is therefore only a *variety* of it."

To me it appears rather to arise from the same causes as the cauma, for it commences with the cauma type. The proper rank for all of them appears to be that of species; and the present system in the text-book, in allotting them this character, steers just a middle course between Dr. Cullen's actual arrangement and his real opinion. And in this view it is distinctly regarded by Dr. Stoll, who sometimes describes it as an inflammatory fever assuming a putrid guise; sometimes as equally inflammatory and putrid; and sometimes as an inflammatory fever passing into a saburral fever.—(*Rat Med.*, vol. iii., pp. 97, 106, 113, iv., 61.) By Kausch, and other German pathologists, it is hence denominated febris inflammatorio-putrida.—(*Grüner Almanach*, 1788, p. 37.) It is, in many instances, the inflammatory typhus of Dr. Armstrong.

Occasionally it shows a considerable tendency to terminate its course abruptly by a critical sweat; it is sometimes peculiarly marked with yellowness of the skin; sometimes with great stupor of the head; and sometimes with inflammatory tension of the peritoneum. And it hence furnishes us with four varieties:—

Elliotson's Lectures at Lond. Univ., as published in *Med. Gaz.* for 1832, p. 162.

- α Sudatorius. Carried off by a critical sweat in an early stage of its progress.
 Sweating synochus.
 β Flavus. With yellowness of the skin, attended with a sense of burning heat.
 Yellow synochus.
 γ Soporosus. Accompanied with stupor from the beginning.
 Comatose synochus.
 δ Puerperarum. Accompanied with an inflammatory tenderness of the belly :
 Puerperal fever. mostly occurring on the third day after
 Childbed fever. childbirth.

The symptoms of the FIRST VARIETY open with great violence. There is usually an intense pain in the head, with a vehement vomiting and purging, which is rarely removed, and sometimes augmented, by an emetic : the skin is peculiarly dry and hot. The balance of the circulating system is here greatly disturbed, and there is an evident determination of blood to the head, and probably to the liver. Like the yellow fever, it rushes forward rapidly to a state of great sensorial debility ; and is best checked in its progress by a free use of the lancet, which more than any thing else takes off the tendency to congestion, and the hardness from the pulse. A diaphoresis commonly breaks out soon afterward, which proves critical, and should be maintained by diluent drinks, and small doses of antimonials or other relaxants.

In the YELLOW-TINGED SYNOCHUS there is a high degree of hepatic irritation, and consequently an excessive secretion of bile, part of which is absorbed and carried into the system : whence Galen denominates it *synochus biliosus*. —(*De Differ. Febr.*, cap. ii. ; *De Crisibus*, cap. ii.) It is found chiefly in the summer season, among young persons of a bilious habit, and is generally produced, like the genuine *cauma*, by too violent exertion under a sultry sky. It is accompanied with intolerable thirst and sleeplessness. In few words, it is a *causus*, or ardent fever without any apparent remission ; its symptoms, with this exception, are the same, and the same mode of treatment is demanded : for which the reader may turn to the second species of the preceding genus.*

While the symptoms rage violently, there is sometimes a great determination to the head, with a sudden exhaustion of sensorial power ; and hence, notwithstanding that this local affection is more severe and confirmed than in the first variety, there is a dull and obtuse, rather than an intense and pungent pain. It is the SYNOCHUS Soporosus of Guarinon and Sauvages, as well as of the present system ; and the continual fever of Sydenham for the year 1763. Among the chief symptoms, says he, was a coma, for the patient soon became drowsy

and obscurely delirious. Occasionally, however, it was a direct lethargy, which continued for two or three weeks, during which nothing but a violent noise would rouse the patient ; when, after opening his eyes, and being persuaded, perhaps, to take a little food or some medicine, he again fell into a sleep so profound, that Sauvages calls it a febrile cataplores. In some cases, however, instead of a lethargy, there was a low muttering delirium, in which the patient spoke incongruously and with fretfulness, with short snatchings of stertorous sleep interposed. The fever rarely terminated in less than fourteen days ; and, when the lethargy prevailed, generally ran on to twenty-one or even thirty days. The first symptom of recovery was usually a capricious longing for some absurd kind of meat or drink. The head for many days still discovered great weakness, and even the muscles were incapable of supporting it in an erect position. Warm cordials were always mischievous : a free and repeated use of the lancet, with brisk purgatives, formed the best plan of cure, with diluting diaphoretics afterward. Sauvages asserts, that blistering the head was serviceable. Epithems of ice-water over the whole head, repeated as soon as they became warm, would probably have proved far more beneficial, as soon as the vessels of the head had been sufficiently emptied.

We find the same fever still more frequently commencing with a like tendency to the peritoneum, instead of to the head, and running rapidly into a state of inflammation, with an imperfect attempt at suppuration ; and especially where this membrane has been excited by a sympathetic action with the uterus or any other adjacent organ, or by exposure to the atmosphere in consequence of a wound through the abdominal integuments. And hence this disease occurs occasionally in cases of tapping for a dropsy of the abdomen, and still more frequently after labour : on which account, it is commonly known by the name of PERITONEAL, PUERPERAL, or CHILD BED FEVER. From the days of Hippocrates to those of Boerhaave and Van Swieten, the uterus was supposed to be the chief seat of inflammation when the disease arises from this cause. But there is now no question that it originates in the peritoneum itself, and that the uterus is often very little affected ; and this too, though the inflammation should spread, as it often does, to other organs in the vicinity.*

* Puerperal fever is much better understood at the present time, than when Dr. Good wrote this part of his work ; and instead of its being essentially a disorder proceeding from peritonitis, as was once the common belief, it is only sometimes accidentally conjoined with it. Hence the idea of the case being the same as peritonitis from tapping is completely erroneous. "From the 1st of January, 1827, to the 1st of June, 1832," says Dr. Lee, "162 cases of well-marked puerperal fever came under our immediate observation in private practice, and in the British Lying-in Hospital, and other institutions in the western districts of London. We watched the symptoms and progress of these cases with the closest attention, observed the effects of the different remedies employed,

* This form of fever often prevails during the summer and fall, in different parts of the United States. It may occur in marshy soils and on the dry prairie grounds. It demands an early and vigorous treatment.—D.

The disease usually commences on the second or third day after delivery; though sometimes it occurs rather later, and, according to Professor Frank, sometimes a little before delivery. —(*De Curand. Hom. Morb.*, tom. ii., p. 189, 8vo., Mannh., 1792.) [Dr. Blundell has known death occur, with all the symptoms of puerperal fever, within the first four-and-twenty hours after parturition; and Dr. Haighton used to relate the case of a woman who died of a puerperal fever, which commenced ten or twelve days after delivery. According to Dr. Blundell, the later the attack, the less is generally the pertinacity of the symptoms.] It is marked by all the common symptoms of a severe febrile incursion, in combination with the tenseness and tenderness of the belly. The muscles of the back and hips are in great pain; the abdomen is tender, often acutely painful, and the pain is greatly increased by pressure, which peculiarly distinguishes this disease from enteritis; and, as the diaphragm is affected by contiguous sympathy, the breathing is also short and laborious, accompanied with most distressing anxiety. [In puerperal fever, the pulse is noted for its extraordinary frequency. Dr. Blundell says that it is scarcely ever below 115 in a minute, unless the disease be yielding to remedies; and more commonly it rises to 120, 130, or 140; and he has counted pulses of 165 or 170.] The head rarely suffers much at first; but, in the progress of the disease, is apt to become stupid and

and, where death took place, we carefully examined the alterations of structure in the uterine and other organs. Of fifty-six cases which proved fatal, the bodies of forty-four were examined, and in all there was found some morbid change, the effect of inflammation, either in the peritoneal coat of the uterus or uterine appendages, in the muscular tissue, in the veins, or in the absorbents of the uterus, which accounted, in the most satisfactory manner, for all the constitutional disturbance which had been observed during life. The peritoneum and uterine appendages were found inflamed in thirty-two cases; in twenty-four cases there was uterine phlebitis; in ten there was inflammation and softening of the muscular tissue of the uterus; and in four, the absorbents were filled with pus. These observations are subversive of the general opinion, now prevalent in Europe and America, that there is a specific, essential, idiopathic fever, which attacks puerperal women, and which may arise independent of any local affection in the uterine organs, and even prove fatal, without leaving any perceptible change in the organization of any of their different textures. As the constitutional symptoms thus appear invariably to derive their origin from a local cause, it would be more philosophical, and more consistent with the correct principles of physiological arrangement, to banish entirely from medical nomenclature the terms *puerperal* and *childbed fever*, and to substitute in their place *that of uterine inflammation*, or inflammation of the uterus and its appendages in puerperal women. The terms *puerperal peritonitis* and *peritoneal fever*, employed by some English and foreign physicians, are not less objectionable than puerperal fever; for, in many of the fatal cases, there is no proof whatever of the existence of any affection of the peritoneum."—Dr. R. Lee in *Cyclop. of Pract. Med.*, art. PUERPERAL FEVER.—ED.

comatose. The flow of the milk and of the lochia are usually suspended, though the latter is not always so; but, in this last case, the discharge is thinner and more acid. The stomach is sometimes, but not generally, troubled with sickness, and frequently discharges an offensive porraceous saburra; and a troublesome diarrhœa attacks the bowels.*

In the opinion of Mr. John Hunter, the disease takes place in consequence of an injury done to the peritoneum, as forming a cavity, by which its present state is either suddenly changed or rendered imperfect. The injury done to the peritoneum in the case of women after delivery, he ascribes, as his sentiments are delivered by Mr. Cruickshank, to two causes. Sometimes it proceeds from a want of disposition in the womb to recover itself after labour; by which the peritoneum, as a cavity, must necessarily be affected. At other times from a too sudden emptying of the abdomen; whence the peritoneum cannot always recover itself so as to be properly adapted to its new condition. This last cause, he observes, may also hold with men after the operation of the paracentesis. But, in them, besides the sudden emptying of the abdomen, there is the additional circumstance of a wound, which renders the peritoneum, as a cavity, imperfect. When an inflammation of the peritoneum occurs, it most frequently happens, as he still farther remarks, that it spreads over all the cavity of the abdomen. An extravasation of fluids takes place into that cavity, mixed with pus. The different viscera adhere by their peritoneal coats. The intestines are distended with air. And the irritation thus induced, kills the patient long before granulations, or an obliteration of the cavity in the second method, can occur.†

Neither of these two causes, however, by

* "If we consult the works of the most celebrated writers in this country on puerperal fever, it will clearly appear," says Dr. Robert Lee, "that they all describe the disease as commencing with a sense of soreness, or exquisite tenderness, in the region of the uterus; and that where it proves fatal, the appearances on dissection are such, as afford unequivocal proofs of inflammation of one or more of the pelvic and abdominal viscera. Strother, Burton, Millar, and Wallace Johnson state, that the distinguishing marks of the disease are pain of the hypogastric region, abdomen, and loins, and that relief often follows venesection."—(*Cyclop. of Pract. Med.*, loc. cit.) These unintended confirmations of the modern doctrine (which Dr. Good represents as having been also that of Hippocrates and Boerhaave) are highly deserving of attention.—ED.

† *Edin. Med. Comment.*, vol. iii., p. 322. Now that the pathology of puerperal fever is better understood, these reasonings about the cause of peritonitis, the imaginary essence of the disease, are not of great importance. That the peritoneum is frequently inflamed, is undoubtedly true; but that it is always so, is not the fact. In 222 cases, examined after death by M. Tonellé, the uterus was affected in 197, and the peritoneum in 193. There was pus in the uterine veins and lymphatics in 134 cases. Des Fièvres Puerpérales observées à la Maternité de Paris, pendant l'Année 1829; *Arch. Gén. de Méd.*, Mars et Avril, 1830.—ED.

themselves, will often, if ever, produce the fever before us, or even peritoneal inflammation alone. For the uterus is perpetually exhibiting a morbid enlargement, without a disposition to recover itself: and the abdomen, sudden evacuation, while no such fever ensues. There must co-operate a peculiar temperament, or a peculiar condition of body at the time; and, in puerperal patients, there is especially the general pyretic excitement which necessarily follows the very great change in various organs after delivery, and the transfer of accumulated action from one organ to another. Another accessory is also frequently found in the constitution of the atmosphere; for whatever change is most calculated to produce fever from a morbid excitement of the abdominal viscera, cannot fail to co-operate in the production of this disease from a local cause. I have already observed that such a change most usually occurs in autumn, and have stated the grounds on which it depends, under the history of *epanetus autumnalis*, to which the reader may turn at his leisure.—(See Cl. III., Ord. I., Gen. III., Spec. 2.) And hence, so far as I have observed, a tendency to peritoneal or puerperal fever occurs more frequently at this season than at any other; and, on this account, it is said by Dr. Douglas of Dublin, M. Vandenzande,* Dr. Blundell, and some other writers,† to happen occasionally as an epidemic.—(Clark, *Edin. Med. Comment.*, vol. iii.) There is much reason, indeed, for regarding it in this last view; for as most of the auxiliaries that unite in the production of contagious miasm are present in a lying-in chamber, such miasm is frequently the result; often, indeed, as we have reason to believe, generated after the manner of typhous miasm, and completely elaborated in the circulating and secreted fluids of the patient herself. Of this fact, indeed, we seem to have a striking illustration in the official report of the malignant puerperal fever that raged so fatally in the lying-in department of the General Hospital at Vienna in 1819 (*Edin. Med. and Surg. Journal*, No. lxxx., p. 83); but there can be no longer any question, after the accounts of the disease published by Dr. Gordon of Aberdeen, and Dr. Young of Edinburgh, as it appeared in the lying-in infirmaries of these cities; in which woman after woman continued to be infected to a very great extent, and especially where they had close communication with puerperal patients, or had even been attended by nurses or midwives who had previously attended the latter without sufficiently changing their malignant dress. This disease was only subdued by the ordinary means employed to exterminate contagious miasm, such as great cleanliness, repeated change of sheets and body-linen, free ventilation, and a total separation of those who were

labouring under the disease from those who were about to be confined.*

In all kinds of contagious fevers, we find that some persons are more liable to be infected than others from incidental circumstances; and, as I have already had occasion to observe, in laying down the laws of febrile miasm so far as we are at present acquainted with them, the miasmic corpuscles are modified in a few of their properties by the accessories to which they are exposed, or by which they are produced. And, by bearing these facts in mind, we shall have no difficulty in accounting for the limitation of this contagious fever to puerperal women, and the exemption possessed by persons who are not under the same circumstances. For, operative as the miasm unquestionably is, where the predisposition exists, and the abdominal organs are thrown out of the balance of healthy action, it is inert where no such predisposition is to be found, and these organs are in elastic vigour. Dr. Douglas extends this view of the case further than many pathologists; for he conceives that women, whether pregnant or nursing, or for several months after confinement, though not nursing, are susceptible of the disease upon the application of contagion.†

* Compare Dr. Campbell's Treatise on the Epidemic Puerperal Fever, as it prevailed at Edinburgh in 1821–2, *Edin.*, 8vo., 1822.

† Report on Puerperal Fever; Dublin Reports, vol. iii., p. 145. Dr. Robert Lee does not attach much importance to this view of the subject; and, according to the observations which he made on the epidemic typhus of Edinburgh in 1816 and 1817, and during the last five years in this metropolis, lying-in women are rarely affected with common typhus. "It is to the uterus, which is left in a condition after delivery in which no other organ of the body is ever similarly placed, and which renders it peculiarly liable to attacks of inflammation, that we are to look for an explanation of all the phenomena of puerperal fever."—(*Cyclop. of Pract. Med.*) Supposing this doctrine to be correct, we must presume that the statements of puerperal fever being contagious, and capable of exciting a similar disorder in other women, cannot be free from doubt. Dr. Hulme maintains that it is not more contagious than pleuritis, nephritis, or any other inflammatory disease. "M. Tonellé, who has recorded the history of the most fatal epidemic which has ever occurred in Paris, asserts that the idea of contagion was clearly out of the question there; for, in the Maternité, the women who were newly delivered had each a separate apartment, and yet were attacked with the disease; while, in the sick ward of the hospital, no instance of the propagation of puerperal fever ever occurred. The evidence of M. Dugès against the doctrine of contagion is equally strong; for he states that in numerous instances, pregnant women have been placed in the infirmary, where they were surrounded by cases of peritonitis, without imbibing the germe of the disease; and that still more frequently he has seen women, newly delivered, brought with some other complaint into the infirmaries, who did not contract the reigning malady, notwithstanding the miasmata which surrounded them. In no instance has he observed a midwife, charged with the care of two women at the same time, communicate peritonitis from a sick to a healthy individual, as

† Treatise on the Puerperal Fever, illustrated by Cases which occurred in Leeds and its vicinity in the years 1809–1812, by William Hay, Jun., &c.

But whether the miasm thus generated be the common febrile miasm we have contemplated in several of the preceding species, merely modified in its powers by accidental circumstances, or a contagion specific and peculiar to itself, is a question which, at present, we have not the means of determining.

I have said, that in the inflammation which takes place, there is an imperfect attempt at suppuration. The fluid secreted or effused is usually a whey-like material, or milky ichor, or as Mr. Cruickshank has described it, an extravasated matter mixed with pus. But Dr. Hulme (*Treatise on the Puerperal Fever*) asserts, that he has sometimes found genuine pus apparently secreted without ulceration; and Dr. Meckel informs Baron Haller, that he has witnessed the same very extensively.—(*Epist. ad Haller. Script.*, vol. iii.) The nature of the fluid will, indeed, entirely depend upon the vehemence and rapidity of the inflammatory process. Where this is less violent, the secretion, as from the surface of other serous membranes, may be purulent, or even genuine pus, and has sometimes amounted to several pints; but where more violent, it will be a milky, caseous, or whey-like serum. It is rarely, however, so mild and temperate in its march as to produce pus; often running on, as Dr. Hulme has observed, to a state of gangrene at once; and, in some instances, has been found to involve the intestines, omentum, and all the neighbouring viscera in the common mischief, as has been abundantly established by post-obituary examinations.—(*De la Roche, Recherches, &c.*) And hence, the uterus itself has sometimes participated in the inflammation, and has shown pus or gangrene, according to the vehemence and rapidity of the morbid influence.* The secreted fluid, from

is reported to have happened in London; and never has this inflammation been propagated from patient to patient in the wards set apart for the reception of healthy women.—(Baudelocque sur la Péritonite Puerpérale, 8vo., Paris, 1830.) "In the earlier description, however, of uterine inflammation, it is referred, not only to the corrupted atmosphere of hospitals, but also to contagion. In the Dublin Lying-in Hospital, the Edinburgh Infirmary, the General Lying-in Hospital at Vienna, and in most of those in this metropolis, it has raged as an epidemic, at different periods, with great violence, and appeared to be propagated by contagion."—(Dr. R. Lee, in *Cyclop. of Pract. Med.*, loc. cit.) This able physician inclines to the doctrine of contagion; but candidly admits, that his facts have not, perhaps, been sufficiently numerous to dispel every doubt on the subject. His valuable writings on this disease particularly claim the notice of the profession. The researches of Dr. Lee confirm the fact, that inflammation of the uterine organs, like inflammation of the lungs, and other affections assuming an epidemic form, takes place more frequently in one season than another, and that, at one period, the peritoneal covering of the organ is the tissue most commonly affected, while, in other seasons, the deeper tissues are almost invariably found inflamed.—Ed.

* Bang, Act. Soc. Hafn., i. One great mistake in Dr. Good's account is that of supposing the peritonitis to be the essential affection, and the inflammation of the uterus and its appendages to be merely

its abundance, is called by Professor Frank, "acutus purulentusque hydrops;" who further tells us, that he has sometimes traced it in the lungs, pleura, cavity of the chest, and even in the pericardium, where these organs have associated in the inflammation.*

The general treatment of this disease should closely resemble that already laid down for the severer varieties of the malignant remittent, which it very much resembles, with the exception that the fever is continued instead of being remissive; and that the local irritation is seated in the peritoneum (or, as Dr. Good should have said, in the uterus and its appendages), instead of in the liver or any other organ. This inflammation must be subdued, and that speedily, or the patient will perish; and hence abstraction of blood and calomel purgatives are the arms on which we have chiefly, if not solely, to depend; and both should be employed decidedly, and to as great an extent as we dare.

Eighteen or twenty ounces of blood should be drawn from the arm as soon as possible after the commencement of the disease, and repeated within twelve hours, if necessary, and the strength will allow; but if venesection have not taken place before the third day, the debility will have gained so high an ascendancy, and the general symptoms put on so putrescent a complexion, that little benefit is to be gained from it. The bowels should, at the same time, be moved by six or eight grains of calomel, given

an occasional circumstance. The same mistake prevails in the works of Bichat, Pinel, Dr. J. Clarke, the late Dr. Gooch, and other men of eminence. Dr. Gooch, in his dissections, seems to have been satisfied with simply inspecting the peritoneal covering of the uterus; but Dr. Robert Lee is inclined to believe, that "if he had carefully examined the spermatic and hypogastric veins, the absorbents, the uterus and its appendages, with the sub-peritoneal tissues, he would frequently have found acute inflammation, or some of its products. The following is the general inference drawn by Dr. Lee respecting the nature of puerperal fever:—"That inflammation of the uterus and its appendages must be considered as essentially the cause of all the destructive febrile affections which follow parturition, and that the various forms they assume, inflammatory, congestive, and typhoid, will, in a great measure, be found to depend on whether the serous, the muscular, or the venous tissue of the organ has become affected."—(*Med.-Chir. Trans.*, vol. xv., part ii., p. 405, 1829.) A large proportion of typhoid puerperal fevers arise from uterine phlebitis and its consequences. In the report of the epidemic puerperal fever which occurred in the General Hospital at Vienna, in 1819, we are informed that the accession of fever was always preceded by marked changes in the whole system, particularly in the uterus, clearly indicating an inflammatory state.—*Med. Annals of the Austrian States*, 1822; and Dr. Robert Lee's Paper in *Cyclop. of Pract. Med.*—Ed.

* De Cur. Hom. Morb. Epit., tom. ii., p. 196, 8vo., Mannh., 1792. Whoever has studied the nature and effects of phlebitis, will here discover at once evidence of the existence of inflammation of the veins of the uterus and its appendages. Phlebitis, in its extensive and fatal forms, commonly occasions inflammations and depositions of pus in various organs and tissues.—Ed.

in the form of a pill; and the same preparation, to the amount of three or four grains—Dr. Douglas advances the dose to not less than ten grains—should be continued every six hours till the tension and soreness of the abdomen have abated. And it will often be useful to accompany the calomel with one or more doses of castor-oil, or the essential oil of turpentine, or both combined.*

Dr. Vandenlande (Op. cit.) depends upon a free exhibition of calomel without venesection, which, after the manner of Dr. Hamilton, of Ipswich, he unites with opium; and he boasts of the certainty of success which this treatment has developed; though, in conjunction with opium and calomel, he sometimes employs mercurial friction. There can be no question of the benefit of a liberal use of calomel in an early stage of the disease; but to let it supersede the use of the lancet, is to abandon our first chance of success, and to encounter an unnecessary peril.

It happens not unfrequently, however, that the patient's frame is so weak and delicate, that we should risk more by drawing blood generally, than even by leaving the case to nature; as it does also that the stomach and bowels are, from the first, in a very high degree of irritation, with violent purging and vomiting, and will not bear any additional stimulant. Our wisdom is here to yield to circumstances, and let the general rule admit of particular exceptions. Instead of the lancet, we should have recourse to leeches, and, in this manner, remove twelve ounces of blood at the least; and unite opium with smaller doses of calomel. It does not follow that calomel in such a combination will increase the irritation of the stomach or bowels; I have often seen the contrary; and that by the exhibition of two or three grains with one grain of opium, repeated every five or six hours, the irritation has yielded to the commencement of a new action.

It is also in such cases of extreme debility that the essential oil of turpentine has often been found highly beneficial when employed internally by itself; for while it operates as a mild aperient, it acts as a counter-irritant, and hence directly influences the morbid state of the peritoneum, while the pulse is supported by its stimulant power, and a pleasant moisture is sometimes diffused over the surface. It is, in truth, with the exception of camphire, the only cordial we can safely venture to employ. For the purpose before us, the dose should be about two drachms; which may be repeated every two or three hours.†

Warm and anodyne fomentations to the abdomen are usually prescribed at the same time,

and are often found palliative, particularly the essential oil of turpentine, which may be used externally as well as internally; but the common mode of applying them makes the bed wet, and gives great fatigue to the patient. And hence, I have ordinarily prescribed a large piece of folded flannel, wrung out forcibly in as hot water as can be borne, to be applied over the whole of the pubes and abdomen, and covered by a broad flannel or linen swathe, passed under the loins, and folded over the epithem of recking flannel, which is to remain for many hours, or till it becomes dry, as all that is wanted in this application, as in a common bread-and-water poultice, is warmth and moisture; the flannel answers the purpose as well as the bread; and while I do not recollect a single instance in which this application has not been soothing and serviceable, I have never met with a case in which a chill has been complained of.

In the meantime, a diaphoretic, or breathing perspiration on the surface, should be attempted by small doses of ipecacuanha, or Dover's powder, and with the addition of a solution of acetate of ammonia; and if the debility be very considerable, we may employ free doses of camphire, beginning with half a scruple, and proceeding to half a drachm at a time, every four or five hours, with great advantage.

If this plan should not answer, and the skin be still hotter, drier, and more pungent to the touch, the pulse quicker and more wiry, and the tongue more deeply furred, it may be advisable to exchange epithems of hot for those of cold, or even ice-water, as already recommended in cases where the head is chiefly affected, instead of the peritoneum (uterus and its appendages).* I freely confess that I have

* Puerperal fever may or may not be conjoined with peritonitis, though the latter condition is the more frequent form; and it is unquestionably more consonant with the principles of modern pathology to consider the disease as essentially an inflammation of the uterus, extending at times to the appendages of that organ: the greater susceptibility of the lying-in woman to inflammatory action from accidental exciting causes, must account for the more frequent occurrence of this complaint at particular periods. It seems sometimes to be aggravated by certain specific causes, and thereby to have its type modified. Hence many clinical writers have divided hysteritis into two kinds, the inflammatory, and the typhoid, or contagious. It may occur at any time sporadically, and, in particular seasons, it sometimes prevails almost with the violence and destructiveness of an epidemic. Dr. Dewees, of Philadelphia, however, remarks:—"So far as we know, this disease has never appeared as an epidemic in this city, though sporadic cases have been more frequent at one time than at another."—Dis. of Females, Phil. edit., 1833, p. 375. Other cities have not been similarly favoured.

This disorder occurs more frequently in Great Britain than on the continent, and is comparatively rare in its more malignant form in the United States; this fact seems explainable, when we consider the better condition in this country of that class among whom it is most frequent abroad.

The English editor has given a valuable and sat-

* Dr. Channing, Prof. of Obstetrics in Harvard University, Cambridge, has remarked, that during puerperal epidemics, those women have been most frequently observed to do well who have suffered least from costiveness during pregnancy, and more especially if the bowels have been freely opened during labour.—D.

† See Edin. Med. and Surg. Journ., 1822, p. 538. Communication from Dr. Hy. Paine.

not tried this plan myself hitherto, but it is strongly recommended by Loeffler and other physicians of great repute; and as it is a practice in common use in our own country in the case of flooding, without any evil resulting from it,

isfactory statement of the morbid changes caused by this affection, as seen in dissection: and Dr. Gooch also has recorded the post mortem appearances, which correspond with those usually observed as arising from general peritoneal inflammation.—(Diseases of Women.) “The disorder, however,” says Dr. Francis, “sometimes extends its ravages even farther than is noticed by Dr. Gooch; and other serous membranes become affected; the pericardium is occasionally coated with lymph, and serum is found in its cavity; and the pleura is also in a like condition; a fact long since recorded by Clarke. In some instances, great cerebral congestion occurs. These extensive evidences of morbid derangement were noted in the examinations of several cases of puerperal fever, made by Professor Bushe, in Dublin, 1825, and at Chatham, in 1826-7. Many of the like morbid phenomena, occasioned by this disease, were observed as it prevailed in the Penitentiary at New-York, in 1828; and I have in my collection of morbid parts, the uterus of a subject who died during this last-named prevalence of the complaint on the third day after delivery; the parietes of which are nearly three quarters of an inch throughout, and at the fundus one and a quarter inches in thickness.”—(Denman’s Midwifery, edited by Prof. J. W. Francis, 3d edit., New-York, 1829, p. 676.) We have seen other specimens, exhibiting most of the phenomena so accurately recorded by Dr. Lee, in the extensive and very valuable cabinet of morbid anatomy possessed by Dr. Francis.

In regard to treatment, we can add but little to what is already stated: we would refer, however, to Dr. Francis’ valuable edition of Denman already quoted; to Dr. Dewees’ chapter on Puerperal Fever, in his Diseases of Females; and to Dr. G. S. Bedford’s highly useful translation of Baude-locque’s Prize Essay on Puerperal Peritonitis, New-York, 1833.—D.

* The practice recommended by Dr. Good is not materially different from what has the sanction of those writers who have given a better theory of puerperal fever. Where inflammation of the peritoneal coat of the uterus is fully developed, and where the affection occurs in a severe sporadic or epidemic form, Dr. Lee is an advocate for general and local bleeding, mercury, opium, cathartics, diaphoretics, and blisters. He begins with taking away from twenty to twenty-four ounces of blood, and, if necessary, lets the use of the lancet be followed by the application of two or three dozens of leeches to the hypogastrium, afterward promoting the bleeding from the bites by means of fomentations, or a thin linseed poultice. At the same time, he prescribes ten grains of calomel, with five of antimonial powder, and gr. iss. or gr. ij. of opium, or with gr. x. of the pulv. ipecac. comp.; and these medicines are to be repeated every three or four hours, until the symptoms begin to subside. After the second dose of calomel, he has often seen great benefit result from giving the

D d 2

we have no reason to expect any harm from it in the case before us; for the sensibility is here still more obtunded than in flooding, and nearly as much as in delirium.*

infusion of senna with salts, and repeating it according to circumstances. Dr. Lee finds that there are few cases in which it is requisite to repeat the bleeding from the arm; and where such practice does become necessary, not more than xxii. or xxiv. of blood should be drawn. After the violence of the attack has been subdued, the calomel is to be continued every six hours, until the mouth is affected, or the uterine tenderness has been removed, but only in doses of gr. v. combined with the same quantity of the pulv. ipec. comp. When the attack is less formidable, the depletion, mercury, and opium, need not be carried to the extent above recommended. With respect to the oil of turpentine, Dr. Lee seems to place no confidence in its usefulness, the statements about its effects, delivered by Dr. Brennan, who first employed it in the treatment of puerperal fever, and by Drs. Douglas, Joseph Clarke, and Armstrong, being altogether contradictory. The same view is taken of colchicum and digitalis. As for emetics, advised by Doucet, Dr. Lee has met with no case in which he considered it safe to administer them in any stage of the complaint. The application of blisters or oil of turpentine to the hypogastrium, after general and local bleeding, has often been found advantageous. The warm-bath, and even warm injections into the uterus, are favourably spoken of by some foreign practitioners. When the stomach is severely disturbed, and not relieved by anodynes and saline effervescing draughts, Dr. Lee recommends zj. of subcarbonate of potash to be dissolved in zv. of aqua menth. vir., and zj. of the mixture to be given every two or three hours. When the inflammatory symptoms have been subdued, and the patient is left in a state of great exhaustion, quinine, ammonia, and wine are to be administered. With regard to the treatment of inflammation of the uterine appendages, and of the deep-seated tissues of the uterus itself, whether of the absorbents, veins, or muscular structure, Dr. Lee finds the symptoms from the commencement to contra-indicate general bloodletting. He approves of leeches and fomentations, where the pain is severe. The French practitioners confide in mercury, so employed as to excite salivation: but Dr. Lee appears to have no reliance on this, or any other means yet suggested for the relief of inflammation of the deep-seated tissues, the veins, absorbents, &c. of the uterus.—(See Cyclop. of Pract. Med.) As M. Tonellé has noticed, the presence of pus in the vessels, and its necessary transmission through the circulation, causes a rapid and palpable infection of the blood, and various phenomena which communicate a specific character to the fever. It is then the fever of phlebitis, which is known to be often complicated with inflammation and depositions of pus in different textures, viscera, and regions of the body. The reader will see some valuable observations on puerperal fever in Dr. Ryan’s Manual of Midwifery, p. 635, ed. 2, where he refers also to some of the best works on the subject.—Eo.

ORDER II. PHLOGOTICA. INFLAMMATIONS.

FIXED HEAT AND PAIN OR SORENESS; INCREASED SECRETION; LESION OF A PARTICULAR PART OR ORGAN; MOSTLY ACCOMPANIED WITH FEVER.

THE diseases comprised under this order are sometimes called Local Inflammations; as the term General Inflammation is, by a few writers, and particularly by Dr. Fordyce, applied to Cauma, or Inflammatory Fever. In the present text, the ordinal name made choice of is PHLOGOTICA, from *φλέγω*, "incendo," "ango." Linnæus employs *phlogistica*, from the same root; but as the chymists have long since laid hold of phlogiston, and the term, though lately disused, has a chance of being restored, the derivative PHLOGOTICA seems preferable. Dr. Cullen has PHLEGMASIÆ, after Galen and Sauvages; but as *phlegmasia* and *phlegmatic*, from the same source, import, in common medical language, a very different and almost an opposite idea, the author has also purposely passed by this term in order to prevent confusion. The nature of the fever accompanying the inflammation, cannot enter into the definition; for this will vary with the nature of the inflammation itself, and not unfrequently with the structure of the organ.

When an inflammation takes place near the surface of the body, there is not only heat and pain, or soreness, but more or less swelling, hardness, and redness, and we hence infer the existence of these last symptoms in inflamed parts which lie beyond the reach of vision.

In most cases, inflammation begins at a point; for, at the commencement, all the local symptoms lie within a very small compass. The spreading of the inflammation is owing to continued sympathy, the surrounding parts participating with the point of irritation; and, in proportion to the health of the surrounding parts and constitution, this sympathy is less.

* Three elementary parts of the body are primarily and essentially affected in inflammation, viz., the bloodvessels, the nerves, and the blood. In the various views taken of the nature of inflammation, the share which the nerves have in the process has generally been too much overlooked.* Will the arteries begin the increased action, whatever this may be defined, unless influenced to do so by the nerves? In the summary of the changes which occur in inflammation, as this process is described by Kaltenbrunner (*Récherches Experim. sur l'Inflammation*), we find, therefore, increased sensibility of the part specified very correctly as *followed* by increased action of the vessels, quickened circulation, increased influx of blood, dilatation of the small vessels and capillaries, admission of red blood into vessels previously colourless, turgescence, swelling, and

* This remark is extremely just. In a post-mortem examination made at the Hospital la Charité at Paris, by Roux, it was remarked, that the nerves of the arm and forearm were inflamed, and several of them, particularly the median nerve, contained small abscesses of pus.—See *Mémoires de l'Académie Royale de Médecine*, tome troisième, 3e fascicule, p. 50, Paris, 1834.—D.

The act of inflammation seems to consist in an increased action of the vessels; mostly, if not altogether, of the extreme vessels; for wherever inflammation appears, it may be confined to a point, in which none but the smallest vessels can exist. Independently of which, we have already had occasion to observe, that the capillaries are endowed with the property of contractility, and consequently are more capable of sustaining the phenomena of inflammation than the arterial trunks.

The first act of the vessels, when the stimulus which excites inflammation is applied, Mr. Hunter supposes to be precisely similar to a blush; and to consist in a simple distention or increased diameter beyond their natural size; such as we see takes place on the application of a gentle friction, or of gently stimulating medicines, to the skin; and the consequence of which is a warm glow, when limited to the degree we are now supposing; but which, if carried farther, would be followed by excoriation, suppuration, and ulceration.*

The inflamed vessels, being thus enlarged and irritated, begin to separate from the blood they contain some portion of its coagulating lymph, together with some serum, red globules, or whatever other fluid the vessels may be loaded with; and to throw these materials out on the internal surface of the part inflamed; probably through the exhalants, or, perhaps, through new vessels which may be now forming around them; whence the sides of the cellular membrane, which receive the effusion, become covered with it, unite with the opposite sides with which they are in contact, and thus form the first foundation of adhesion. "It appears," says Dr. Lucas, "that whenever the vessels act with unusual force, there is a tendency in the coagulating lymph to separate from the other constituent principles of the blood; by the effusion of which, as the most sanguineous part of the blood, it is probable, that the circu-

sometimes a slow and embarrassed circulation. This is the first stage, or that of *active congestion*. If the disorder advance further, the contractility of the vessels is paralyzed by their over-distention, the blood stagnates and undergoes changes in its composition, disease of the coats of the bloodvessels, rupture of many vessels, extravasation and effusion of blood, coagulable lymph, and serous fluid, and changes in the structure of the part affected, take place, constituting complete inflammation. As Drs. A. Crawford and Tweedie, the authors of the article INFLAMMATION, in the *Cyclop. of Pract. Med.*, have observed,—"This view of the theory of inflammation has the advantage of accounting, in the most satisfactory manner, for many of the modifications of common inflammation. The exciting cause may be of such a nature as at first to stimulate both the sensibility and vascular contractility of the part, and induce a degree of congestion. But if its action be increased beyond a certain point, it may have an opposite effect in lessening both the sensibility and vascular contractility, and inducing a state of torpor; the blood will then stagnate, not from excessive irritation and distention of the vessels, but in consequence of their deficient vitality and relaxed condition."—Ed.

lation of the remaining part is facilitated, independent of the relief obtained by the diminution of volume.”—(*On the Principles of Inflammation and Fever*, 8vo., 1822.) We may at least hereby readily account for much of that diminution of pain which often takes place while the swelling still continues, or is even augmented. The increased bulk of an inflamed part is produced chiefly by the effusion; and the increased redness, partly by the larger quantity of blood contained in the distended old vessels, and partly by the production of new vessels formed out of the coagulating lymph thus extravasated.*

Inflammation, therefore, consists in an increased impetus and accumulation of blood in the vessels affected, accompanied with a proportionate swelling and sense of heat. The pathologists have pretty generally concurred in ascribing this accumulation of blood to an obstruction of some kind or other; but they have differed upon its nature and origin; and have not been able to determine whether it be dependant upon the crisis of the blood itself, or the resistance of the vessels that contain it.

Generally speaking, however, it has, by all the schools of medicine, been ascribed to whatever has been supposed to be the proximate cause of fever: and hence the humoral pathologists attributed it to a lentor or viscosity of the circulating fluid; and the corpuscular, to an error loci, concerning both of which we have already treated; the cause of obstruction, in the view of either hypothesis, being seated in the nature or misdirection of the constituent parts of the blood itself: while Dr. Cullen refers it to the same kind of spasm, which he regards as the proximate cause of fever; and hence derives the obstruction from a constrictive resistance in the vessels of the part affected: which, he farther supposes, forms but a mere link in the tensive chain of a phlogistic diathesis, which more or less runs through the entire habit at the time of inflammation, and constitutes the predisposition to its rise and progress.

“That a spasm,” says he (*Pract. of Phys.*, vol. iv., sect. ccxlvii.), “of the extreme vessels takes place in inflammation, is presumed from what is at the same time the state of the whole arterial system. In all considerable inflammations, though arising in one part only, an affection is communicated to the whole system; in consequence of which an inflammation is readily produced in other parts besides that first affected. This general affection is well known to physicians under the name of *diathesis phlogistica*. It most commonly appears in persons of the most rigid fibres; it is often manifestly induced by the tonic or astringent power of cold; increased by all tonic and stimulant powers applied to the body; always attended by hardness of the pulse; and most effectually taken off by the relaxing power of bloodletting.

* The generality of pathologists at the present day do not adopt the opinion that the new vessels are formed out of the coagulable lymph, but that they extend or shoot into such lymph from the neighbouring original vessels.—Ed.

From these circumstances it is probable, that the diathesis phlogistica consists in an increased tone or contractibility, and, perhaps, contraction, of the muscular fibres of the whole arterial system.”

To the first two of these hypotheses the same objections apply, that we have already seen apply to them as causes of fever. That an error loci occasionally takes place, or, in other words, an entrance of red or other particles of blood into minute vessels to which they do not naturally belong, is unquestionable; but then this is rather a secondary than a primary link in the chain of inflammation, and consequently an effect rather than a cause.

Yet the hypothesis of Dr. Cullen does not seem to be more satisfactory, and is especially open to the two following objections, to say nothing of various minor difficulties with which it is attended.

It supposes, in the first place, as a general rule, that inflammations of every kind, however minute and circumscribed, are dependant upon a particular habit of body at the time, distinguished by the name of a phlogistic diathesis. But we see inflammations occurring in habits of every kind, and varying in many of their features according to the variety of the habit; and we see them also arise in individuals who have no such phlogistic habit or diathesis as is here referred to. And we often, moreover, see examples of this very diathesis operating upon individuals for years, without producing any such effect as inflammation in particular parts. And we cannot, therefore, regard such a diathesis as a proximate cause of inflammation in general, though it may often be so of a particular kind of inflammation. Dr. Cullen, indeed, was aware of this difficulty, and even admits it. “Such a state of the system,” says he, “seems often to arise and subsist for some time without the apparent inflammation of any particular part: but such a state of the system renders it *likely* that a spasm *may*, at the same time, readily arise in any of the extreme vessels, and a particular inflammation be there produced. It does, however, appear also, that the general diathesis frequently arises from inflammation begun in a particular part.”

Now, this is not only to admit the difficulty, but to fall prostrate before it. It is to admit what at once settles the entire question. The cause and the effect are made to change places: and the phlogistic diathesis is as broadly stated to originate from inflammation in a particular part, as inflammation in a particular part is stated to originate in the phlogistic diathesis.

But, secondly, this hypothesis seems not only to be chargeable with incongruity, but to be directly at variance with the ordinary train of phenomena by which inflammation is accompanied. That the habit here alluded to, under the name of diathesis phlogistica, exists, and that very frequently, is not to be questioned; and Dr. Cullen has very lucidly described what is ordinarily meant by it. “It seems probable,” says he, “that the diathesis phlogistica consists in an increased tone or contractibility, and,

perhaps, in an increased contraction, of the muscular fibres of the whole arterial system ; " it appears most commonly in persons of the most rigid fibres." But I believe it will be found by every one who investigates the subject, that so far from this being the habit of body in which inflammation is most frequently to be met with, it is that in which it occurs more rarely than in many others. That it occurs in it at times is unquestionable ; for inflammation, under some form or other, occurs in habits of every kind : but if we look for specimens of larger or smaller inflammation, of deep-seated or superficial, nay, even of suppurative or ulcerative, we shall meet with them, if I mistake not, far more generally in constitutions marked by mobile and irritable than by firm and rigid fibres ; in habits characterized by atonic, rather than by entonic action. It is not till the constitution has been broken down, and the liver rendered feeble and torpid by the influence of a tropical sun, that hepatitis makes its appearance in its ordinary course of attack ; phthisis occurs in relaxed and delicate, and not in hardy and robust frames ; psoas abscess, peritoneal inflammation, struma, and those vast formations of pus which are sometimes found in parabysmic tumours or physconies, for the most part follow the same track ; while the best, if not the only remedy for the innumerable host of erythematic inflammations, whether erysipelatous, gangrenous, or vesicular, pernio or intertrigo, is to raise the part or the constitution to that scale of vigour, the reduction of which is well known to form a common predisposition to all of them.* That there may exist such a condition of body as an inflammatory diathesis, or a predisposition to inflammatory action of some kind or other, according to the idiosyncrasy or established habit, or some controlling accident, is unquestionable ; but such a diathesis cannot be made synonymous with the phlogistic diathesis as described by Dr. Cullen, unless there be but one kind of inflammation, and that such an inflammation as has a natural and necessary relation to the entony and rigidity of fibre which are here presupposed.

The little that we know upon the subject may, perhaps, be comprised in a few words : the standard of firm health is the best guard

against inflammations of every kind, or the state in which a man is least susceptible of them ; and a deviation in either direction, whether towards a habit of entony or atony, capacifies him for breeding them. But it does not capacify him equally ; for, in the latter case, they are produced far more easily and generally than in the former.

And, as in weak parts or habits, a peculiar susceptibility of irritation seems to be a necessary adjunct in the production of inflammation, it is possible that it may be equally necessary in the opposite state of excessive firmness and rigidity of fibre ; since this also will, at times, continue for years without giving rise to any inflammation whatever, and seems equally to demand an exciting accessory. And hence the real inflammatory or phlogistic diathesis, constituting, however, a remote, more properly than a proximate cause, is, perhaps, to be found in increased irritability of the living fibre, rather than in an increased rigidity and vigour.

The great difficulty in the subject is that of reconciling the increased action which seems to take place in the vessels of an inflamed part, with the general intumescence of such part, and, as is commonly conceived, the augmented diameter of the inflamed vessels themselves ; since the ordinary effect of increased arterial action seems to be that of an increased contraction, and consequently a diminished diameter of the affected vessels, which would lead to an extenuation, rather than an enlargement of the inflamed part. And hence a directly opposite view of the subject has been taken by many pathologists of deserved authority in our own day, who have regarded the proximate cause of inflammation as consisting in a *decreased*, instead of an *increased* arterial action, and consequently as evincing a lower, instead of a higher degree of contractility. Upon this hypothesis, the inflamed arteries give way too readily to the impetus of the blood from the heart, and the part affected becomes swollen from the excess of blood that flows into it, and acquires additional heat and redness from the same cause.

There is something highly plausible in this explanation : and those who wish to trace it further may find a very neat and interesting statement of it in Dr. Bostock's valuable *Elementary System of Physiology*.—(Vol. i., p. 420, 8vo., 1824 ; also, in *Thomson's Lect. on Inflammation*.) It was first advanced by Vacca, an Italian physiologist, about the middle of the last century, and has since been supported by Mr. Allen in his lectures at Edinburgh, by Dr. Parr, Dr. Wilson Philip, Dr. Thomson, and Dr. Hastings.*

* The doctrine that erysipelas is necessarily connected with debility, and that its treatment essentially requires tonic remedies and stimulants, is one that was generally prevalent about fifty years ago, and still continues to influence the precepts of particular schools. From the foregoing passage, it appears that Dr. Good entertained a similar belief ; but though erysipelas sometimes occurs in debilitated subjects, and sometimes, by the severity of its course, reduces the patient to a state requiring tonics and stimulants, just as other inflammations do, experience proves that its existence is not inseparably connected with weakness ; that, on the contrary, it frequently takes place in strong, young, plethoric constitutions ; and that it is often most benefited by bleeding and other antiphlogistic measures. On this point, the writings of Mr. Lawrence will tend to dispel a great deal of prejudice.—See *Med. Chir. Trans.*, ol. xiii.—ED.

* In John Hunter's theory of inflammation, the increased size of the arteries is conceived to depend upon a diminution of the muscular power of these vessels. In this respect, though in few others, there is an approximation of Vacca's doctrine to the Hunterian view of the subject. While John Hunter ascribes the increased flow of blood to and through inflamed parts to the dilatation of the arteries, some other pathologists explain the fact by

I have said that there is something highly plausible in this hypothesis *at first sight*. Beyond this, however, its plausibility does not proceed; and hence these respectable authorities, while they agree in the main principle of diminished action of the capillary arteries, differ widely concerning the actual state of the vessels, and particularly upon the question whether the velocity of the fluids they contain is diminished or accelerated.* Let these effects, however, be as they may, the hypothesis, as it appears to me, equally fails in accounting for the heat, and the soreness or pain, which are essential characters of inflammation, and which accompany it from its commencement.

The augmented heat is accounted for by the accumulation of a larger proportion of blood. But a mere accumulation of blood can produce no such effect. Its natural temperature is 98°

the great power of contractility in the minute ramifications of these vessels. Yet many of the small arteries are plainly discerned to be increased in size, and, in certain stages of inflammation, the motion of the blood in them, instead of being quickened, is retarded. Great obscurity prevails, however, respecting the exact state of all the vessels, and the circulation through them in inflammation; and though some be enlarged, and more or less obstructed with stagnant blood, certain facts tend to prove, that, at all events, there is an augmented determination of blood to an inflamed part, and a greater return of blood from it. It is by the capillary arteries, "that the functions of nutrition and secretion are performed, and it is absolutely necessary for the uniform and uninterrupted accomplishment of these varied and highly important functions, that they should have the power of controlling the motion of the fluid circulating within them. The relative momentum of the blood in different parts of the body, or the quantity of blood and its velocity, are perpetually varying from the influence of external stimuli or internal causes; and this variable state of the momentum of different portions of the arterial system is a decisive proof of the vital contractility of its vessels. We thus observe the minute vessels of the cheek, in the act of blushing, acquiring increased activity, and admitting more blood; while, under the influence of depressing passions, such as fear, they are suddenly emptied, and the countenance becomes pale. Local inflammation is stated by all pathological writers to be characterized by a rapid throbbing pulsation of the vessels in the part affected, while the action of the heart and arteries of other parts of the body may not be increased. If a person, having an inflammation in one hand, be bled in both arms at the same time, twice or thrice as much blood will flow from the diseased side as from the other."—(See Cyclop. of Pract. Med., art. INFLAMMATION.) Whatever may be our theory of the proximate cause of inflammation, whatever may be our view of the exact state of the vessels of the inflamed part, and the circulation in them, we must admit, that more blood is propelled to it, and a greater quantity returned from it, than in the natural state.—Ed.

* This is now known to depend very much upon the stage of inflammation; at first the velocity of the blood in the part affected is generally increased; but, afterward, if the disorder make progress, the blood moves more slowly than in the healthy state, or even becomes stagnant.—Ed.

of Fahrenheit, and, however it may be congested, it cannot, without some other change, give forth a heat of 99° or 100°. In the exercise of walking or running, the increased heat produced is the result of increased action, and, so far from being that of increased accumulation of blood, the heat continues to augment as the blood, in conjunction with the other fluids of the body, continues to diminish. The soreness or pain is ascribed to the distention. But distention in vessels or organs of any kind that are in a state of relaxation, and possess little contractility, produces no pain or soreness even when carried to an extreme; while, in the case before us, these symptoms, as just observed, show themselves from the first, and are even most severe when the distention is least of all.

But, independently of these objections, both the exciting causes and the treatment of inflammation seem far better to coincide with the idea of redundant than of defective action; and the case upon this point is put so candidly by Dr. Bostock (*Physiology*, p. 426), that the reader will thank me for substituting his words for my own. "All those circumstances," says he, "which we are usually in the habit of considering as stimulants, excite inflammation; and where the same effect is brought about by sedatives or by agents of a more powerful operation, still we can generally perceive the existence of what has been termed reaction, which is the immediate precursor of the change in the state of the circulation. In the same way, the remedies for inflammation appear to me to be more adapted to remove or relieve an excess than a defect of vital energy, as for this purpose, except under peculiar circumstances, we always apply either direct or indirect sedatives, and find stimulants to be as injurious as the others are beneficial. For these considerations I am induced to recur to the former idea of increased action being the proximate cause of inflammation, or, at least, as being essential to it, and to inquire whether there be no correct method of combining a state of increased action with distention of the vessels."

In the prosecution of this inquiry, Dr. Bostock observes, that the distention must be produced by an obstruction of some kind or other, and he suggests that the cause of such obstruction may be derived either from the contained fluid, or the containing vessels. The first he seems to think may be produced by an actual increase of fibrin, or a greater tendency in its usual proportion to coagulate, occasioned by the inflammatory action itself; or by some new arrangement in respect of sanguineous globules, so that they may coalesce, or be more strongly attracted together. And the second may spring from a relaxation in the minute arteries, augmented in proportion to the vigour of their contraction, so as to admit the fibrin and the globules of the blood into vessels which have hitherto been impervious to them, where they must necessarily become impacted from a *vis à tergo* on the one hand, and the decreasing diameter of the minuter vessels opened into on the other.

Future experiments and inquiries may find no

small degree of truth in the one or the other of these suggestions. But, it should not be forgotten, that increase of action by no means necessarily imports increase of strength, and that the motific or contractile power communicated to the muscular fibres never flows, even in a state of health, in a continuous or interrupted tenor, but with an alternation of jets and pauses. Upon this subject we shall treat at some length when examining the morbid actions of the nervous system, as well in the Proem to that class as under several of its subdivisions, particularly the genus CLONUS, or CLONIC SPASM (Cl. IV., Ord. III., Gen. II.); where we shall show that, in weakly habits, in which a morbid increase of nervous action must frequently take place, the more violent the jet, and consequently the contractile effect that ensues, the more prolonged and complete the alternating pause, and consequently the relaxation in the same fibre; excepting in cases of rigid or entæstic spasm, which will be explained in its proper place. And hence the very fact of increased contraction paves the way for a subsequent and alternating dilatation, and this too in proportion to the violence that the contraction exhibits; since the stream of nervous power, thus communicated by jets from the sensorial fountain, is expended instantaneously, and before the next supply arrives. This must be the result in all cases of inflammation, whether the part affected or the whole constitution be in a state of atony or of entony. But, as we have already shown that inflammation far more generally takes place in the former than in the latter; and as we have shown also, that the capillary vessels in which inflammation seems to commence, are endowed with a far higher proportion of contractile power than the larger arteries, it must follow, that the morbid irregularity of action which exists of necessity in the vessels of an inflamed part, by such sudden and alternate exhaustions of contractile power, and consequently such intervening periods of rest and relaxation, must lay a foundation for distention; the posterior current of blood now rushing forward, almost without resistance, into the inflamed part; where, also, it must accumulate, as, in the same vessels, beyond the inflamed limit, there is no such morbid rest and relaxation, and consequently a continuance of the uniform resistance of a healthy state. And when to these facts we add also the necessary intermission of the globular and larger corpuscles of blood into vessels whose ordinary diameter is too small to receive them, we can be no longer at a moment's loss to account for

the phenomena of an enlargement of the inflamed vessels, and a distention of the inflamed part.*

Concerning the proximate cause of inflammation, however, there is yet much to be unravelled. Of its remote causes, and a few of its laws, we are in some degree better informed. The remote causes may be contemplated under the three following divisions:

First, some accidental violence applied to a part, so as to make a wound or bruise, from which it cannot recover except by the process of inflammation, or which, at least, has a natural tendency to excite such a process.

Secondly, some irritation which does not destroy the texture of the part, but merely its natural action; as pressure, heat, cold, blisters, pungent applications, and often fevers of every kind.

Thirdly, a particular disposition to inflammation, founded, perhaps, as we have just observed, on an irritability in the morbid part itself, and which we often behold in constitutions of the best state of health; affording proof, that the general habit is not, in such cases, concerned in the morbid change. Inflammations from any of these causes will, however, partake of the character of the constitution; and hence proceed kindly or unkindly, according as the constitution is in a diseased or a healthy condition. Yet the general principle of inflammation is the same in all; for we can only contemplate it as a remedial process, an instinctive effort or exertion of the vis medicatrix nature, to bring about a reinstatement of the parts nearly to their natural functions.

Yet, though inflammation is uniformly the same in its principle, it often differs widely in its mode of action, and consequently in its result; for, as it has a tendency to partake of the character of the constitution, and especially where it is extensive, according as the constitution is healthy or unhealthy, so will be the nature of the inflammation and the diversity of its progress.

Healthy inflammation consists probably of one kind alone, and is no farther divisible than into different stages of a restorative action, the effect of an instinctive stimulus, rather than of morbid irritation. Unhealthy inflammation consists of many species; for, numberless are the diseases that affect the health of the constitution; and, consequently, that may influence the character of the inflammation, by superadding peculiarities or specific actions of its own: though it is often affected also by the particular condition of the part in which the inflammation

* From the experiments and microscopic observations of Dr. W. Philip, Dr. Thomson, and Dr. Hastings, it appears, that in inflammation the small vessels, veins as well as arteries, are dilated. The increased action of the minute arteries, so generally and vaguely spoken of as the cause of inflammation, may be a convenient expression; but, when it is to be employed for the purpose of really illustrating the nature of inflammation, an exact definition of its meaning should always precede its use. Thus, if it be understood as implying an alternate increased contraction and dilatation

of the minute arteries of an inflamed part, proofs of the fact are wanting. No such motions of the minute arteries in inflammation have ever been seen with the microscope. It was a meaning, also, never entertained by Mr. Hunter; who, when he speaks of the increased action of the arteries in inflammation, appears to signify, among other changes, a dilatation of them, attended with a diminution of their contractile or muscular power. Dr. W. Philip's researches lead him also to conclude, that the dilated capillaries are in a debilitated state.—Ed.

takes place. And hence it is no uncommon thing for particular parts to run into particular inflammations, with the character of which the constitution has little concern; such as those that are occasionally found on the skin, particularly the erysipelatos, as they are commonly, but not quite correctly, denominated, and which we shall presently have to describe under the name of erysipelatos erythema.*

Simple or healthy inflammation is capable of producing three different effects, which, where the whole take place healthily, follow in regular order, and constitute so many stages. These are, adhesions of the parts inflamed, suppuration, and ulceration; to which three different effects Mr. Hunter has given the names of the adhesive, the suppurative, and the ulcerative inflammation.†

There is good reason for this division into different heads; for although, where the whole takes place healthily, they follow in the order now enumerated, yet the whole do not always take place either healthily or unhealthily, nor is the order thus enumerated in every instance attended to. For pus, as we shall have occasion to observe more largely hereafter, is often produced where there is no adhesive inflammation; and ulceration, where there is neither adhesion nor suppuration; while occasionally the suppurative and adhesive inflammations take place simultaneously; the former being hurried on before the other has completed its own bounds, as is often the case in peritoneal inflammation after childbirth. The degree of violence also with which the inflammation commences, produces a considerable influence upon these points; and the nature of the parts themselves still more.

With the nature of the parts that constitute the chief fields of inflammation, it is of high importance that we should make ourselves deeply acquainted from the first, that we may be able to determine concerning the particular course the inflammation is likely to run, and regulate our treatment accordingly. And it is of still farther importance that this subject should be

* Erysipelas is probably always connected with some constitutional derangement or peculiarity. In that form of it which is preceded by fever, this is manifestly the case. That persons who lead intemperate lives are more frequently affected with erysipelas than other subjects, is familiarly known to all practitioners. Atmospheric causes also, by their influence on the constitution, make erysipelas often prevalent in particular seasons and districts.—Ed.

† This account of adhesion, suppuration, and ulceration, following "in regular order, where the whole take place healthily," cannot be received as correct. Adhesive inflammation often prevents both the other consequences. Yet, you may occasionally see the adhesive, suppurative, and ulcerative forms of inflammation, and even gangrenous mischief, exemplified at different points of the same disease. Suppuration sometimes precedes and leads to ulceration, by the agency of which the pus gains an outlet; but, frequently, the ulceration is the forerunner of suppuration, a chasm is formed in the inflamed tissues, and then the secretion of a puriform fluid begins.—Ed.

attended to on the present occasion, because it is on this distinction of parts, producing a natural tendency to distinct inflammations, that the genera of the order before us are principally constructed.

The whole of the observations of Mr. Hunter upon this interesting point are entitled to the most patient study, and cannot be too closely committed to memory. In the present place, I can only remark, that, in treating of inflammation, he divides the body into two parts: firstly, the circumscribed cavities, organs, and cellular membrane which connects them; and, secondly, the outlets of the body, commonly called mucous membranes, as the ducts of the glands, alimentary canal, and similar organs. He distributes inflammatory affections, as I have just observed, into three sorts; adhesive, suppurative, and ulcerative. Adhesive inflammation belongs chiefly to the former of the above two parts of the body, *where they are deeply seated*, and appears intended to take place for the purpose of preventing suppuration. It applies, therefore, peculiarly to that genus of the present order which we shall denominate EMPRESMA, and which will embrace the visceral organs, allowing for one or two exceptions that are occasionally interposed. Suppurative inflammation belongs chiefly to the same division of parts *placed near the surface*; and consequently applies to the two genera here denominated PHLEGMONE and PHYMA, embracing small cutaneous abscesses of various kinds. The ulcerative inflammation belongs chiefly to the second order of parts, as the mucous and serous membranes and outlets; and hence applies principally to the genus ERYTHEMA, or INFLAMMATORY BLUSH; often, but improperly, called erysipelas, which is an exanthem or eruptive fever, accompanied with erythema. It also applies to that peculiar inflammation which characterizes the whitlow, and will be found in the present arrangement under the genus PHLYSIS. Deep-seated suppurative inflammations and abscesses cannot well be placed in either of the genera we have thus far noticed, and have a claim to be considered by themselves. They are hence included in the genus APOSTEMA, with which the order will be found to open.

In circumscribed cavities, where from a peculiarity of constitution, or the peculiar nature or degree of excitement, an inflammation is deflected from its common tendency to produce adhesion, we often find it run on with great rapidity from one part of the cavity to another, till the whole becomes affected. We have already had occasion to notice this inflammation of the peritoneum (Cl. III., Ord. I., Gen. VI., Spe. 3); and we shall have further occasion to notice it in psoas abscess (Cl. III., Ord. II., Gen. I., Spe. 2) and acute rheumatism. And we may hence account for the alarming progress of the same morbid action when it attacks the surface of arteries or veins, from an accidental wound, as in venesection, from true aneurism, or from any other cause; of which acute rheumatism seems, at least, occasionally to be one. The French writers, who have studied the sub-

ject with considerable attention, are disposed to regard these inflammations as in many instances idiopathic, and have distinguished the former by the name of *ARTERITIS*.* But I am not aware of their having hitherto been found to occur otherwise than as concomitants or sequences of other affections.

The inflammation of veins, by some writers called *PHLEBITIS*, has of late occupied more attention than that of arteries. It is occasionally a result of an irritated varix, and especially where such varix has undergone the operation of removal, as we shall further observe when treating of this complaint (Cl. III., Ord. IV., Gen. XI., Spe. 2); it has also occasionally followed venesection where the lancet has been affected with rust or some other irritant; and especially where the constitution, or perhaps the vein alone, has been in a state of morbid irritability. And it has sometimes occurred where no distinct cause could be assigned, either during life, or on dissection afterward. It is by no means easy, and for the most part altogether impossible, to trace an inflammation of a vein or artery by external signs; for although, in the former, there is sometimes a red streak or two accompanying the general pain and swelling of the limb, and in the latter a more rapid pulsation or throbbing, and in both a line of hardness like that of a cord; yet, in various cases, nothing of the sort is to be found, and consequently they cannot be regarded as pathognomonic criteria. And, on this account, the author has allotted no distinctive place or name to these affections in the course of his classification; as feeling that to do so would be to make an empty display, and a verbal subdivision unattended with any real use. In a striking case which proved fatal, described by Dr. Duncan, the disease was so little indicated by either the general or local symptoms, that it does not seem to have been suspected, and was only accidentally discovered on a post-obit examination. At the time when the symptoms were most aggravated, and less than twenty-four hours before death, when the swelling had extended up the arm, and the pulse was at 120, the limb had a uniform appearance, the intumescence a defined margin, "but still without much redness, heat, or pain, unless in a point at the bend of the arm on considerable pressure, and on the outside of the elbow."† A knowledge, however, of the precise fact could have made little or no difference, nor ever can do so, in the mode of treatment, which must uniformly be founded upon the general process for diffuse

inflammation, whether more or less complicated in its range.

It is on this account that Dr. Duncan has rather chosen to regard such wide-spreading phlogoses, whether of veins, fasciæ, tendons, or lymphatics, as mere modifications of what he has specifically called "Diffuse Inflammation of the Cellular Texture" (op. cit.), which, in truth, is in almost every instance more or less affected, and, in many instances, with gangrenous supuration that knows no bounds. Perhaps this may be to generalize rather too much, and especially in the case of that very singular and more definite description of inflammation which takes place from contagion absorbed by a sore or wounded part in dissecting, and which the present author will be found, therefore, to have separated for a particular investigation under the name of *ERYTHEMA anatomicum* (Cl. III., Ord. II., Gen. IV., Spe. 5); but he is well aware of the difficulty of making even this distinction; and of the tendency there is for the diffuse kind of inflammation we are now considering to run into every form, exhibit every variety of combination, be conjoined with every type of fever, and productive of every diversity of danger, from the peculiarity of the general or the local constitution, the influence of the patient's habit of life, or some other incidental predisponent or concomitant.

Inflammation, therefore, is influenced by the nature of the part in which it takes place. It is also, as we have already observed, equally influenced by the nature of the constitution itself; and, thirdly, it is influenced by the nature of the remote cause. And we may add, that, where the inflammation is regulated by the constitution, and the constitution itself is healthy, specific irritants will not change the nature of the inflammation, but only determine its situation, extent, duration, or some other peculiar property. But where the constitution is unhealthy, or predisposed to any particular morbid action, as that of erysipelas, putrid fever, or plague (for some individuals receive even the plague much more readily than others), as soon as the specific virus is communicated, the disease will degenerate into a mixture of both, and discover its double source; it will give proof that a specific inflammation has been set down upon a constitution of a peculiar kind, and will partake of the nature of both. In consequence of which, the specific properties will by no means be so distinct or well formed as if they were to appear in a sound and untainted constitution.

Thus, if the constitution have a tendency to fall into a state resembling that of typhus fever, and the smallpox attack it, the inflammation will be that of the smallpox combined with the constitutional disposition to typhus; which will so far affect the action of the smallpox as to interfere with the specific difference of its inflammation. In consequence of which, the pustules will spread, but not suppurate, and assume a livid hue, and perhaps prove fatal; while, if another person, possessing an uncorrupt, and, so to speak, unbiased constitution, be inoculated even with this mixed virus, the variolous

* See *Enciclopedia Cauma*, Cl. III., Ord. I., Gen. IV., Spe. 1; as also *Arthrosia Acuta*, Cl. III., Ord. II., Gen. XII., Spe. 1; and Cl. III., Ord. IV., Gen. X., Spe. 2, *Exangia Varix*. The *gangræna senilis*, or dry gangrene of elderly persons, is ascribed by Baron Dupuytren to the effects of arteritis.—ED.

† Case of an inflamed Vein, *Trans. Medico-Chir. Soc. Edin.*, vol. i., p. 443, 8vo., 1824. The later observations of Rose, Arnott, Cruveilhier, Andral, and others, have thrown considerable light on the nature of phlebitis. The researches of Cruveilhier, in particular, are of great value.—ED.

principle will separate itself from the principle with which it is combined, improve with the improvement of the new soil, and yield a crop of genuine and unadulterated pustules.

In like manner, vaccination is, generally speaking, a specific preservative against the smallpox. But it sometimes happens that it is not so, and that the smallpox is caught and makes its appearance many years after vaccination has been performed with all possible circumspection. And it generally happens in such cases, though not always, that a mixed or hybrid disease, a sort of degenerate smallpox, of a milder character than the true, is hereby produced.

The remarks just laid down will furnish us with a clear and sufficient clew to these singular and interesting facts. Some persons have a peculiar predisposition to smallpox, which is by no means easily eradicated, and far less so than in others. Vaccination, which permanently counteracts the predisposition among mankind in general, does not permanently counteract it here. It introduces a new but less rooted diathesis, and the former is rather suppressed than extirpated. In process of time the predisposition revives, reacquires its anterior influence, and the moment it comes in contact with varolous contagion, subjects the system to smallpox. But while the varolous diathesis is thus again predominant, the vaccine diathesis has not altogether lost its hold; and the disease, as in the preceding cases, is a mixed product of both causes in co-operation, or rather in antagonism. It is smallpox, raised upon a constitution not yet totally liberated from the influence of vaccination; I say, "not yet totally liberated," because we occasionally meet with instances in which the constitution, little open to the impression of the vaccine disease, even when first communicated, becomes in time liberated from its influence altogether, and receives the smallpox, after vaccination, as freely as if it had never been vaccinated, and with a violence that proves fatal in a few days.

It is a wise and beneficent law of Providence, and affords an incontrovertible proof of the existence of an instinctive remedial power, that inflammation, wherever seated, is always more violent on the side of the inflamed point nearest the surface, and shows a constant tendency to work its way externally rather than internally. This law applies equally to the thorax, to the abdomen, and to parts which lie close to the different outlets of the body. Thus, if an inflammation attack the peritoneum covering an intestine, and adhesions are hereby produced between the two, the inflammatory action works upwards through the thick walls of the abdominal muscles, while the proper coats of the intestines, in most instances, remain sound. This, indeed, is not always the case; for the inflammation may be so violent as to pass in both directions with great rapidity, or some accidental circumstance may force it inwardly; but it is so common as to form a general rule. We see the same thing in the obstruction of the natural passage of the tears producing a fistula lachrymalis; for here the ulceration points externally to

the inner angle of the eye, while the inside of the nose defends itself by becoming thicker; so much so, in many cases, as to block up the cavity of the nostril, and produce inoculations with the septum; which has been an occasional cause of failure in the usual operation for this disease.

—(*Hunter on Blood, Inflammation, &c.*, part ii., chap. ix.) We even find, that, if an abscess form in a frontal sinus from an obstruction in its duct, the matter will rather work its way externally through the frontal bone than descend into the nose. In like manner, if an inflammation attack the cellular membrane on the outside of the rectum near the anus, although the latter be in contact with the inflamed part, the inflammation will extend to the skin of the buttock, while the gut itself is often but little affected.

For the same reason, we behold eruptive fevers conducting the specific poisons which excite them, as smallpox, measles, rosalia, or scarlet fever, and even the plague itself, to the surface of the body, rather than throwing them on parts that are deep-seated and vital. The cancer is said to form an exception; but even here the progress of the disease towards the surface is quicker than its progress towards the centre; while syphilis exhibits something of a similar disposition, though not in an equal degree.

It appears, then, that simple or healthy inflammation is a remedial process for restoring a part to soundness when affected by a morbid impression that has a tendency to injure or destroy it; and that the first stage of this process consists in the effusion of a coagulable lymph, which binds the weakened organization into a closer bond of union, creates new vessels, and consequently introduces new life. If this effort do not succeed, and the morbid action still continue its progress, the affected part dies to a certain extent; but the coagulable lymph which has been thrown out, and introduced new vascularity around it, still sets a boundary to the destructive career, and prevents it from spreading into the neighbourhood, or at least from spreading as far as it otherwise would do. When, however, a part is thus killed or destroyed, it becomes a substance foreign to the body, and must be removed, and have its place supplied by a formation of new living matter. The process of suppuration, which we shall explain under the genus APOSTEMA, prepares equally for the removal of the dead matter and the formation of that which is to fill up its post. This, however, is the progress of healthy inflammation alone; for, as already observed, in unhealthy inflammation, the morbid action will often run on to the ulcerative process, or last stage, at once; or the adhesive, or the suppurative, may intermix with it; or all may imperfectly take place together.

In attempting the cure of inflammation, our first endeavour should be to obtain what has been called a resolution of the general enlargement; or, in other words, a restoration of the part to its state of former health, without the necessity of its going through the entire range of the inflammatory process. And, in doing this, we are to be guided by the principle of being

able to make a new impression upon the part, and to oppose a healthy or remedial, to an unhealthy and mischievous action. The nature of the cause must hence be sedulously inquired into: for, till this is ascertained and removed, it will be in vain to expect that resolution can take place, and, where we can speedily accomplish such removal, resolution will often follow spontaneously; for the animal economy, having a disposition in itself to discontinue diseased action, such action will readily subside upon a disappearance of the cause that maintains it. And hence, by taking off the venereal action by the use of mercury, in the case of a bubo, the inflammation will gradually cease, provided no other morbid action has already arisen and united itself with the syphilitic.

Resolution, however, is not always to be attempted; for there are many cases in which the attempt would be in vain, and possibly a few in which it would be improper. It is not to be attempted in accidents, where there is a considerable exposure of the injured part, and still less in accidents where the part has been killed by their violence; for in these suppuration is the first natural step to a cure, and we cannot prevent it if we would.

Where inflammation arises from a morbid predisposition in the constitution, and belongs to the description which has been called critical, there is some doubt, and much demand for circumspection: and in this case, resolution is called repulsion. If the inflammation be really a concentration of the constitutional complaint, which, by being driven from the part fixed upon, may be again diffused over the entire frame, and in waiting to fasten on some other part, it will often be better to encourage its stay. But the determination, even in this case, must be subject to the two following conditions: first, that the inflammation, so concentrated, will readily admit of a cure; and next, that the part on which it fixes is not of vital importance; for, otherwise, the remedy may prove worse than the disease.

When resolution is determined upon, independently of removing the cause of the inflammation, we may advantageously follow up its effects by all the common modes employed for this purpose, according to the nature of the particular case. The undue degree of action may be diminished by bleeding and purging; the distention by local applications that tend to contract the diameter of the vessels, as cold, and metallic or other astringents; and if along with the distention there should be great pain, narcotics and relaxants will generally be found useful auxiliaries. To these in the present day are often added nausea and vomiting; the former of which operates by lowering the action of the vessels, the latter by giving a tendency to a new action. The nature of the case must determine our choice.*

* To these remedies should have been added mercury, one of the most powerful means of counteracting many forms of inflammation: perhaps, next to bleeding, it is the most important means which the practitioner can avail himself of in the

GENUS I.

APOSTEMA.

APOSTEME.

LARGE SUPPURATIVE INFLAMMATION IN A DEEP-SEATED ORGAN; PUS COPIOUS AND CONFINED.

THE term APOSTEMA is Greek, from *ἀπὸ τῆς*, “discedo,” “abscedo,”—whence the Latins employed *abscessus*, to express the same general idea. Yet they did not, strictly speaking, apply either *abscessus* or *apostema* to every suppurative inflammation, but only to those that were deep-seated, and of considerable extent; chiefly, indeed, to collections of pus consequent upon fevers, or some previous disorder of particular parts, especially abdominal diseases. This limitation is accurately drawn by Celsus immediately after his description of struma, furunculus, and phyma. “Sed cum omnes hi nihil nisi *minuti abscessus* sint, generale nomen trahit *latus vitium ad suppurationem spectans*. Idque ferè fit aut post febres, aut post dolores partis alicujus, maximeque eos qui ventrem infestarent.”—(Lib. v., cap. xxviii., § 11.) The term *abscess*, however, which was colloquially used in a loose sense in the time of Celsus, is used so much more loosely in our own day, that it is impossible to recall it to its precise and original meaning. Yet APOSTEMA has not been thus generalized; and it is here, therefore, laid hold of and restrained to the signification expressed in the generic definition; after the authority, indeed, of Sauvages, who has employed it with the same limitation.

The genus apostema, in the arrangement before us, will be found to include five species: the first of which is common to most fleshy parts, and possesses a common character; while the remaining four are distinguished by some peculiarity of character, attributable to their situation.

1. Apostema Commune. Common Aposteme.
2. ——— Psoticum. Psos Abscess.
3. ——— Hepatis. Abscess of the Liver.
4. ——— Empyema. Lodgment of Matter in the Chest.
5. ——— Vomica. Vomica.

SPECIES I.

APOSTEMA COMMUNE.

COMMON APOSTEME.

INFLAMMATION COMMON TO THE FLESHY PARTS:

PAIN OBUSE: TUMOUR SPREADING EXTERNALLY: TENDER TO THE TOUCH; PUS LAUDABLE: READILY INCARNUING WHEN OPENED.

IN whatever part an aposteme is seated, it will sometimes spread to a wonderful extent, and be loaded with a prodigious weight of pus. M. Balme gives us an account of an abscess that extended through the whole parietes of the chest and abdomen on one side, and reached from the scapula to the thigh (*Journal de Médecine*, &c., tom. xvii.); and Hildanus was present when, upon opening a patient after death, twelve pints of pus were found effused from a

treatment of the generality of visceral inflammations.—ED.

visceral aposteme into the cavity of the abdomen.*—(Cent. ii., obs. 57.)

In all such cases, the first stage of inflammation, that of adhesion, must have been overshot in the violence of the action, or from some other cause the suppurative and ulcerative have commenced simultaneously from the first. For otherwise, the coagulable, or, as Mr. Hunter prefers to call it, the coagulating, lymph thrown forth, as has been already explained, into the cellular membrane in the earliest stage of the inflammation, would have formed a boundary wall, by the production of new vessels and reticulations, much nearer to the salient point of inflammatory action, and confined the secretion of pus to a much narrower limit.

The secretion of coagulable lymph, and the reticulate adhesion and formation of new vessels which issue from it, is indeed designed, as has been explained already, to prevent the necessity of the suppurative and ulcerative stages of inflammation; and the natural cure of the adhesive stage is by resolution.

When, therefore, an aposteme takes place in a healthy frame, or, in other words, when the inflammation passes into the two ensuing stages of the suppurative and ulcerative, and pus is formed, and a cavity scooped out for its reception, we are to take it for granted, that the instinctive and remedial power of nature is incapable of producing a cure by the first intention; that some dead part or extrinsic substance is required to be removed,† and that the two ensuing stages of inflammation are had recourse to for this purpose.

In the formation, then, of an aposteme in a healthy constitution, we are to suppose that some part of the organ in which inflammation occurs, as, for example, a piece of the muscle of an arm or a leg, is become dead, and an incumbrance to the living parts that surround it,

* In the New-York Medical Journal, No. iv., p. 293, Dr. David L. Rogers, of New-York, has given the details of two interesting cases of abdominal abscess in which he operated in the usual mode of operating for hernia at the internal ring; in both cases, large quantities of pus were discharged, and the patients recovered. Dr. R. thinks, and justly, that abdominal abscesses are overlooked, in many cases, when the existence of matter in some part of the abdomen might be detected by close observation, and by a timely discharge of it the patient might be rescued from danger.—D.

† The removal of "some dead part, or extrinsic substance," is not an essential circumstance in the formation of an abscess. The purulent matter is more commonly only interposed between parts, or diffused in their tissues, which are not to be looked upon as absolutely destroyed. It is chiefly on the principle of distention that the pus forms a cavity for itself; and frequently, very soon after the abscess has been discharged or burst, the parts appear to be all perfect again, none of them being deficient. There may be, however, in some instances, sloughing combined with suppuration; but these are not common apostemes; and, very generally, in a certain stage of the disease, ulceration takes place in order to bring the matter through the parts intervening between it and the cuticle.—Eo.

instead of assisting in their office. In effecting, therefore, the important object of a cure, it is obvious that two distinct actions are necessary; the dead part must be carried off, and the loss must be filled up by a substitute of new matter possessing the precise properties of the old. And, in the process which takes place to accomplish these two purposes, we meet with another clear and striking instance of that wonderful instinctive power which pervades every portion both of the animal and the vegetable world, and which is perpetually stimulating them to a repair of whatever evils they may encounter, by the most skilful and definite methods.

In order to comply with this double demand of carrying off the dead matter, and of providing a substitute of new, the absorbent and the secernent vessels in the living substance, immediately surrounding that which requires to be removed, commence equally, and nearly at the same time, a new mode and a new degree of action. A boundary line is first instinctively drawn between the dead and useless, and the living and active parts; and the latter retract and separate themselves from the former, as though they had been skilfully divided by a knife. This process being completed, the mouths of the surrounding absorbent vessels set to work with new and increased power, and imbibe and carry off whatever the material may be of which the dead part consists, whether fat, muscle, ligament cartilage, or bone; the whole is equally sucked up and taken away, and a hollow is produced where the dead substance existed.

While this is proceeding, the mouths of the correspondent secernent vessels from the first, and perhaps somewhat antecedently, commence a similar increase and newness of action; and, instead of the usual fluid, pour forth into the hollow a soft, bland, creamy, and inodorous material, which progressively fills up the cavity, presses gradually against the superincumbent skin, in the gentlest manner possible distends and attenuates it, and at length bursts it, and exposes the interior to the operation of the gases of the atmosphere. From this period the process of incarnation commences: granulations of new living matter pullulate on every side, assimilating themselves to the nature of the different substances that are lost, till the hollow is sufficiently filled up, and the organization completely regenerated.

On the bursting of an abscess externally, we occasionally find that a portion of the dead matter still remains, which afterward gradually sloughs away, or is thrown off by a separation at its base. This is particularly the case in furuncles or biles; and still more strikingly so in large abscesses that include bones, or the tendinous parts of muscles, which are more difficult of absorption, though even these are sometimes absorbed and completely carried off.

The attenuation of the superincumbent integuments of an abscess appears to be produced by the stimulus of distention, occasioned by the pressure of the accumulating pus. And it is to the same stimulus that Mr. Hunter refers the absorption of the dead matter itself; conceiving

that, for this purpose, the secretion of the pus commences somewhat earlier than the absorbent process.

The formation of pus, and consequently the existence of an aposteme, are evidenced by a cessation of the pain of distention, which gives way to a throbbing pain, synchronous with the dilatation of the arteries; and by irregular shiverings, and sometimes rigour. After a few days, a weight is felt in the part, the throbbing pain itself subsides, the tumour becomes soft, and, if it point sufficiently towards the surface, fluctuates to the touch.

There is some doubt to whom we are indebted for the first insight into this wonderful process; for it was taught at the same time, or nearly so, on the continent by De Haen, Pleniz, and Schroeder, and, in our own country, by Hewson, Hunter, Home, Cruickshank, and Professor Morgan, but, upon the whole, Mr. Hewson appears to have taken the lead, and the rest to have followed closely in his steps.* Antecedently to which period, pus, instead of being a peculiar secretion, was supposed to consist in a dissolution of the bloodvessels, nerves, muscles, and other solids, in the ordinary exhaling fluid when augmented by effusion; or in a conversion of the serum, thrown forth on the occasion, into the new matter, by a change effected in its gluten during its state of stagnation: the first of which hypotheses was that of Boerhaave (*Aphor.*, 387), Platner (*Instit. Chirurg.*, sect. liv.), and almost all who practised antecedently to their time: and the second that of M. Gaber (*Acta Taurinensia*, vol. ii.), and Sir John Pringle.†

* Dr. Morgan, of Philadelphia, seems to have anticipated Mr. Hunter. In his inaugural thesis at Edinburgh on the formation of pus, printed in 1763, he contended for the doctrine that pus was a secretion.—D.

† Treatise on the Diseases of the Army, App.—Laennec and Gendrin are induced by their researches to consider suppuration as the result of a direct conversion of the coagulable lymph of inflammation, and of the fibrine of the blood, into pus. Laennec believed pus to be simply softened coagulable lymph. This is proved by analysis to consist, not only of the fibrine of the blood, from which it differs by its lesser consistency, but also of a small proportion of albuminous serum. It is supposed, therefore, to be formed of an intimate combination of the fibrine of the blood with a small proportion of albumen, rendered more viscid and coagulable by the vital influence of the inflammatory action, and deprived also of the colouring matter. The opinion that pus is formed directly from the blood by the fibrine simply undergoing some slight modifications in its properties during inflammation, is supported by various interesting experiments, detailed by Gendrin.—(*Hist. Anat. des Inflammations*, vol. ii., p. 470; *Cyclop. of Pract. Med.*, art. INFLAMMATION; and Andral, *Anat. Pathol.*, tom. i., p. 397.) In the Museum of the University of London is a heart which contained a coagulum, in the centre of which was found a collection of pus. Andral maintains throughout all his pathological observations the theory of the blood having the power to form pus, even within the vessels of the living body as well as out of them.—(*Anat. Pathol.*, tom. i., p. 388.)

These conjectures were ingenious, but they were nothing more; and their errors are sufficiently pointed out in the "Experimental Inquiries" of Mr. Hewson, to whom physiology, and especially the science of morbid anatomy, is almost as much indebted as to any person whatever. He travelled, with a comprehensive mind, and a zealous and indefatigable step, in what was at that time new and untried ground; and, though he was mistaken in a few points, he correctly explored much, and, by the course he laid down, indicated to his successors the truest methods both of confirming his facts and correcting his misconceptions.

He proved decidedly that pus is a peculiar secretion, and that it is often, indeed, secreted where there is no abscess or breach of surface; and he ingeniously accounted for its production by supposing it to be formed out of the coagulable lymph by a new power, given to the seccernent vessels in consequence of the inflammatory action. "And if pus," says he, "in these cases, is produced merely by a secretion, so likewise it would seem probable that even in abscesses, where there is a loss of substance, it is not the melting down of the solids that gives rise to the pus, but the pus being secreted into the cellular membrane from its pressure, and from other causes, *deadens the solids and then dissolves them.*"—(*Experimental Inquiries*, part ii., p. 118.)

The idea of the solids contained in an abscess being deadened and dissolved by the pus which surrounds them, in the ordinary sense of the expression (for in one sense, as will appear hereafter, they may be said to be dissolved), was one of the erroneous opinions of Mr. Hewson to which I have just alluded; and originated from too close an adherence to the earlier and still more mistaken hypothesis we have just noticed.

And hence, with all his ingenuity, Mr. Hewson advanced not much more than half way in explaining the entire economy of suppurative inflammation. It remained for the exploring eye and commanding genius of Mr. Hunter to penetrate through a considerable portion of the re-

Suppuration is certainly not always merely the conversion of a mass of extravasated blood, or coagulable lymph, into pus; for it takes place both on the surface and in the interior of inflamed organs by a process analogous to secretion, through the medium of vessels either previously in existence, or newly formed. It constitutes in this manner a new function, which sometimes lasts for a considerable period after the inflammation has subsided; as is seen in fistulous sinuses, chronic ulcers, &c. When pus is found in the vascular system, or in the blood itself, sometimes the veins containing it are returning from parts in which there are abscesses; but sometimes also without the latter occurrence. In cases of phlebitis, the formation of matter in various organs, viscera, and even the synovial membranes, more or less distant from the original mechanical injury or inflammation, is a subject which has of late years been investigated in a most interesting manner by Rose, Arnott, and Cruveilhier. The reader will find some views of the theory of suppuration, published by Dr. Benjamin Babington, well deserving of attention.—Ed.

maining half of this curious process, and to prove that the solid parts contained in the arca of an abscess, instead of being deadened by the pressure of the surrounding pus, are dead beforehand, destroyed indeed by the violence of the accident or of the inflammation; and that, instead of being merely dissolved in the circumambient pus, they are absorbed and carried off by a new and increased action of the circumambient absorbers; thus showing, that even ulceration itself, when of a healthy kind, is only another link in the restorative chain of nature, made use of on this occasion.

That pus, instead of being a mere solution of dead animal matter, is a distinct and peculiar secretion, is now known to most practitioners from personal observations, who must have witnessed it repeatedly in situations in which there has been no ulceration or breach of structure, and consequently where there could be no dead animal matter to dissolve.

It was noticed in this form by De Haen so far back as the middle of last century; and was pointed out by Mr. Hewson as frequently found, in dissections, on the surface of the pleura, the peritoneum, and the pericardium, in a perfectly genuine state. A very decided case, to which both Dr. Hunter and Mr. J. Hunter were witnesses, was published by Mr. Samuel Sharp about the same time that De Haen first brought the subject before the public. Nothing is more common or more copious than the secretion of pus without ulceration in the first stage of purulent ophthalmia, and in purulent inflammation of the mucous membrane of the urethra; and I remember having attended, about twelve years since, a gentleman in Bedford Row, who had irritated this passage by improperly introducing a bougie into the bladder, and about three days afterward discharged with his water not less than half a pint of pure pus, which separated itself from the water and subsided, and thus gave me an opportunity of examining it minutely. I requested Mr. Cline's attention to this case, and we saw not the slightest reason for suspecting any ulceration whatever.

Genuine pus is peculiarly distinguished by its consisting of white globules swimming in a fluid, which to the eye has the appearance of serum, but possesses characters of its own, equally different from those of serum and of every other secretion we are acquainted with; and which render it coagulable in a saturated solution of muriate of ammonia, which is its specific test. Pus, however, is not globular at its first formation, but a transparent fluid of a consistence in some sort resembling jelly: the globules are produced while it lies on the surface of the sore, usually, when not exposed to external air, in about fifteen minutes after its secretion. The perfection of pus seems to depend upon the large proportion which its globules bear to its other parts. It is specifically heavier than water, and approaches nearly to that of blood. [Professor Brande states its specific gravity to be about 1.030.] It has a sweetish, mawkish taste (apparently from its containing sugar), very different from that of most other secretions. After

putrefaction it is acid. Dr. Bruggmans, who has analyzed it with much care, asserts that it contains an acid before putrefaction: but this has been denied by Sir Everard Home.—(*Dissertation on the Properties of Pus*, p. 20.) [And it is also mentioned by Professor Brande, that it does not affect vegetable colours till it has been for some time exposed to the air, when it becomes slightly sour; nor does it easily mix with water, alcohol, or dilute acids.—(*A Manual of Chymistry*, vol. iii., p. 190.)] For a further account of its chymical properties, the reader may consult Dr. Pearson's elaborate paper.*

In the process of the natural cure of an apostome, we find that the stage of granulation, and consequently of incarnation, immediately succeeds that of ulceration, or the removal of the dead matter. "The vessels," says Mr. Hunter, "forming themselves into a certain structure which fits them for secreting pus, it is so ordered that the same structure also fits them for producing granulations; and thus these two processes are concomitant effects of the same cause, which cause is a peculiar organization superadded to the vessels of the part.—(*On Inflammation; Of Pus*, p. 433.)

The idea of a change of organization is hypothetical, but ingenious, and perhaps correct. Change of action and change of effect we know; but at the rest we can at present only give a guess, and must leave it to future times to ascertain.

The obvious design of granulation, or incarnation, as it is often called, is that of repairing the loss the parts have sustained by the injury done: it is that of producing new flesh. Granulation, like vegetation, takes place from the centre below, in a direction upwards towards the skin; and hence exactly contrary to the course of ulceration, which always begins in the superior part of an abscess. The process commonly succeeds best upon exposure to the air, or at least after an opening externally; though there are instances of its having occurred where there has been no exposure whatever. The granulating pullulations, according to Mr. Hunter's explanation, consist of exudations of coagulating lymph from the vessels. He conceives it probable, not only that the old vessels extend into these pullulations and become elongated, but that new vessels also form in them, and, like the old, still continue to secrete pus. The granulations, as they become formed, mutually and readily unite; inosculation, or the attraction of cohesion, is established between them; and their vessels thus joined are transformed from secreting into circulating tubes. Immediately upon their formation, cicatrization seems to be in view. The parts which had receded, in consequence of a breach being made into them, begin now, from their natural elasticity, and, probably, from the contraction of the new created substance, to be brought nearer together; and the contraction of the sore proves a sign that cicatrization is speedily about to follow. This contraction takes place in every

* Phil. Trans., vol. for 1809, p. 313. See also a further description, under Marasmus Phthisis, in the sequel of the present volume.

point, but principally from edge to edge, which brings the circumference of the sore towards the centre; so that the exposed surface becomes smaller and smaller, even before there is any formation of a new skin.

There are two parts, at least, of this wonderful economy that still demand explanation. The first is, the real use of the pus after it is secreted; and the second, the means by which the absorbents carry off the dead matter. The same explanation may perhaps apply to both.

That pus is a peculiar secretion, distinguished by peculiar properties, and not a solution of the dead animal matter which it is the design of nature to remove, has already been sufficiently shown. "But I am apt to believe," says Mr. Hunter, "that we are not yet well, or perhaps not at all, acquainted with its use, for it is common to all sores; takes place in the most perfect degree in those sores which may be said to be the most healthy, and especially in those where the constitution is most healthy."—(*On Blood*, &c., part ii., ch. v., p. 436.) It forms, indeed, an exit to foreign bodies: is supposed by many to carry off humours from the constitution, or convert general into local complaints; and, by others, to act as a preventive of numerous diseases. Yet all these services, even admitting them to exist, are but secondary, and the final intention still remains to be accounted for.

In like manner, since the dead matter of an apostome does not constitute the pus that is found in it, and hence can only be carried off by absorption, we have yet also to learn by what means it becomes prepared for an entrance into the delicate mouths of the absorbent vessels. There is no small difficulty in conceiving how these very minute mouths can apply themselves with sufficient activity to the various tough and hard substances they have to remove, as tendon and bone, when in close contact with them; but, as soon as the dead part becomes separated from the living, they are often no longer in close contact with them, except at the base, where there is little or no absorption at all; and, in many cases, as in biles, carbuncles, and other imperfectly suppurating tumours, possessing cores or tenacious sloughs, are at a considerable distance from them, with the entire body of the contained pus placed intermediately in the hollow.

In the last case, it seems impossible for them to act except through the medium of the pus; in reality, except through a solvent power possessed by the pus, and exercised upon the matter to be removed. And, if such be the nature of the action in this case, it is doubtless the nature of the action in all other cases: and hence we arrive at one immediate and direct use of pus, which is, that of becoming a solvent of the dead animal matter that requires to be carried off: not, indeed, by converting the whole substance at once into a solid mass, and still less into a fluid mass of its own nature, as supposed by Sir John Pringle, but only the surface of the substance to which it is applied; and which hereby is rendered fit for absorption, carried forward to the mouths of the imbibing vessels,

and absorbed accordingly. And, as the same power is exerted in succession upon every fresh surface of the dead matter that becomes exposed to its action, the whole is at length carried away, and a cavity produced where before was solid substance.

That pus first kills and then dissolves the organized matter of an abscess was, as we have already seen, the opinion of Mr. Hewson. In the first part of this opinion he was completely mistaken; for, as we have already observed, the organized matter is dead before the process of suppuration even commences; in the second, he seems, to a certain extent, to have been correct, though he still erred in supposing the dead substance to be melted down into its own nature, and was unacquainted with the important process of its absorption. But, in advancing his own full and more elaborate hypothesis against the mistake of Mr. Hewson, Mr. Hunter ran into the opposite extreme; and contended that pus is not designed to be a solvent at all, and that animal substances are decomposed in it with very great difficulty: thus leaving us totally at a loss to account for its use; and equally so to explain the manner in which the mouths of the absorbents of an abscess can operate upon, or even, in many instances, get at the material they are to remove.

Mr. Hunter, however, with the candour that so peculiarly belonged to him, made this question a subject of experiment, and the experiment, as he conceived, fully established his preconceived opinion; and gave proof that the pus of an abscess does not act as a solvent. This conclusion of his only shows how difficult it is for the most honourable mind, when biased by a favourite hypothesis, to weigh with an even hand the evidence that lies before it. "To see," says he, "how far the idea was just, that dead animal matter was dissolved by pus, I put it to the trial of experiment, because I could put a piece of dead animal matter, of a given weight, into an abscess, and which could, at stated times, be weighed. To make it still more satisfactory, a similar piece was put into water, kept to nearly the same heat. They both lost in weight; but *that in the abscess most*. And there was also a difference in the manner, for that in the water became *soonest putrid*."—(*On Blood*, &c., part ii., ch. v., p. 419.) There is nothing in animal chymistry, strictly so called, that decomposes animal substances so rapidly as putrefaction. And yet, in the present instance, the pus of an abscess evinced a more active decomposing power than the fluid of water, though aided by the accessories of putrefaction. It is not very wonderful that Mr. Hunter, though regarding this result as in his favour, should not be disposed to "rely on its accuracy," and he refers us, therefore, for a further proof, to a more competent experiment of Mr. (now Sir Everard) Home, which consisted in immersing a portion of muscle, weighing exactly one drachm, "in the matter of a compound fracture in the arm of a living man, and a similar portion into some of the same matter out of the body; also a third portion

into fluid calf's-foot jelly, in which the animal substance was pure, having neither wine nor vegetables mixed with it. These portions of muscle were taken out every twenty-four hours, washed in water, weighed, and returned again."

The result of this experiment is still more in favour of the solvent power of pus than the preceding. At the end of forty-eight hours, there was indeed no great difference, as the muscle in the abscess was reduced to thirty-eight grains, and that in the other two fluids to thirty-six. But from this period to ninety-six hours, the muscle in the jelly continued the same, while that in the abscess was reduced to twenty-five grains; and that in the exposed pus dissolved (*Dissertation on the Properties of Pus*, p. 32), the power of putrefaction, as Mr. Hunter observes, being, in this last case, super-added to that of the pus itself.

We hardly stand in need of other experiments. The solvent power of pus above that of water, of animal jelly, and hence, we may conclude, of animal fluids in general, is sufficiently established by the very evidence that is advanced in opposition to this power. And it should hence seem, that one at least of the direct uses of pus is to reduce, surface after surface, the dead animal matter which is exposed to its action to that state in which it may be rendered fit for absorption, and at the same time conveyed to the mouths of the absorbent vessels.

But I have for many years thought that it has also another equally important use; that, I mean, of assisting in the process of granulation; and a late article of Sir Everard Home, containing the observations of Mr. Bauer upon the germination of plants, and his application of those observations to the growth of the new vessels in animals (*Phil. Trans.*, 1818, pp. 180-194) seems, if not to have settled the question, at least to have very considerably favoured this view of it.

Having sown a quantity of wheat, for the purpose of noticing the changes which occurred from the first, Mr. Bauer took up every day several grains or plants for examination till they were ripe; and, in the course of his attention, was much struck with the rapid increase of the tubular hair of the root of a young plant of wheat in its earliest stage of vegetation; and, fixing his view entirely to that part of the plant, he observed small pustules, of a slimy substance, arising under the epidermis in the surface of the young root; and, in a few seconds, a small bubble of gas bursting from the root into the slimy matter, which it extended in a moment to the length the hair was to acquire; when the slimy matter surrounding the gas immediately coagulated and formed a canal. He repeated his observations on another plant, whose pubescence consisted of a jointed hair, and observed the same effect; a bubble issued from the young stalk, and extended the slimy mucus to a short distance, forming the first joint, which immediately coagulated and became transparent; and at its extremity a new pustule of the same slimy matter accumulated, into

which, in a short time, the gas from the first joint rushed: and thus, in a moment, a second joint was formed. In the same manner, he observed the formation of the hairs of ten or twelve joints take place.

Impressed with the importance of these facts, Sir Everard Home immediately began to inquire how far the same course is pursued in the production of new animal matter. He first ascertained, by experiments of Mr. Brande, already noticed in the Proem to the second class of this work, that blood in a state of circulation contains a considerable proportion of air, which, in the process of its coagulation, escapes in the form of carbonic acid gas, and, in its escape, produces bubbles, as in the slime of plants; and that it escapes equally from the coagulating blood of veins and arteries, from effused serum, and from pus. And, in pursuing the subject, he found that on the coagulation of a drop of blood, placed in the field of a microscope, an intestine motion occurred, and a disengagement of a something took place in different parts of the coagulum; beginning to show itself where the greatest number of globules were collected, and from thence passing in every direction with considerable rapidity through the serum, but not at all interfering with the globules themselves, which had all discharged their colouring matter. Wherever this extricated colouring matter was carried, a network immediately formed, anastomosing with itself on every side through every part of the coagulum. When the parts became dry, the appearance of a network remained unaltered. In some instances, bubbles were seen to burst through the upper surface of the coagulum; this, however, did not prevent the ramifications that have been described from taking place. "When this happens," continues Sir Everard, "in living animal bodies, from whatever cause, and in whatever circumstances it takes place, no difficulty remains in accounting for its afterward becoming vascular, since all that is necessary for this purpose is the red blood being received into the channels of which this network is formed." He next proceeded to the subject immediately before us. "As the globules of pus," says he, "are similar to those of blood, I made experiments upon the fluid in which they are suspended, and found inspissation produce the same effect on it as coagulation does on the other; that a similar network is formed, and apparently by the same means; since, if pus be deprived of its carbonic acid gas (of which it contains a large quantity) by exhaustion in the air-pump, no such network takes place."

Additional experiments are still necessary upon this interesting subject; but, so far as they go, they seem very clearly to indicate the important and double use to which pus is subservient; that it acts as a solvent upon the dead matter, preparing it for absorption, and as a fomes for granulation and the production of new vessels.

Nor let it be observed, in opposition to this conclusion, that we are thus endowing it with incongruous and contrary qualities; and that,

if it be erosive in the one instance, it cannot be nutrient in the other; for the animal economy presents us with various examples of like effects, contrary, indeed, but not contradictory, produced by one and the same secretion on dead and on living matter, for which we need go no farther than to the very common operation of the gastric juice; which, while the most powerful solvent of dead animal matter in the whole range of animal chymistry, is a healthy stimulant to the living stomach, and even to other living organs; and has successfully been applied externally for this purpose by surgeons, to weak and ill-conditioned ulcers, and employed by physicians as an internal tonic in cases of dyspepsy and cardialgia.

SPECIES II.

APOSTEMA PSOATICUM.

PSOAS ABSCESS.

PAIN AND TENSION ABOUT THE LOINS, SHOOTING DOWN THE SPINE AND THIGHS; DIFFICULTY OF STANDING ERECT; FLUCTUATING ENLARGEMENT ALONG THE PSOAS MUSCLE; APEX OF THE TUMOUR IMMEDIATELY BELOW THE GROIN.

This is one of the most lamentable diseases we can ever be called upon to attend. It commences insidiously, and, at the same time, in parts so deeply seated as to render it very difficult to determine the place of its origin; and hence the psoas muscle itself, the cellular substance interposed between the peritoneum and the loins, the lymphatic glands, and the lumbar vertebrae, have been pitched upon by different writers. It is probable that most of these have formed the primary seat of affection in different cases, and that the inflammation has subsequently spread to one or more of the other parts: and hence, assuming no inconsiderable degree of latitude, M. Chaussier denominates the disease *Femoro-coxalgie*.

[The cellular substance behind the peritoneum, or about the psoas muscle, is now ascertained to be the most common seat of the abscess in its commencement. When the spine becomes carious in consequence of the pressure of an abscess, it has been correctly observed by Mr. Brodie, that the symptoms are different from those which attend a caries of the spine, commencing in the spine itself. For instance, the paralytic affection of the lower extremities is generally absent. Caries of the vertebrae and intervertebral cartilages, however, is sometimes the primary disease (*Brodie's Path. and Surg. Obs. on Dis. of the Joints*, pp. 301, 302, ed. 2), and the abscess the subsequent one. This case would be characterized by the peculiar paralysis of the legs, resulting from original caries of the vertebrae and disease of their ligaments and cartilages.] The pain attending the formation of lumbar abscess, is at first by no means violent, and the patient thinks lightly of it; it is sometimes felt in the back rather lower than the region of the kidneys; and generally extends down the thigh. [The testicle of the affected side is frequently retracted, and more or less uneasiness and pain are felt in the

course of the spermatic cord. A very little exercise fatigues the patient, who mostly inclines the trunk forward, and in bed generally keeps the thigh of the affected side bent, a relaxed state of the psoas muscle being the most easy to him. The symptoms frequently continue stationary a long time. At length, a change occurs, indicated by rigours, loss of appetite, and followed by considerable acceleration of the pulse. Soon afterward the fluctuating tumour presents itself.] From the deceptive manner of its attack, medical treatment, which might have been of essential service at first, is fatally postponed; and the symptoms are regarded as those of an accidental strain. After the abscess is formed, however, the pain, in most cases, increases considerably, and, in common instances, the matter follows the course of the psoas muscle, and points externally a little lower than the inguinal glands; or it passes down the thigh, where, however, it is apt to dis sever the muscles and form sinous abscesses. Sometimes, though rarely, the matter passes through the muscles of the back, and is discharged in the loins; and, in a few instances, it has been known to fall into the cavity of the back part of the pelvis. The abscess, on account of its great extent, is highly dangerous: an extent which it generally attains ere it points externally, or admits of being discharged. Hence, the patient very frequently sinks under a hectic fever, produced by the local irritation; while in most cases in which it has made a natural opening for itself, it has been found connected with so many deep sinuses, which cannot be followed up, that the same effect ensues.

[It is a curious fact in relation to this subject, that psoas abscess should rarely be met with in the United States of America. Professor Gibson saw only four cases of the disease during thirteen years, although professionally connected with extensive hospitals and alms-houses most of that time. Dr. Physic never met with a case of psoas abscess in America, unconnected with disease of the spine.—(*Gibson's Surgery*, vol. i., p. 214.) If these statements coincide with the experience of other practitioners in America, they are highly interesting, as affecting the question, whether, as is generally supposed in England, the psoas abscess is necessarily connected with a scrofulous constitution.*]

No mode of medical treatment has been found productive of any good purpose; and the case has been, in a very early stage of the suppuration, given over to the surgical practitioner. Yet even here different individuals have pursued different lines of conduct. [Kirkland believed that the patient had the best chance of recovery when the abscess was allowed to burst of itself, and discharge itself very gradually by

* The German medical authorities seem to support the above opinion, but in America the case is otherwise. Psoas abscess is not unfrequent in the United States; it sometimes exists where no spinal disease can be detected. This opinion is confirmed by the experience of Professor Stevens, Dr. McLean, Dr. J. K. Rodgers, Dr. Cheesman, and by other practitioners of ample experience.—D.

a small outlet. The latter precept has been found to be one of great importance.] Mr. Bell advises an early evacuation of the matter, lest the bones should become injured; while Mr. Abernethy apprehends less danger from its being suffered to remain, and at last evacuates it at different intervals, and by successive operations: by which means the cyst, in which the pus is principally lodged, may have an opportunity of contracting; and this, he thinks, it has a greater tendency to do than in abscesses where the inflammation is more violent. He is also attentive to close the opening the instant the matter is discharged, so as to prevent any increase of the inflammation by an access of air.

The real cause of danger does not seem to have been hitherto hit upon; but it may probably be referred to that tendency to a rapid spread of inflammation over their entire surface, which Mr. Hunter has shown to exist in all internal cavities, and the hazard of which is in proportion to the extent of the cavity; a subject already touched upon in the discussion of puerperal fever, and which we shall have other opportunities of illustrating as we proceed, particularly in some cases of varicose enlargement of the veins. Now, in the disease before us, we have not, it is true, any natural cavity, but we have an artificial cavity of long standing and large extent, in a highly irritable state, and which is therefore peculiarly predisposed to run into all the fatal effects of large natural cavities, when injured or otherwise rendered imperfect. The author throws out this hint, however, for future and general consideration.

[Mr. Crowther relates a few cases in which psoas abscesses were dispersed by the application of large blisters to the swelling, which were kept open with the savin cerate. The same practice, combined with the occasional employment of emetics, was also recommended by Mr. Abernethy.]

SPECIES III.

APOSTEMA HEPATICUM.

ABSCCESS OF THE LIVER.

DIFFUSE PULSATING TUMOUR IN THE REGION OF THE LIVER; PRECEDED BY PAIN, A YELLOW COUNTENANCE, AND SHIVERING.

[THE ordinary symptoms, besides those spoken of in the definition, are, swelling and tension of the right hypochondrium, sometimes extending beyond it; pain in the right side, much aggravated by inspiration or pressure, and occasionally shooting up to the shoulder. In the case recorded by Dr. O'Brien, there was also great weakness of the right arm; a pale, anxious countenance, without yellowness; pulse 120, small and feeble; and no vomiting.—(*Trans. of Physicians in Ireland*, vol. i., p. 44.) Much doubt having been expressed by some physicians, whether true laudable pus could be formed in the substance of the liver, that distinguished pathologist, C. P. A. Louis, investigated the question, and, in the dissection of 430 subjects, met with five cases of hepatic abscesses, all of which presented genuine puru-

E e 2

lent matter.* It appears also from his dissections, that the abscesses are frequently encysted, and that the neighbouring portion of the liver is sometimes softer, but sometimes more indurated, than natural. In the cases of encysted abscesses, examined by himself, he could not decide positively whether they preceded, or were the consequence of, a dissolution of a greater or lesser number of tubercles; but he inclines to the latter opinion. In one very interesting case, reported by this author, the patient had voided large quantities of blood from the anus, and, after death, a clot of blood was found in a cyst in the liver; from which part, it is inferred, the blood had passed into the intestinal canal. As no communication could be traced, however, between the cavity and the biliary ducts, the conclusion appears questionable.—(*Louis*, op. cit., p. 385.) A common complication of abscesses of the liver seems to be a softening and ulceration of the mucous membrane of the bowels, especially that of the large intestines, the same affection of the lining of the small ones not being very frequent, except in phthisis pulmonalis, and fevers. The mucous coat of the stomach in some cases had red specks on it, was much softened, and, in certain places, incompletely ulcerated. Abscesses of the liver are mostly not single, but more or less numerous.† Their general fatality is partly ascribed by M. Louis to the liver not

* Louis, *Mém et Recherches Anatomico-Pathologiques*, p. 352, 8vo., Paris, 1826. The fluid discharged from an abscess connected with the liver, by Mr. Cæsar Hawkins, was not like common pus, but thick and adhesive, of a dark yellowish-green colour, and of a peculiar, though not offensive smell; and, upon being mixed with nitric acid, it appeared to contain biliary matter.—(*See Med. Chir. Trans.*, vol. xviii., p. 100.) In another case the matter was thin, of a light brown colour, and could scarcely be called purulent.—(*Op. cit.*, p. 106.) In these two instances the abscesses were only connected with the liver, and not in it. The punctures were followed by ulceration and sloughing of the skin, hemorrhage, and a destruction of nearly the whole thickness of the abdominal parietes. The disease had, in each patient, been preceded by symptoms of inflammation of the liver, and, after death, the cavity in which the matter had collected was so far obliterated, that it was difficult to decide positively where the fluid had been situated. The further particulars of these cases will be found interesting by the pathological inquirer.—ED.

† Dr. Stokes mentions, in his lectures (*Am. Journ. of Med. Sc.*, No. xxx., p. 503), a curious fact, that it has often been found impossible to salivate persons labouring under hepatic abscess, so that the presence of matter in the liver, or its absence, may be determined by the circumstance of the patient being, or not being, susceptible to the full effect of mercury. This fact is confirmed by Dr. Marshall, a gentleman of great experience, and very conversant with the diseases of India, who states that he has never known a case in which abscess actually formed in the substance of the liver, in which salivation could be produced; and that when the patient became salivated he believed it to be a proof that there was no inflammation of an intense character, or that no abscess had formed.—D

having, perhaps, the power of repairing the mischief, as he never observed traces of cicatrization in it. Yet this inference seems to be contradicted by the cures which are upon record.—(*Louis*, op. cit., p. 385–394, 408.)]

This is also a very fatal disease, and usually terminates in one of the following ways :

Firstly, The substance of the liver is gradually and almost entirely absorbed from long-continued irritation; the melancholy accompaniments of which are, a tedious, icterical marasmus, hectic fever, great anxiety, and a sanious and fetid diarrhœa, which is the forerunner of death.

[In one example, recorded by Dr. O'Brien, the abscess extended over two thirds of the liver, the biliary ducts were nearly annihilated, and all but one sixth of the gall-bladder destroyed.* In another case, reported by Professor Gibson (*Surgery*, vol. i., p. 211), he says that, upon dissection, the fistulous orifice in the side was traced into the liver, or rather into its remains; for its substance had disappeared, and nothing of its structure could be found, except a shell, or cyst, somewhat larger than an egg, and filled with brownish matter.]

Secondly, The abscess breaks internally, and discharges itself into the belly; by which means the rest of the viscera are affected, and the termination is marasmus, ascites, and dissolution.† According to M. Louis, this mode of evacuation only takes place in chronic hepatitis. —(*Mém. et Recherches Anat. Path.*, p. 372.)

Thirdly, The pus sometimes finds a passage into the biliary ducts, and thence into the intestines; from these it is occasionally thrown into the stomach, and vomited in the form of a dark offensive material: but far more generally it is carried downward, and produces a violent looseness. Acids and acescent medicines may here palliate for a time; but the issue is always fatal.

Fourthly, The enlarged liver becomes, in some cases, united by adhesive inflammation to the peritoneum, and the abscess opens externally; and, in this case, there is a chance of cure. The openings should be expedited by a caustic or the knife: and the cure will greatly depend upon the nature of the fluid which is discharged.

Fifthly, There is reason to believe that, in a few rare instances, the matter is carried off by absorption, when a healthy granulation takes place, and a cure is completed without any opening. This termination is more reasonably to be expected in a constitution otherwise

sound, and where the liver has not been weakened or rendered torpid by any former affection. It is hence rather to be looked for in a temperate than in a tropical climate, and in youth than in advanced life.

[Sixthly, In certain cases, the matter of the abscess has made its way by ulceration through the diaphragm, and been either effused in the chest, or, opening a communication with the bronchiæ, been coughed up from the lungs. In hot climates, where acute and chronic hepatitis are very common complaints, abscesses of the liver are often noticed. In Great Britain they do occur, but not very frequently, except in those who have returned from a long residence in warm latitudes. The liver may suppurate, however, from other causes besides common hepatitis, as from blows or injuries of the head,* biliary concretions, phlebitis,† and the presence of worms in the biliary ducts.‡ In the Surgical Museum of the University of Pennsylvania is a preparation in which the substance and ducts of the liver are filled and perforated in every direction by numerous and very large lumbrici. The patient, a child, fell a victim to the irritation and suppuration.—(*Gibson*, vol. i., p. 209.)]

When the cure takes place without an opening, it is not always an easy matter to determine for a certainty that pus has actually been formed. But sometimes we can trace a fluctuation; and, at other times, the subsidence of the tension, pain, and pulse, after one or two severe shivering fits, may be regarded as sufficient indications. In a case of this kind that occurred to me in a young gentleman of about thirteen years of age, the shivering was so considerable as to make the teeth chatter; and within eight-and-forty hours, the pulse sunk from a hundred and forty to a hundred and twenty; and the abdominal tension and tenderness were considerably abated; as was also the distressing cough with which he had almost perpetually been harassed for some weeks. He was put upon a tonic plan of columbo and sulphuric acid immediately after this change, and recovered gradually.

[In India, the rapidity with which inflammation of the liver frequently proceeds to suppuration, has sometimes been so great as scarcely

* See *Trans. of Physicians in Ireland*, vol. i., p. 43. The editor opened the body of a woman about three years ago, where the same morbid changes were noticed. A very small portion of the fundus of the gall-bladder remained, and at least two thirds of the liver were occupied by abscesses. The preparation, which is now in his possession, will shortly be sent to the museum of the London University.—Ed.

† The ordinary effect of such passage of the matter into the cavity of the abdomen is a rapid and fatal degree of peritonitis.—Ed.

* Quesnay, in *Mém. de l'Acad. de Chir.*, tom. i., p. 147. *Bertrandi de Hepatis Abscessibus; Œuvres Chir. de Desault*, tom. i. Also, a valuable paper by Mr. Rose on depositions of pus, &c. in the viscera, after injuries of different parts, in *Med. and Chir. Trans.*, vol. xiv., p. 251, &c. The fact of abscesses of the liver arising from injuries of the head is doubted, however, by the very eminent pathologist, M. Louis. See his *Recherches Anat. Pathol.*, p. 405. The editor suspects that the frequency of the occurrence from this particular cause has been exaggerated by writers.

† See *Crucveilhier, Anat. Pathol.* Andral refers to a case in which an abscess of the liver communicated with the interior of the vena cava; and to another in which the matter made its way into the pericardium.—*Précis d'Anat. Pathol.*, tom. ii., p. 598.—Ed.

‡ See *Kirkland's Inquiry into the present State of Medical Surgery*, vol. ii., p. 186. Also, *Bond, in Med. Obs. and Inq.*, vol. i., p. 68.

to admit of time for the employment of antiphlogistic remedies. As Dr. O'Brien observes, this should never be neglected in chronic hepatitis, even where mercury may subsequently become necessary; and he commends general bleeding, and the use of cupping and leeches. In this country, surgeons rarely open abscesses of the liver in an early stage; but, in India, the contrary practice is said to prevail, and to be found the most advantageous.*]

SPECIES IV.

APOSTEMA EMPYEMA.

LODGMET OF MATTER IN THE CHEST.

FIXED PAIN IN THE CHEST: BREATHING LABORIOUS, BUT EASIEST IN AN UPRIGHT POSITION; DIFFICULT DECUMBITURE ON THE SOUND SIDE; FLUCTUATING ENLARGEMENT ON THE SIDE AFFECTED; DRY, TICKLING COUGH.

To the symptoms enumerated in the above definition, Hippocrates adds (*Περί Πλευρίων*, pp. 476, 496) œdema of the feet, hollowness of the eyes, and a gurgling sound on shaking the shoulder. Of these additional signs, the first two belong rather to the hectic fever that generally accompanies empyema, than to the disease itself. The last has sometimes been met with in modern times.—(*Trécourt, Mémoires de Chirurgie*, &c.) Dr. Cullen regards empyema as a mere sequel of pneumonia, which, with him, includes inflammation of the pleura, as well as of the lungs; but as it may take place from inflammation of the mediastinum, pericardium, or diaphragm, to say nothing of that from external injuries, and as it is often doubtful what particular organ is directly injured, a separate species seems decidedly called for.

An empyema is sometimes produced by the bursting of a large vomica of one of the lungs into the cavity of the pleura: in which case, the cough becomes more frequent than before this result, and is either dry, or accompanied with a scanty, frothy, and noisy expectoration. The breathing becomes extremely difficult, with repeated fainting fits, and the dew of a cold sweat hanging over the throat and forehead; the cheeks and lips are of an ominous red, while the nails are livid, the pupils dilated, and the sight dim.

If percussion or the stethoscope be employed, before the vomica has broken, to the part in which the matter is seated, little or no sound will be returned, in consequence of the pressing fulness which exists there;† but if these meth-

ods be resorted to afterward, it will be found restored, in a considerable degree, to the part affected, from the hollowness which now exists there, while it will be comparatively found diminished in the posterior and inferior parts of the chest to which the discharged load is transferred. For the history and relative value of these diagnostics, the reader must turn to the treatment of PHTHISIS.—(Cl. III., Ord. IV., Gen. III., Spe. 5.)

[Laennec does not seem to approve of the application of the term empyema to the bursting of a large vomica into the chest. "I apprehend" (*Op. cit.*, p. 448), says he, "no one now considers empyema as the product of a vomica, which has burst into the cavity of the pleura. A softened tubercle may, indeed, discharge its contents in this manner, and may thus become the cause of a considerable effusion, by exciting a chronic pleurisy; but, in such a case, the tuberculous matter must only be considered in the light of an extraneous body, determining inflammation, and consequent effusion, by its mechanical or chymical qualities. It is also to this species of pleurisy that we must refer those histories of lungs entirely destroyed by suppuration, which we find recorded in the older writers." In this country, however, whatever may be the principal source of this purulent fluid in the cavity of the pleura, the term empyema is employed. In acute pleurisy, besides an effusion of coagulating lymph, a serous fluid is poured out, which is of a light yellow colour and transparent, or with its transparency only slightly lessened by the internixture of small fragments of concrete pus or lymph. In the latter case, it resembles unstrained whey. The fluid is generally devoid of smell. Many physicians suppose, that, in acute pleurisy, no effusion takes place till after some days; but Laennec declares (*Op. cit.*, p. 423-5), that he has several times observed all the physical signs of effusion; that is, ægophonism,* and absence of the respiration and sound on percussion, in one hour from the commencement of the disease; and he has seen the side obviously dilated at the end of three hours. On the other hand, he does not remember to have met with a single case, in which the effusion was doubtful under the stethoscope during the first and second day. The utmost that he admits on this point is, that the effusion continues to increase for several days, and that it is only at the end of this time that it becomes too manifest to be overlooked, from the dilatation of the affected side, and the total absence of sound on percussion. He is convinced that the effusion of serum is contemporaneous with inflammation in all serous membranes. The fluid effused is generally absorbed after the inflammation has subsided; and it is only when it remains in such quantities as to occasion very urgent symptoms, that any opera-

* Prof. Horner thinks that hepatic abscess may be managed by opening it even when adhesion to the side has not occurred, provided the liver be attached to the side by one or two stitches, which prevents the effusion of pus into the abdomen.—*See Am. Journ. of Med. Sc.*, No. xxvii., p. 90.—D.

† Dulness of sound on percussion, and absence of the respiratory murmur on the diseased side, which remains perfectly motionless. Puerile respiration in the opposite lung, accompanied with increased action of the respiratory muscles, and frequently a displacement of the heart, descent

of the diaphragm, and protrusion of the abdomen.—E.

* A tone or echo of the voice, distinguished with the stethoscope; and so named by Laennec, from its having a trembling or bleating sound, like the voice of a goat.

tion should ever be contemplated for its discharge.

The disease which Laennec represents as producing the most common species of purulent empyema, is chronic pleurisy, of which he describes three kinds: 1st, that which is chronic from its origin; 2dly, acute pleurisy, become chronic; 3dly, pleurisy complicated with certain organic productions on the surface of the pleura, bearing a gross resemblance to cutaneous eruptions.

According to Laennec, chronic pleurisy does not differ essentially in its anatomical characters from the acute: the pleura, however, is generally of a deeper red, and the serous effusion is more abundant, and almost always less limpid, being mixed with small albuminous floculi. In chronic pleurisy, the extravasated fluids have a more fetid smell than in the acute, and often yield a strong alliaceous odour, analogous to that of gangrene.* The effusion is rendered daily more considerable. The affected side becomes manifestly larger; the intercostal spaces grow broader, and rise to a level with the ribs, and sometimes even higher. The lung, compressed towards the mediastinum and spine, and retained in this position by pseudo-membraneous exudation, is sometimes so reduced in size as not to be more than four or six lines thick, even in its middle. In this state, the pulmonary tissue is soft, pliant, and dense, without any crepitation, more pale than natural, and almost without blood; yet the alveolar texture very distinct.†]

Modern researches prove, that collections of pus in the chest frequently occur without any appearance of ulceration. To such cases Mr. Hewson has several references. "The cavities of the pleura, pericardium, &c.," says he, "are

* The fluid effused in acute pleurisy is of a pale yellow or straw colour, and generally a little turbid, from an admixture of coagulable lymph. In chronic pleurisy, the fluid is not only in larger quantities, but of a consistence approaching to that of common pus, and generally mixed with flakes of coagulable lymph. However, as Dr. Townsend has observed, it is not always easy in practice to determine *à priori* the precise nature of the fluid collected within the chest, as its physical characters are found to vary considerably, even in those cases that most closely resemble each other, in their origin, progress, and symptoms.—Cycl. of Pract. Med., art. EMPYEMA.—Ed.

† As in empyema the matter is usually contained in only one side of the chest, its pressure sometimes displaces the heart. The editor has seen several examples, in which a considerable quantity of fluid in the left sac of the pleura has caused such a change in the position of the heart, that its pulsation could only be felt on the right side of the sternum. The pus, however, may be circumscribed by the adhesive inflammation, and then this effect will not be produced. In the case lately published by Mr. Woolley, the heart pulsated on the right side, in a situation precisely corresponding to what it ought to have occupied on the left. This was in a child between five and six years of age, that was cured by paracentesis alone.—(Med. Gaz. for Nov., 1833, p. 318.) Such displacement is one of the least fallible symptoms of a collection of fluid in the chest.—Ed.

sometimes observed to contain considerable quantities of pus without the least marks of ulceration. In one patient I found three pints of pure pus in the pericardium, without any ulcer either on that membrane or on the heart. In another, the cavity of the pleura of the right side was distended with a pus that smelt more like whey than a putrid fluid, and the lungs were compressed into a very small compass: but there was no appearance of ulcer or erosion, either on these organs or on the pleura; but only under the pus was a thin crust of coagulable lymph." We have already made some observations upon this secretion of imperfect pus, and it is not necessary here to dwell upon it.

Numerous cases are recorded, in which the contained fluid has disappeared.* It has passed off by the intestinal canal (*Kelner, Diss. de Empyemate*, Helm., 1670; *Marchetti*, Obs. 82, 89), by the bladder,* and by the vagina (*Schlichting, Phil. Trans.*, vol. xlii., p. 70), in the form of pus. It has also been frequently carried off by an opening formed by nature, and the patient has recovered his usual health. This opening has commonly been between the ribs; most usually between the third and fourth, but in one instance we find the abscess pointing and bursting under the scapula.—(*Hurten, Diss. de Empyemate*, Argent., 1679.) [The escape of the effused fluid through the intercostal muscles, from gangrene of a portion of the pleura, is regarded by Laennec as very rare. He says that he has only seen one case of it himself, and that M. Recamier has not seen more than two; and with respect to another mode in which the fluid finds vent, namely, in consequence of the formation of an abscess in the intercostal spaces, and its rupture both externally and internally, Laennec has only met with a single case of this kind. Andral reports three others. There can be no doubt, from the numerous examples on record, that these events are much more common than Laennec imagined. Dr. Forbes expresses his belief, that in cases of chronic pleurisy, the escape of the matter through the walls of the chest is by no means very uncommon. He has himself met with more than one instance of it. Laennec states (*Op. cit.*, p. 435), that a cure has, perhaps, more frequently followed the evacuation arising from these kinds of abscesses, than from an operation. The cure, however, is not always complete; as a fistula is apt to remain, frequently kept up by a caries of the ribs.

Morgagni has recorded (*De Sed. et Caus. Morb.*, ep. xxii., art. 13) a singular case of a double empyema; a lodgment of pus being formed on both sides: and Balme a still more ex-

* In the Medical Recorder for 1825, p. 553, Dr. Reese has stated a case of empyema, in which large quantities of pus passed off from the stomach and bowels. The patient died; and on dissection an opening was found in the œsophagus, about an inch and a half from the cardiac orifice of the stomach, through which the pus had passed.—D.

† Büchner, Diss. sistens solutionem Empyematis per mictionem purulentam.—Hal., 1762, N. Act. Nat. Cur., vol. i., obs. 5.

traordinary case, in which the pus entered the cellular membrane, and spread over almost the whole trunk.—(*Jour. de Méd.*, tom. lxxi., p. 244.)

Dr. G. Hawthorn has given an instance of this disease, that for its severity and danger, and particularly for its successful issue, is well worth recording.—(*Edinb. Med. and Surg. Journ.*, No. lxi., p. 513.) The patient was thirty years of age, and the disease had been brought on by exposure to damp night air in a state of intoxication. He suffered greatly from quickness of pulse, incessant cough, oppression, and dread of suffocation. A distinct fluctuation was perceived in about three weeks from the attack; shortly after which he was a little relieved by a discharge of purulent matter effused into the bronchial cells, and expectorated to the extraordinary amount of five or six pounds daily, for many days in succession, a fluid of an intolerably offensive smell and putrid appearance. He continued, however, to grow worse and weaker; his feet and legs swelled; his countenance was ghastly, and he had colliquative sweats. About twelve weeks from the attack, the operation was performed; nearly 20 lb. of pus was discharged on the first day and night; and he gradually recovered.*

[The evacuation of the matter by the bronchiæ is stated by Laennec (*Op. cit.*, p. 436) to be more common than that through the intercostal muscles. The fact, he believes, was first clearly established by Bayle. It scarcely ever occurs but in chronic pleurisy; though Andral relates one example of it in the acute disease.—(*Clin. Médicale*, tom. ii., obs. 36.)

The symptoms indicating the propriety of an operation are, the dilatation of the affected side; œdema of the same side and arm; depression of the liver, and displacement of the heart towards the side free from fluid. Laennec has shown, however, that all these symptoms may be absent; and it even frequently happens that at the very time when an operation is proper, the affected side, although full of pus, is smaller than the opposite one, in consequence of the absorption which has already taken place. But in all such cases, the results of percussion and auscultation leave no doubts respecting the effusion.—(*Op. cit.*, p. 475.) Laennec points out two cases of pleurisy, requiring that an operation should be performed for the discharge of the fluid from the chest. The first is when, in an acute pleurisy, the effusion is very copious from the beginning, and increases so rapidly as to give rise, after a few days, to general or local anasarca, and to threaten suffocation. The second is a chronic case, either in consequence of a pleurisy originally chronic, or of the acute disease changed into this state. In such cir-

* A patient under Dr. Croker, of Dublin, was tapped for an empyema, and fourteen pints of pus were discharged from the left cavity of the pleura. In Dr. Archer's case of successful paracentesis of the thorax (*Trans. of Dubl. Assoc.*, vol. ii.), eleven pints of inodorous fluid were drawn off, and in a few weeks the patient was convalescent. The interior of the pleura in such cases is almost always lined by a pseudo-membrane, such as constitutes the cyst of an abscess.—Ed.

cumstances, when œdema of the affected side has come on, when the long continuance of the disease, the progressive emaciation and debility of the patient, and the failure of every measure employed to produce absorption, leave nothing to be expected from other means, the operation is warrantable.]

When the fluid is discharged by paracentesis, Hippocrates repeatedly urges the surgeon to evacuate it only by degrees (*Περί Νοσῶν*, ii., p. 476, l. 42; *Περί τῶν θῶκος Παθῶν*, p. 536, l. 15): and Borelli (*Cent. i.*, obs. 72) gives a case in which the patient seems to have sunk under a sudden evacuation. There has also been no small discussion concerning the part of the thorax to which the scalpel may be most advantageously applied. David advises near the sternum (*Mem. pour le Prix de l'Acad.*, x.); Mr. Sharp between the sixth and seventh ribs (*Crit. Inquiry*, &c., chap. vi.); Mr. Bell wherever the pain or fluctuation may direct.—(*Surgery*, vol. ii., p. 390.)

Mr. Warner, whose success made it many years ago a favourite operation in our country, seems to have been of Mr. Bell's opinion, and varied the point of opening according to the nature of the case. And so little danger did he apprehend from the use of the scalpel on any occasion, that he not only evacuated in all instances the whole of the matter at once, but in one or two examples, operated where there was neither a polarized pain, nor fluctuation, nor visible discoloration, nor any external sign whatever to direct him to one part rather than to another, or even to determine the real nature of the disease, otherwise than from the specific symptoms laid down in the preceding definition.—(*Original Cases and Dissections*, &c., by John Forbes, M. D., p. 257, 8vo., Lond., 1824.)

In Mr. Warner's cases, about twenty ounces of pus formed the average of discharge at the time of the perforation (*Phil. Trans.*, vols. xlvii., xlviii., li., as also his works in their collected form): the patients usually found instant relief; the pain, cough, and quickness of pulse diminishing, and the breathing becoming easier. He dressed the wound with a sponge tent till there was no longer any discharge, and afterward superficially; and, in about six weeks, the patients were cured. In this case, it is perhaps more necessary to keep the wound open than in any other operation; for otherwise the secreted pus is apt to accumulate, and the operation must be renewed.*

[The following remarks by Professor Laennec are interesting:—The place of election, he says, commonly adopted by surgeons for this operation, is the most depending point in the anterior and lateral parts of the chest: a rule that cannot be good always, because the most dependant point varies with the position of the patient. The natural posture of a patient affected with empyema is to lie on the diseased side; and, in this case, the most depending point is the space

* Another case of two successful operations on the same person is related in Horn's Archives for March, 1826; an interval of twenty-two years elapsed between the operations.—D.

between the fifth and sixth ribs. Many other reasons, Laennec observes, point out this spot as the best. For instance, we know that the upper lobe adheres to the ribs more frequently than any other part of the lungs, and that the lower lobe is frequently attached to the diaphragm. On the right side, we know that an enlarged liver frequently reaches as high as the sixth, or even the fifth rib; and that on both sides the thickest false membranes, and consequently adhesions, exist at the junction of the diaphragm with the walls of the chest. Finally, we know that the greatest portion of the effused fluid is collected about the middle of the side. The best point is a little anterior to the digitations of the serratus major. Should there chance to be any old adhesions in this point, we shall readily discover them by means of some remains of respiration over their place.* But if, on percussion, the sound be dead at this spot, and the sound of respiration be wanting, we may safely make an incision.] Riedlin operated with success twice on the same person.—(*Lin. Mcd.*, ann. v., obs. 30.)

The matter, when discharged or examined on dissection, has been found of very different consistences: sometimes like what Laennec has described; sometimes pure pus; sometimes cheesy; and sometimes gelatinous. And the mischief to the interior of the chest has, in some cases, been very great. Several of the ribs have been found carious (*Hurmann, Vermischte Bemerkungen*, vol. ii., p. 217); the lung on the affected side totally eroded (*Kelner, Diss. de Empyemate*, Helmst., 1670); and, in one case, the pericardium destroyed as well as the lung.—(*Gockel, Gallicinium Medico-pract.*) The morbid changes described by Laennec have already been noticed.

[Owing to various causes, the operation is generally unsuccessful. 1. The first of these, as specified by Professor Laennec, is the bad condition of the lung itself, which is frequently tuberculous. 2. The irritation of the pleura, by the entrance of air into the chest, has been considered the chief cause of the great and offensive discharge, which too often ensues and destroys the patient. The admission of air into the chest, Laennec admits, must affect the action of the organs contained in it; but its immediate impression, he says, is not on the pleura, which, in acute pleurisy, is covered with lymph, and in chronic with thick pultaceous matter. 3. The greatest impediment to the success of the operation is, in Laennec's opinion, the compression of the lungs against the spine and medi-

astinum, and the nature of the investing false membrane. The lung, from the long compression, has lost its elasticity and expansibility, the inspired air peunctates it with difficulty, and the original dimensions of the organ are very slowly recovered. Indeed, it never returns to its natural size. Hence, with a view of favouring the expansion of the lung, Laennec had it in contemplation to revive the plan of exhausting the air from the chest with cupping-glasses: a plan best accomplished with a syringe, as advised by Mr. Jowett, and formerly recommended by Scultetus and Anel.—(*Op. cit.*, p. 476-479.)

SPECIES V.

APOSTEMA VOMICA. VOMICA.

DERANGED FUNCTION OF A THORACIC OR ABDOMINAL ORGAN; SUCCEEDED BY A COPIOUS DISCHARGE OF PUS INTO SOME PART OF THE ALIMENTARY CHANNEL; AND ITS EVACUATION BY THE MOUTH OR ANUS.

The specific term is a derivative from the Latin *vomo*, "to eject," especially from the stomach, but not exclusively so; and hence, on the present occasion, it is used in the comprehensive sense in which it is employed by Celsus, who applies it to a bursting of pus from the liver, or any other large internal organ, as well as the lungs.—(*De Medecin*, lib. iv., cap. viii.) Sauvages follows Celsus in this interpretation, but distinguishes the vomica from the aposteme, by making the discharge from the latter consist of pure pus, and that from the former of a mixed matter, being at first a sort of adipose mucus (*mucus quidam adiposus*), which at length becomes purulent. Avenbrugger, to whom we are indebted for the *Inventum novum*, or method of ascertaining diseases of the chest by percussion, takes nearly the same range, or rather carries it to a still wider extent, so as to include other depositions than that of genuine pus, and hence divides vomica into purulent and ichorous, meaning by the latter term the reddish yellow fluid occasionally found in a sac from the destruction of a hepatized or scirrhous lung, or other organ.* Boerhaave and Cullen confine vomica to the lungs, and this in a more restrained sense than most writers; for they limit it to what has been called, though with no great accuracy, *occult vomica*, "*vomica clausa*." Linnæus and Vogel, on the contrary, while they confine the term to the lungs, explain it by *open vomica*, "*vomica aperta*," in which the pus is thrown forth profusely and suddenly. One termination of the hepatic aposteme may be regarded as a variety of this species; for, as we have observed, it sometimes issues in a discharge of pus by the mouth or rectum. [Dr. Good supposed that pulmonary vomica consisted in conglobate glands, first enlarged by a strumous congestion, and afterward slowly and imperfectly suppurating. Others have described them as abscesses, the

* Under such circumstances, the place for the incision should be varied. In one case of this description, Laennec, after making an incision through the integuments, over the space between the fifth and sixth ribs, introduced a trocar; but no fluid came out. The patient died; and in the *post-mortem* examination it was found that the instrument had entered the cavity of the abdomen, after transfixing the diaphragm, which had been pushed upward by an enlarged liver, and had become firmly adherent to the seventh rib. A similar accident occurred in Lainotte's practice.—ED.

* *Inventum Novum ex percussione thoracis humani, ut signo, abstrusos interni pectoris morbos detegendi*. Vien., 8vo., 1761.

result of inflammation. On the contrary, Professor Laennec (Op. cit., p. 354) sets down an abscess in the lungs from inflammation as an extremely rare case; as at least a hundred times as rare as a true vomica. He represents vomica as the result of the softening of a tuberculous mass of large size, and that the copious expectoration, usually taking place after their rupture, is the secretion from the sides of the large tuberculous excavation.] Vomicae are not, however, always so large as described by this author; they vary in size from the diameter of a millet-seed to that of an orange. The smallest rarely contain any fluid, and sometimes not even a cavity (in which state, indeed, the editor conceives they are only tubercles); but they are often highly irritable, and maintain a very considerable degree of hectic fever. When ulceration has taken place, and pus is secreted, the irritability frequently subsides; the pulse improves, the febrile exacerbations are less frequent and violent, and the patient flatters himself he is recovering. The vomica at length bursts and discharges him; he sinks gradually from the quantity of the daily discharge, and the confirmed hectic; or if the disease be seated in the lungs, and the cavity extensive, he may be suffocated by the volume of pus that overwhelms the trachea.

Bartholine gives a singular case of an occult vomica of the lungs, that, accompanied with an asthma, produced great emaciation; but was fortunately cured by the wound of a sword, the point of which passed between the ribs and opened the sac. A considerable flow of pus followed, and the patient recovered gradually from the time of the accident.—(*Hist. Anat.*, xiv., cent. 6.)

The methods of percussion and mediate auscultation are now very generally resorted to on the continent and in our own country, to ascertain the existence and extent of this affection when seated in the chest; the theory and employment of which the reader will find explained at some length, under the treatment of PHTHISIS.—(Cl. III., Ord. IV., Gen. III., Spe. 5.)

GENUS II.

PHLEGMONE.

PHLEGMON.

SUPPURATIVE, CUTANEOUS TUMOUR; TENSIVE; GLABROUS; PAINFUL; AT LENGTH FLUCTUATING, AND BURSTING SPONTANEOUSLY; THE PUS UNIFORM AND GENUINE.

UNDER the last genus, we took a general survey of the process and economy of suppuration, and noticed many of the most extensive and dangerous forms in which suppuration ever presents itself. We are now advancing to inflammatory affections, consisting of tumours of small extent, and either entirely confined to the integuments, or dipping but a little way below them.

The term phlegmon, from φλέγω, "inflammo," was used among the Greeks for inflammation generally. It has long since, however, been employed in a far more limited sense by medical writers of perhaps every school; though few

of them have given a very clear definition of the exact sense in which they have intended to use it; or perhaps have formed such a sense in their own minds. Thus Dr. Cullen makes it comprise a multitude of tumours or tubercles of different degrees of inflammation, some suppurative, some unsuppurative, some serous, some callous, some fleshy, some bony; as bile, minute pimple, sty, stonepock, abscess of the breast, and spina ventosa, or carious bone; with many others altogether as discrepant; while by Sauvages it is limited, and far more correctly, to spheroidal tumours, possessing redness, heat, tension, violent throbbing pain, spontaneously suppurating. Not, indeed, essentially different from the character now offered, and involving most of its species. Vogel, however, makes it a part of its generic character, that the inflammatory tumour, in order to be a phlegmon, must be at least as large as a hen's egg; while Dr. Turton, in his useful glossary, not knowing how to reconcile the clashing descriptions which are thus given of it, merely explains it, after the Greek manner, "an inflammation," leaving the reader to determine the nature of the inflammation according to his own taste.

It is necessary, therefore, to come to some thing more definite; and I believe that the character now offered embraces the common idea of phlegmon; or, if not, will propose what should seem to form a boundary for it. And, thus explained, it will comprise the following species:—

1. Phlegmone Communis. Push.
2. ——— Parulis. Gum-bile.
3. ——— Auris. Impostume in the ear.
4. ——— Parotideæ. Parotid Phlegmon.
5. ——— Mammæ. Abscess of the breast.
6. ——— Bubo. Bubo.
7. ——— Phimotica. Phimotic Phlegmon.

[By other writers, phlegmon is described as inflammation of the cellular membrane of any part of the body; but, as this tissue is also affected in erysipelas, the definition fails. The editor, in his surgical writings, always understands by phlegmonous inflammation, the healthy, simple form of this affection, particularly when situated near the surface of the body. But there is every reason to presume, that an inflammation of a similar character often affects many of the deeply seated parts. Such an opinion, he believes, will be found to agree with the doctrines inculcated, and the facts pointed out, by Mr. Hunter.]

SPECIES I.

PHLEGMONE COMMUNIS.

PUSH. COMMON PHLEGMON.

TUMOUR COMMON TO THE SURFACE; BRIGHT RED; HARD; DEFINED; HEMISPHERICAL; POLARIZED; GRADUALLY SOFTENING AND BURSTING AT THE POLE.

IN vernacular language, this species is denominated a *push*; and, in size, has a near approach to a bile, or furuncle; but essentially differs from it in having its pus uniform and mature, while that of the bile is always intermixed with a core. It is commonly a mark of high

entonic health, or a phlogotic diathesis; and rarely requires any other medical treatment than bleeding, or a few cooling purgatives.

Where, however, pushes appear in crops, and especially in successive crops, they support a remark we had occasion to make in opening the present order, that, in conjunction with the phlogotic diathesis, there is probably a peculiar susceptibility of irritation; since we frequently find persons of the highest health, with firm and rigid fibres, pass great part, or even the whole of their lives, without any such affection as the present. Such susceptibility is far more common, indeed, to a habit of an opposite character; but it seems from this, as well as from other circumstances, not unfrequently to inhere in the temperament we are now contemplating.

SPECIES II.

PHLEGMONE PARULIS.

GUM-BILE.

TUMOUR SEATED ON THE GUMS; DEEP RED; HARDISH; UNDEFINED; PAIN OBTUSE.

This is sometimes limited to the substance of the gums, and sometimes connected with a caries of a tooth or socket. In the first variety, it is only a disease of a few days duration, and ceases almost as soon as it has burst or is opened; in the second, it will often continue troublesome till the carious tooth is extracted, or the diseased socket has exfoliated, or the whole of its texture is absorbed; in which case the tooth will become loose, and may at length drop out spontaneously.

Gum-biles, and especially when connected with a morbid condition of the subjacent teeth, or their alveoli, rarely disperse without passing into the suppurative stage: and hence, the means of prohibiting this termination are usually tried in vain, much time is lost, and protracted pain encountered. For these reasons it is better to encourage than to repel the suppurative process, by warm cataplasms or fomentations; and to open the tumour as soon as it begins to point. An early opening is of importance; for, from the toughness and thickness of the walls of the abscess, it is seldom that the confined pus obtains a natural exit with sufficient freedom; while, in some instances, the ulceration assumes a sinuous character, or works into the substance of the cheeks, and at length opens on their external surface. The worst and most painful gum-biles are those which form on the dentes sapientiæ; the swelling, from the violence of the irritation, spreads rapidly and widely; so that the entire cheek is sometimes involved in it, the neck indurated, and the eye closed.

SPECIES III.

PHLEGMONE PAROTIDEA.

PAROTID PHLEGMON.

TUMOUR SEATED UNDER THE EAR; REDDISH; HARD; PAIN OBTUSE; SUPPURATION SLOW AND DIFFICULT.

It is not a little singular that Dr. Cullen,

who extends the genus of phlegmone wide enough to embrace not only inflammation of the ear and of the breast, gum-bile, and phimosi, but also furunculus, varus, gutta rosea, sty, and, as already observed, several affections of the bones, should have banished suppurative inflammation of the parotid and inguinal glands, not only to another genus, but to a very remote part of his system; where they occur in the class and order of *local tumours*, in company with warts, corns, and sarcomata, which have naturally no inflammatory character. Here, too, they are conjointly described under the generic name of *bubo*, with the generic character of “*glandulæ conglobatæ tumor suppurans*,” a definition which does not apply to the parotid gland, whose structure is not conglobate, but conglomerate. The present, therefore, is the proper genus for including suppurative inflammation of the parotid and inguinal, as well as of the mammary glands.

Phlegmonous inflammation of the parotid gland offers us the two following varieties:—

- | | |
|-----------------------------|--|
| <i>a</i> Simplex. | Incarning and cicatrizing easily. |
| Simple parotid phlegmon. | |
| <i>β</i> Maligna. | Accompanied with a foul slough, and incarning with difficulty. |
| Malignant parotid phlegmon. | |

In the SIMPLE or BENIGN VARIETY, though the suppurative process is slow and inactive, the incarnation subsequent upon the breaking of the abscess is regular and unobstructed. I was requested not long ago to see a young lady of fifteen years of age, who had been troubled with this species of phlegmon for more than three months: there had been, for about a fortnight, an evident pointing towards the surface, and a feel of irregular fluctuation: it afterward broke; a large quantity of good pus drained away daily; and the tumour, which at first was extensive and hard, by degrees very considerably diminished, and clustered or divided into lobes, and at length disappeared altogether. Her general habit was relaxed, but did not seem to be stumous. She had menstruated earlier than usual, and was of a disposition peculiarly sprightly and cheerful. The local treatment at the commencement was leeches, frequently applied, and alternated with mercurial plaster. But no benefit proceeding from the discutient plan, lotions of water and liquor ammoniæ acetatis, in equal parts, were afterward employed to aid the suppurative process.

The abscess, in some cases of this variety, is of considerable magnitude, and consequently the discharge of pus very large. And we have some instances on record in which the pus has been absorbed, and carried off by metastasis to some remote organ. Dr. Saunders gives a case in which it passed away by the rectum (*Observations on the Red Peruvian Bark*); Alix, by a fontanel at the navel (*Obs. Chirurg.*, Fascic. i.); and the Transactions of Natural Curiosities, by the bladder.—(Vol. i., obs. 39.) It has sometimes been confounded with parotitis or mumps;

and has hence been said to sympathize with one or both testicles in males, and to be contagious. Cavallini has made this mistake in his collection of surgical cases (*Collezione di Casi Chirurgici*, vol. i., p. 447); and we find a like error in the *Memoirs of Toulouse*.—(*Histoire et Mémoires de l'Académie de Toulouse*, tom. i., 1782.)

The SECOND VARIETY of parotid phlegmon is of a malignant character. It seldom appears in early life, and in females sometimes follows the cessation of the catamenia. It is still slower in its progress than the preceding; and when at length it breaks, the pus is imperfect and cheesy, or serous. It is also profuse, and protracted to a long period, and accompanied with foul sloughs. The patient is debilitated by the discharge, the irritation excites hectic fever, and the case frequently terminates fatally. Bark, hyoscyamus, conium, and similar tonics and narcotics, have been tried; but for the most part with little success.

It assumes, occasionally, a scirrhus hardness, and grows to a considerable extent. It has been extirpated, but with variable success, when upwards of three pounds in weight (*Kaltschmid, Pr. de Tumore scirrhus trium cum quadrante librarum glandulæ Parotidis extirpato*, Jen., 1752); sometimes with a cure (*Siebold, Parotidis scirrhus felicitè extirpatæ Historia*, Erf., 1791); but, at other times, it has degenerated into a foul, bleeding, extensive, and fatal ulcer.—(*Commerc. Lit. Nor.*, 1733–8.)

SPECIES IV.

PHLEGMONE MAMMÆ.

ABSCCESS OF THE BREAST.

TUMOUR SEATED IN THE BREAST; PALE-RED; HARDISH; IN IRREGULAR CLUSTERS; WITH A PRICKING AND ACUTE PAIN; SUPPURATION QUICK AND COPIOUS.

THIS is sometimes produced by some accident, as that of a blow or severe pressure; but more generally proceeds from a redundancy and consequently undue stimulus of milk, when first secreted after childbirth, so that the lacteal tubes have not time to enlarge sufficiently for its reception: in which last instance it is usually called MILK ABSCESS. [Professor Gibson conceives, that one of the most common causes of the mammary abscess is the custom prevalent among nurses, of feeding women, after delivery, upon nutritious, high-seasoned, and stimulating articles, instead of letting them observe a proper regimen, calculated to obviate inflammation.*]

* See Gibson's *Institutes of Surgery*, vol. i., p. 205, Philadelphia, 1824. Also Sir Astley Cooper's *Illustrations of the Diseases of the Breast*, p. 9. "Its principal cause," he says, "is the rush of blood which takes place each time the child is applied to the bosom, and which by nurses is called the *draught*, and is the preparatory step to the secretion of milk. Such occasional, irregular, violent, and frequent determinations of blood, produce inflammation; and the necessary frequent exposure of the bosom in suckling, as well as the active exertions of the child in sucking, add to the occasional irregularities of the circulation. The

"In either case the suppuration commonly begins in many distinct portions of the inflamed part; so that it is not one large circumscribed abscess, but many separate sinuses, all of which generally communicate. Now it usually happens that only one of these points externally, which being either opened, or allowed to break, the whole of the matter is to be discharged this way. But we sometimes find that the matter does not obtain a ready outlet by this opening, and then one or more of these different sinuses make distinct openings for themselves."—(*Hunter on Blood*, p. 469.)

In this case the complaint is usually protracted and tedious, though, where the constitution is good, the issue is always favourable.

[Mr. Hey has described one variety of mammary abscess, which proceeds more slowly to suppuration than ordinary cases. The matter is often discharged by several openings, which become fistulous and lead to narrow sinuses, that wind in every direction in the breast. When these sinuses are laid open, they appear nearly filled with a soft purple fungus.—(See *Hey's Pract. Obs. in Surg.*, 3d edit., p. 522.) Unless properly treated, it is a case that has little chance of cure.

In the early stage of phlegmonous inflammation of the breast, resolution should be attempted by means of leeches, gentle suction of the breast with the mouth or nipple-glass, purgatives, and low diet.* But if suppuration occur, the progress of the matter to the surface should be expedited by fomentations and warm poultices.† When the matter is deeply seated, and approaches the surface very slowly, and the patient is much reduced by severe pain and sleepless nights, an opening becomes necessary.‡ The poultice must be continued until the discharge nearly ceases, and then superficial dressings will complete the cure.§ If sinuses remain, the pressure

nurse also often produces these abscesses immediately after lying-in, by refusing to put the child early to the breast, and stimulating the mother with strong drinks."—ED.

* Evaporating lotions, and purging with sulphate of magnesia, or castor-oil. If cold applications fail to give relief, a tepid poultice, and leeches occasionally.—Sir Astley Cooper.

† Bread poultices, made with the decoction of poppy-heads.—ED.

‡ If the abscess be quick in its progress, placed in front of the breast, and the suffering not excessive, Sir Astley Cooper leaves it to take its natural course. But if the matter be very deeply situated, its progress tedious, the pain very great, the irritative fever considerable, and the patient suffers from profuse perspiration and want of rest, he prefers discharging the matter with a lancet. "Still it is wrong to penetrate with the lancet through a thick covering of the abscess, as the opening does not succeed in establishing a free discharge of matter; for the aperture closes by adhesion, the accumulation of matter proceeds, and ulceration will continue. On this account, the opening should be made where the matter is most superficial, and the fluctuation is distinct, and it should be in size proportioned to its depth." Op. cit., p. 10.—ED.

§ American practitioners often employ a poultice made of the slippery elm bark (*Ulmus rubra*

of a well-applied roller will soon obliterate them. In the variety described by Hey, he recommends laying open all the sinuses; but Professor Gibson has found that, in two very extensive and obstinate cases, the milder plan of passing a seton into each of the sinuses, as prepared by Dr. Physic, accomplished a cure.*

With respect to the question, whether the child should be weaned, the following is Sir Astley Cooper's advice. "If the abscess be small, the child may be put to the diseased breast as well as the other; but, if much of the mamma be involved in the disease, the child should be put to the other breast; but that which is inflamed should be drawn by the mother herself, by means of the glass tube constructed for the purpose. As the pump, which is sometimes employed, bruises the breast, and gives much pain, it ought not to be used. As a general rule, it is best to continue the child at the breast as long as the mother's sufferings will admit of it."—(Op. cit., p. 12.)

SPECIES V. PHLEGMONE BUBO.

BUBO.

TUMOUR SEATED IN A CONGLOBATE GLAND; REDDISH; HARD; DIFFUSE; NOT EASILY SUPPURATING; OPENING WITH A CALLOUS EDGE.

Bubo is a Greek term borrowed from the Hebrew verb בָּעַר or בָּעָר (bo or boā), importing "to swell," and merely doubled according to the analogy of the language, to give it an intense or superlative power, whence bobo, or bubo.

Buboes are chiefly found in the inguinal and axillary glands. They are sometimes simple glandular inflammations, unconnected with any constitutional or foreign evil, and require nothing more than the common treatment; but they are often a result of constitutional affection, and very frequently a symptom of lues and pestis, in which cases they can only be cured by curing the specific taint. Mr. Hunter asserts, that he has seen buboes cured by vomits, after suppuration has advanced.

In an early stage, the inguinal bubo has been confounded with a scrofulous tumour. A nice finger will generally discriminate them with ease. The bubonous tumour is smooth, uniform, and obtusely painful: the scrofulous is to the touch, and sometimes to the eye, a cluster of small tubercles without pain.

of Mühlenberg) as a discutient, and with great success.—D.

* Institutes, &c., vol. i., pp. 206, 207. Sir Astley Cooper recommends the sinuses to be injected with a solution of two or three drops of strong sulphuric acid in an ounce of rose-water, and to apply a similar lotion to the bosom by means of linen wetted with it.—(Illustrations of Diseases of the Breast, p. 11.) For the dispersion of the hardness of the breast, left after milk abscesses, friction with iodine ointment, or camphorated mercurial ointment, or the application of the emplastrum ammoniaci cum hydrargyro, is the common practice.—Ed.

SPECIES VI.

PHLEGMONE PHIMOTICA.

PHIMOTIC PHLEGMON.

TUMOUR SEATED IN THE PREPUCE; DIFFUSE; OBTUSELY PAINFUL; IMPRISONING THE GLANS, OR STRANGLING IT BY RETRACTION.

If, at the attack of inflammation, the prepuce be in its natural state and cover the glans, it cannot be drawn back, and the glans is imprisoned. If it should accidentally have been retracted, or be naturally short and truncated, it cannot, after the inflammation has firmly fixed itself, be drawn forwards, and the glans is strangled. And hence the species offers us two varieties:—

- | | | |
|---|---|---|
| a | Incarcerans.
Incarcerating phimosis. | The prepuce protracted and imprisoning the glans. |
| β | Strangulans.
Strangling phimosis. | The prepuce retracted and strangling the glans. |

The FIRST VARIETY alone is denominated *phimosis* by some writers, the second being distinguished by the term *paraphimosis*, or *circumligatura*. But the inflammation is one and the same, and the same specific name should express it; for the difference is a mere accident.

This inflammation, like the last, though often produced by common causes, and hence perfectly simple, is often, also, the result of a specific virus, as in lues and blenorrhœa. It arises frequently with great rapidity; the prepuce is prodigiously distended with effused serum, and the mucous glands of the internal surface secrete an enormous quantity of pus before there is any ulceration or breach of surface. If the prepuce be retracted violently, and the glans strangulated, and cold applications and topical bleedings prove ineffectual, it is often necessary to divide the prepuce to set the glans at liberty. And occasionally it is also necessary to perform the same operation when the glans is imprisoned by a protraction of the prepuce: for ulceration is apt to take place under these circumstances in either case, and the matter soon becomes erosive; as much of it as possible, however, should be washed out with a syringe several times a day, and an astringent solution be afterward injected, consisting of alum dissolved in water in the proportion of about a scruple to a quarter of a pint.

The imprisoning phimosis is said to occur not infrequently from laborious exertion in a very narrow vagina.—(Essich, in *Ziegenhagen Anweisung alle venerische Krankheiten zu behandeln*, A. D. B., xcv., 421.) I have not met with this result, but often with a lacerated prepuce. In many instances of both kinds, relief has been easily obtained by grasping the penis with a very cold hand, and dexterously urging the prepuce forward or drawing it backward, according to the nature of the case.—(Andree, on the *Gonorrhœa*; Hecker, *Von Venerischen Krankheiten*, &c.)

When the inflammation is very violent, whether in the strangulated or retracted variety, and

surgical attention has been neglected, gangrene will readily ensue, and an amputation of a smaller or larger portion of the penis may be absolutely necessary. In an instance of an amputation of this kind, recorded by Mr. Jamieson of Kelso, in the Edinburgh Medical Essays (vol. v., art. xxxvi.), the whole of the glans penis was restored by a process of pullulation: the new shoots having at first been mistaken for fungus, and attempted to be destroyed by escharotics. The fresh glans was well shaped and proportioned. [The editor scarcely need observe, that the practice of amputating the penis on account of the risk of mortification from paraphimosis, is entirely relinquished by all the best modern surgeons; and that even the removal of a portion of the prepuce for the relief of phimosis, is much less frequently practised than it used to be. Both cases, when dependent on inflammation, generally yield to milder treatment. In paraphimosis that resists common means, an incision through the constriction will often prevent gangrene; and it is only under very particular circumstances, requiring the glans to be immediately exposed, or where the phimosis depends upon a naturally long constricted foreskin, or one permanently thickened and lengthened by disease, that the removal of any portion of the prepuce is necessary.]

GENUS III.

PHYMA.

TUBER.

IMPERFECTLY SUPPURATIVE, CUTANEOUS, OR SUBCUTANEOUS TUMOUR; THE ABSCESS THICKENED, AND INDURATED AT THE EDGE; OFTEN WITH A CORE IN THE MIDDLE.

PHYMA, a Greek term importing a tuber, tubercle, or small swelling, from *φῶμα*, "produco, erumpo," was used among the Greek and Roman physicians with great latitude and no small want of precision: sometimes, as by Hippocrates and Paulus of Ægina, being applied to scrofulous and other imperfectly suppurative tumours; sometimes, as by Celsus and Galen, to tumours perfectly and rapidly suppurative, larger than a bile, but less painful and inflammatory, and without a core or ventricle: and sometimes by other writers, as Celsus also informs us, to fleshy excrescences or warts on the glans penis, which it was then the custom to destroy by caustics. And in consequence of this vague sense of the term, and the latitude of its original meaning, the great body of the Galenists, as Sauvages observes, applied it to protuberances of every kind.

Modern writers have been at a loss in what exact signification phyma should be employed. Linnæus and Cullen have rejected it. Sauvages and Sagar have used it as the name of a distinct and separate order. Vogel, following the example of Hippocrates and Paulus, has reduced it to a genus of imperfectly suppurative and glandular tumours; and, as a genus, it thus occurs in Dr. Willan's table of arrangement, including biles, carbuncles, and similar inflam-

mations as its species. This seems to be the most accurate sense; and as such it is adopted in the present system, and made to include sty, bile, sycosis, and carbuncle; in all which we find some degree of imperfection in the suppurative or the ulcerative process of these small abscesses, or in both conjointly; and hence the pus is foul and sanious, or the walls or edges of the abscess are thick and indurated, or the dead matter is not completely carried off, and remains behind in the shape of a core or a fungus, sometimes black and spongy, and sometimes excrement and granulating.

The following, therefore, are the species included under it:

- | | |
|---------------------|---------------|
| 1. Phyma Hordeolum. | Sty. |
| 2. ——— Furunculus. | Bile. |
| 3. ——— Sycosis. | Ficous Phyma. |
| 4. ——— Anthrax. | Carbuncle |

SPECIES I.

PHYMA HORDEOLUM.

STY.

TUMOUR SEATED ON THE VERGE OF THE EYELID; GRANULAR; HARD; REDDISH; SORE TO THE TOUCH; SUPPURATION CONFINED TO THE POINT.

The vernacular term *sty*, or, as it is sometimes written, *stian*, is to be met with in the earlier writers, who obtained it from the Saxon, in which *stihan* signifies "a rising, springing up, or ascent;" and hence in Bede's Bible, Mar. iv. 7, *stihon tha thornas*, "up spring the thorns." Wickliffe spells the old English derivation *stigh*, but Spenser, who uses the word frequently, drops both the last letters of Wickliffe, as in the following couplet:—

"To climb aloft and others to excel,
That was ambition, and desire to sty."

From the hardness of the margin of the tumour, and the imperfection of the suppurative process, Sauvages compares it to a small bile; and asserts that it is often the result of a morbid state of the stomach; adding, that he knew a man who uniformly had a sty after drinking ardent spirits. The inflammation, though often very troublesome while it lasts, for the most part readily subsides upon the breaking of the minute abscess, or puncturing it at its apex when mature.

SPECIES II.

PHYMA FURUNCULUS.

BILE.

TUMOUR COMMON TO THE SURFACE; DEEP RED; HARD; CIRCUMSCRIBED; ACUTELY TENDER TO THE TOUCH; SUPPURATING WITH A CENTRAL CORE.

The bile is a push with a central core; and like the push is found in persons of an entonic or phlogotic habit, with a peculiar susceptibility of irritation: on which account it often makes its appearance successively in different parts of the body, and sometimes synchronously, so that we meet with a crop at a time. This tumour

is therefore chiefly found in persons of high health and in the vigour of youth.

[It is a hard, painful, and highly-inflamed tumour, of a conical shape, the base of which is below, and the apex slightly elevated above the level of the skin. The colour of the tumour is of a dusky red, inclining to purple, and its summit is tipped by a whitish pustule or eschar, beneath which is lodged a mass of disorganized cellular membrane, commonly called the *core*. Although the tumour always suppurates, its progress is slow, and the matter is sanious and ill-conditioned.]—(See *Cooper's First Lines of the Practice of Surgery*, and *Gibson's Institutes of Surgery*, vol. i., p. 48.)

The existence of a core offers a singularity in this affection that is well worth attending to, and shows that, from some cause or other, the ulcerative part of the process is imperfect. Upon Mr. Hunter's hypothesis, this must depend upon a weak action of the absorbents; but as we have already endeavoured to show that the material to be removed must be prepared for absorption, and conveyed to the mouths of the absorbent vessels before absorption can take place, and have suggested that it seems to be the office of the secreted pus to accomplish this purpose, it is probable that, in the furunculus, the pus, from some cause or other, is not quite genuine, and is possessed of a less solvent power than in common abscesses—whence a part of the dead matter remains attached to the living after the hollow has burst, and is thrown off from the base by sloughing. [In estimating the value of this theory, one fact should be taken into the account; namely, that it is the nature of a bile to produce a central core or small slough of the cellular membrane; whereas many common abscesses occasion no sloughs whatever, so that the solvent power of their matter on such productions is not in reality tried. The idea that the solids are melted down, as it were, into pus, is now completely exploded.]

The mode of treatment is simple. The diathesis should be lowered by purging, and, if necessary, by bleeding. [The best local applications are poultices and fomentations; and, when the apex of the swelling becomes soft, it may be opened, then poulticed until the core is discharged, and afterward dressed with a solution of lunar caustic or a stimulating ointment.]

SPECIES III. PHYMA SYCOSIS. FICOUS TUBER.

TUMOUR EXCRESCENT, FLESHY; FIG-SHAPED; SPROUTING FROM THE HAIRY PARTS OF THE HEAD OR FACE, GREGARIOUS; OFTEN COALESCING; DISCHARGE PARTIAL AND SANIOUS.

The Greeks gave the name of sycosis from *σῦκος*, "a fig," to various tubers and excrescences, the shape of which was conceived to resemble that of a fig. By Celsus, however, it is limited to a particular kind of inflammatory and imperfectly suppurative tuber of the head

and face. Vogel has understood the term nearly in the same sense; and Dr. Bateman has hence correctly described it as such in his list of cutaneous diseases.

It is seated sometimes on the beard, and sometimes in the hair of the head. In the former case it consists of small tumours, hard, roundish, pea-sized; commonly in clusters; occasionally confluent, or running into one another; and spreading from ear to ear: the discharge is small in quantity, and of a glutinous texture, whence the beard becomes filthily matted.

The variety that appears on the head consists of softer tumours of different sizes, and in clusters; they are seated among the hair, and throw forth from a fungous surface an ichorous, copious, and fetid discharge. It is not often that this complaint is connected with any constitutional affection: and, offensive as it is, it will generally be found to yield to cleanliness and mild astringents; of which one of the best is starch-powder alone, or combined with an equal proportion of calamine.* It makes an approach to one or two of the species of porrigo, but has characters sufficiently marked to keep it distinct, and to determine the present to be its proper station.

SPECIES IV. PHYMA ANTHRAX. CARBUNCLE.

TUMOUR COMMON TO THE SURFACE; FLAT; FIRM; BURNING; PENETRANT; LIVID AND VESICULAR; OR CRUSTY ABOVE, WITH A SORDID GANGRENOUS CORE BELOW; IMPERFECTLY SUPPURATIVE.

ANTHRAX is a Greek term correspondent to the Latin *carbunculus* or *carbuncle*; literally a small live coal, so denominated from the redness and fiery heat of the inflammation.

The specific definition sufficiently points out its relation to the furuncle or bile, especially when the latter assumes an unkindly or malignant character, from something peculiar in the part or in the constitution. "The inflammation that produces the carbuncle is, however, of a different nature from any of the former: it is stationary," observes Mr. Hunter, "with respect to place, and is pretty much circumscribed, forming a broad, flat, firm tumour. It begins in the skin, almost like a pimple, and goes deeper and deeper, spreading with a broad base under the skin in the cellular membrane. It

* This disease seems also to have been described by Pliny, under the term "*mentagra*," "*quoniam à mento ferè oriebatur*," and to have appeared with great violence in Rome about the middle of the reign of Claudius. It is sometimes very protracted in its character, and is also liable to recur from neglect. It is occasionally cured by an ointment composed of equal parts of the sulphur and tar ointments, and at times it will yield to a wash of the solution of the chloride of soda. At the Hospital St. Louis, at Paris, it is treated also with internal remedies, as the muriate of gold, arseniate of iron, &c.—D.

produces a suppuration, but not an abscess; somewhat similar to the erysipelatous, when the inflammation passes into the cellular membrane: for, as there are no adhesions, the matter lies in the cells where it was formed, almost like water in an anasarca. This inflammation attacks more beyond the middle age than in it, and very few under it. It is most common in those that have lived well. I never saw but one patient of this kind in an hospital. It appears to have some affinity to the bile; but the bile differs in this respect, that it has more of the true inflammation, therefore spreads less, and is more peculiar to the young than the old, which may be the reason why it partakes more of the true inflammation.”—(*On Blood, Inflammation, &c.*, part ii., chap. iv.)

The carbuncle occurs chiefly, perhaps uniformly, in weakly habits, and hence often in advanced life. But it is not all debilitated persons who have inflammations that exhibit this disease: and we have here, therefore, another striking proof of the influence of idiosyncrasy, or a peculiarity of constitution, upon the general laws and progress of inflammation; or of a peculiarity of that part of the constitution in which the inflammation shows itself, and, but for which, the inflammatory stages of the present disease would in all probability succeed each other in regular order, and the anthrax be reduced to the character of a common and benign abscess. Of the nature of this peculiarity we are too often able to trace out little or nothing: but, so long as it continues, we have only a small chance of bringing the inflammation to a successful issue.

The carbuncle shows itself under the two following varieties:—

- a* Pruna. With a black crust; and Eschar-carbuncle. oozing an erosive ichor, or sanies.
- β* Terminthus. Core or fungus spreading in Berry-carbuncle. the shape and colour of the pine-tree berry.

The first of these varieties was called pruna by Avicenna, from its assuming the colour, and often the oval figure of the sloe, or fruit of the *prunus spinosa*, Linn. The second derives its name from its assuming the figure and blackish green colour of the fruit or berry of the pine-nut, or *τέρμινθος* of the Greeks, the *pinus Abies*, Linn., named by the Latins terebinthus; whence it has been called terminthus and terebinthus indifferently.

As the carbuncle is an inflammation of great weakness set down on a peculiar predisposition, it sometimes shows itself among feeble infants in warm climates. According to Tournefort, in his Travels through the Levant, it attacks them chiefly in the back part of the throat, and proves quickly fatal. He describes it as an endemic in his day, among the islands of the Archipelago.

In more advanced life, for the same general reason, we meet with it frequently in those who have debilitated their frames by an excess of good living, and are verging on the feebleness

of age. We may hence also account for its appearing in an early stage of the plague, the most debilitating disease in the whole catalogue.* It sometimes shows itself in great numbers almost on its onset, or *m'drop* as the Arabians call it, who distinguished carbuncles by the name of jimmerat.

When unconnected with any other disease, a cure has been attempted by local stimulants, as cataplasms of tobacco and muriate of ammonia, which has been a common practice in Russia; or of horseradish (*Paré*, lib. xxi., cap. 32), or stone-crop (*sedum acre*).—(*Buchoz und Marquet neueste Heilkunde*, Nüremb., 1777.) Cantharides (*Riverius, Observ. Med.*, lent. iv.), camphire ointments, and lotions of zinc or mercury, have also been tried. More generally, however, it has been attempted to be destroyed or extirpated. Arsenic was recommended for this purpose as early as the age of Agnola, and has been employed in various forms, from that of orpiment to that of Plunket's caustic; above all which, however, Le Dran preferred corrosive sublimate. Riverius used other caustics, and Pouteau the actual cautery, which has, indeed, been very successfully and skilfully adopted of late in a variety of similar affections by M. Maunoir. But radical success must, after all, entirely depend upon supporting and giving strength to the system by cordials and tonics: for, if this cannot be accomplished, it is perfectly clear that the predisposition will be neither subdued nor subside spontaneously: that the ulcerations will not heal, and the system must gradually sink under their constant discharge and irritation.

[The practice most approved in modern times is to apply in the incipient stage fomentations and emollient poultices to the part, and to have recourse, at the same time, to antiphlogistic treatment in moderation. For the relief of the pain, opium is freely prescribed. After a short time, the antiphlogistic is exchanged for the tonic treatment, with bark, cordials, wine, and a nutritious diet. An early, free, and deep crucial incision should be made in the swelling—a method that is to be preferred to the application of caustic to the skin, on account of the latter not procuring an outlet for the matter and disorganized cellular membrane with sufficient promptitude.†]

* The carbuncle of plague differs from what is met with in this country by being contagious, attacking promiscuously any part of the surface of the body, and the young as well as other persons past the middle periods of life. The common carbuncle, as is well known, has a preference to the posterior parts of the trunk, the nape of the neck, and especially a situation between or over the scapulae.—En.

† In Hays' *Cyclopedia of Pract. Medicine*, part vi., Dr. Reynell Coates, of Philadelphia, has written an able article on anthrax. Where incisions are required, Dr. Coates advocates the crucial form, as proposed by Dupuytren, and as pursued in several cases with the happiest effect by Dr. C. Drake (*N. Y. Med. Rep.*, iv., s. vi., 462); “yet it is evident,” Dr. C. observes, “that there must be many cases in which these incisions are inad-

The carbuncle of cattle is frequently owing to the poisonous sting of various insects; and hence a similar cause has, by some practitioners, been supposed to exist in mankind. Pallas suspects the *furia infernalis*; while others have mentioned the *sirex gigas*, or large-tailed wasp. It is probable that these may have been occasional causes, where there has been a predisposition to the disease in the constitution.*

GENUS IV.

IONTHUS.

WHELK.

UNSUPPURATIVE, TUBERCULAR TUMOUR; STATIONARY; CHIEFLY COMMON TO THE FACE.

IONTHUS (*ἰονθος*) is, literally, a "violet or purple eruption, or efflorescence," from *ἰον*, viola; whose colour is frequently that of a whelky or bubukled face. It includes all those firm and indurated pimples, of whatever description, unconnected with fever, and having a subcutaneous base, with which the face is often disfigured, whether solitary, gregarious, or confluent. These may be comprehended under the two following species:—

- | | |
|--------------------|------------------|
| 1. Ionthus Varus. | Stonepock. |
| 2. ——— Corymbifer. | Carbuncled Face. |
| | Rosy-drop. |

missible or impracticable, owing to the great extent, or to the location of the disease." Dr. C. claims the application of epispastics as purely American. Its author, Dr. Physic, has not found so much benefit from it as he expected. Dr. Beck, however (N. Y. Med. and Phys. Journ. vol. ii., p. 37), thinks them useful, and Dr. Coates remarks, "that the proper period for their employment would seem to be the commencement of the second stage, and the most suitable cases those in which the extent or location of the tumour interdicts the use of the knife, and which show a strong tendency to spread indefinitely, or to become complicated with diffuse inflammation of the cellular tissue." Dr. Hosack treats anthrax by supporting the strength of his patient by a nutritious and stimulating diet, while at the same time he preserves the tone and action of the part, by frequently washing the tumour with spirits or brandy, and by the constant application of a poultice composed of bark and yeast.—(See Am. Med. and Phil. Register, vol. ii., p. 389).—D.

* The carbuncle of cattle, or the malignant pustule, as it is named by foreign writers, is not now believed to have to be occasioned in the manner specified in the text, but is propagated on the principle both of an epidemic and a contagious disease. It is one of the few disorders which can be extended from the brute creation to man—the malignant pustule, cowpox, hydrophobia, and the glands (as clearly proved by the researches of Dr. Elliotson; see Med. Chir. Trans., vols. xvi., xviii.), being perhaps the only four cases* which are of this nature. The itch has sometimes been also specified as capable of affecting both man and animals.—Ed.

* To this list may be added the *milk-sickness*, which, in the eastern and southern portions of our country, has often proved so destructive to human life.—D.

SPECIES I.

IONTHUS VARUS.

STONEPOCK.

TUMOUR RED; HARD; PIMPLY; DISTINCT; GREGARIOUS; SORE TO THE TOUCH; SOMETIMES OZZING A LITTLE FLUID AT THE TIP.

This sort of simple eruption is so common, that there is no one but has seen examples of it; and few who have not at times given examples of it in their own persons. It exhibits two varieties:—

- | | |
|----------------|--|
| α Simplex. | Broad-based, bright red, solid. |
| Simple Varus. | |
| β Punctatus. | Tipped with a black dot, and |
| Maggot-pimple. | discharging, on pressure, a grub-like concretion of mucus. |

The first, on being firmly pressed with the finger, oozes, at times, a little limpid serum, but no concrete mucus; and even for this it is necessary to make the pressure harder than for the discharge of the mucus in the maggot pimple. The mucus concretes in a follicle, or natural passage, and hence there is less inflammation and soreness than in the simple varus: yet the sides and root of the follicle are thickened and indurated: and hence the papulous elevation. Goulard's lotion, and a few other empirical cosmetics, as white paint of bismuth or cerusse, alike deleterious in their effects, and apt to produce palsy, are a common resource among the multitude for both these varieties. They have sometimes succeeded, with little other sacrifice than the exorbitant price which the purchaser has had to pay for them; but the cure has far more frequently been bought (if there have been a cure at all) at the expense of a ruined constitution, and at the exchange of a temporary local disfigurement for a life of general ill health.

Both varieties are occasionally produced by some internal affection, chiefly of the stomach; as a sudden chill from taking a draught of cold water or cold milk; or eating cold vegetables, as turnips, cucumbers, and melons, when in a state of great heat and perspiration. Catching cold in the feet has sometimes produced the same effect. These are cases of direct sympathy; the torpitude of one organ being communicated to another, which is predisposed to associate in its action.

They have occasionally yielded to powerful sudorifics, and especially when combined with narcotics, as the compound powder of ipecacuanha, in strong doses, taken for several nights in succession, the part affected being at the same time wrapped in flannel. They have also yielded to metallic and terebinthinate stimulants; as eight grains of the compound calomel pill, and a scruple of camphire, made into six or eight pills, and taken daily for ten days or a fortnight. But they generally require some local irritant at the same time; as savin cerate, the camphire or mercurial liniment, or the stronger liniment of ammonia, used so as to excite blistering. Yet, after they have resisted

these and other preparations, with great obstinacy, for years, they have at length vanished beneath a severe attack of fever, or have disappeared spontaneously. The complaint, however, is occasionally hereditary, and bids equal defiance to time, to fevers, and to medicines. Dr. Darwin, under the name of gutta rosea, has a copious collection of cases in point; some of them drawn from old maids, and others from elegant young ladies, and each duly authenticated with initials, to which the reader may turn at his leisure. Among the rest is that of "Miss L., a young lady about eighteen, who had tried a variety of advice for pimples over the greatest part of her face, in vain. She took rhubarb, five grains, and emetic tartar, a quarter of a grain, every night for many weeks, and blistered her face by degrees all over, and became quite beautiful."—(*Zoonomia*, cl. ii., i., iv., 6.)

SPECIES II.

IONTHUS CORYMBIFER.

CARBUNCLED FACE. ROSY DROP.

TUMOURS CONFLUENT; CORYMBOSE; MOTTLED WITH PURPLE: OFTEN DISFIGURING THE NOSTRILS WITH PENDULOUS LOBES.

As the preceding species is produced by a sympathy of the excrements of the skin with a torpid state of the stomach, the present is produced by a like sympathy with the liver; and hence it is proverbially regarded as a proof that those who are thus disfigured have indulged too largely in wine and other spirituous potations. So Shakspeare, in describing the physiognomy of a hard drinker, tells us, that "his face is all bubukles, and wheelks, and knobs, and flames of fire!" And in like manner, as I learn from Dr. Perceval, the common name for these protuberances in Ireland is CROG-BLOSSOMS.

The tumours in this species are usually more susceptible of irritation than in the preceding; or, in other words, the cutaneous vessels are in a state of increased debility; and hence they are exacerbated by cordials or exposure to heat.

As this is, in most cases, an habitual affection, or one of long standing, no change of diet, however desirable, should be made suddenly; for this would run a risk of producing dropsy, and, perhaps, paroxysms of atonic gout: but a gradual change to a more sober and temperate regimen is highly to be recommended; and, in the mean time, the patient should have his bowels kept regularly open with warm eccoprotics; as the extract of colocynth and myrrh pill; and be put upon a course of equitation, or such other exercises as may recruit the spirits and invigorate the system generally, in which benefit the liver will become a chief participant. The tumours may not, perhaps, totally disappear, but they will often diminish in magnitude, and assume a healthier hue, or, at least, we shall hereby prevent them from any farther enlargement, and especially from passing into that carbuncular ulceration we have just noticed.

Vol. I.—Ff

GENUS V.
PHLYSIS.
PHLYSIS.

ULCERATIVE, SUBCUTANEOUS TUMOUR; FLAT; TENSIVE; GLABROUS; DIFFUSED; HOT; THROBBING; AT LENGTH FLUCTUATING WITH AN ICHOROUS MATTER.

PHLYSIS, from the Greek φλύω, "serveo," was formerly employed in a very indeterminate meaning, to express cutaneous eruptions filled with any kind of fluid, whether purulent or ichorous: more generally, however, it had a bearing towards the sense of ichorous or vesicular pimples. Dr. Willan has, on this account, correctly limited phlyctænæ, derived from the same root, to this import, in his table of definitions; and such is the restriction of phlysis, and all its compounds, in the present system.

Of the genus now offered, there is but one well-ascertained species; the paronychia, or whitlow.

SPECIES I.

PHLYSIS PARONYCHIA.

WHITLOW.

INFLAMMATION SEATED ABOUT THE NAILS AND ENDS OF THE FINGERS; PAIN ACUTE AND PRICKING, SHOOTING UP THE HAND.

UNDER this species are included the following varieties:—

- | | |
|--------------------|--------------------------------------|
| α Cutanea. | Effusion immediately under the skin. |
| β Tendinis. | Effusion among the tendons. |
| γ Perioste. | Effusion pressing on the periosteum. |
| Malignant whitlow. | |

In the FIRST VARIETY, the ichor, or pus, is poured forth between the skin and the subjacent tendons, to which, however, it is limited.

In the SECOND, it insinuates itself between the tendons and the periosteum; and in the THIRD, between the periosteum and the bone, which is often in the state of necrosis. It is to this last, or malignant whitlow, that the term *felon* is most correctly applied.

Similar inflammations are occasionally to be found in the soles of the feet and palms of the hands. They break through the skin or cuticle with difficulty, from their thickness, and hence become diffused, and, in the latter case, separate the cuticle from the skin beneath.

In the whitlow, the acute and lancinating pain complained of arises partly from the thickness and inelasticity of the skin about the finger-nail, but more from the hardness of the finger nail itself; both which act like a tight bandage upon the inflamed part, and do not allow it to swell, or give way to the extravasation. In these cases, therefore, we can easily see why the application of poultices should be of more service than in any other; for they can here act mechanically, or, in other words, their moisture becomes imbibed by the cuticle, as by a sponge, so that it softens, grows larger in its dimensions, and less rigid in its texture; while the nail itself

loses a part of its hardness, and becomes suppler. It is in consequence of the peculiar firmness of the skin around the nail, that the soft parts below are so often seen pushing out through a very small opening in the skin as soon as this has been effected, and appearing like a fungus, but so exquisitely irritable as to give a more impressive idea of soreness than, perhaps, any other kind of ulceration whatever. All this proceeds from the surrounding belts of the cuticle not giving way to the increase of the parts underneath; whence they are squeezed out of this small opening like paint out of a bladder. It is a common practice to eat away this protruded part by escharotics, as if it were a diseased fungus; but this is to give additional pain without any benefit; for the pressure from below will not be hereby diminished. By continuing the poultice the tumefaction will subside, and consequently the pressure cease.*

In the first stage of the complaint, leeches should be applied; and if the inflammation be hereby diminished, it may sometimes be carried off by astringent lotions, or ardent spirits, which excite the surrounding absorbents to additional action.† Most of the causes of inflammation operate in the production of this peculiar affection. It is also occasioned by an incurvation of the nail (*Vicat. Delcct. Observ. Prac.*); possibly sometimes by a caries or morbid state of the subjacent bone, in the tendinous and periosteous variety, as ascertained by Siebold (*Chirurgisches. Taschebuch.*, xi.); and Mr. John Pearson has shown that it may occasionally result from a syphilitic diathesis, or any other depraved habit.—(*Principles of Surgery*, p. i.) It seems, moreover, in some cases, to be produced by the bite or burrowing of the larvæ of one or more minute, and, to the naked eye, invisible insects, hatched on the leaves of various field plants, and especially fescue-grass: and is said to be also occasioned by the bite of the gordius *aquaticus*, or hair-worm.

GENUS VI.

ERYTHEMA.

INFLAMMATORY BLUSH.

RED, GLABROUS, TUMID FULNESS OF THE INTEGUMENTS; DISAPPEARING ON PRESSURE; PAIN BURNING; INFLAMMATION ULCERATIVE; TERMINATING IN CUTICULAR SCALES, OR VESICLES; OCCASIONALLY IN GANGRENE.

This genus of inflammation is entitled to a

* In a late French periodical, the use of mercurial frictions is highly recommended for the cure of P. Paronychia. The writer states that the finger should be rubbed every thirty minutes with some mercurial ointment, and then a dressing of the same should be applied to it. In a few hours the pain is subdued, and the disease arrested.—D.

† Whitlows, not far advanced, sometimes admit of being resolved by the external use of the nitrate of silver, with which the skin is to be stained, in the manner advised by Mr. Higginbottom, of Northampton. The editor had rarely seen a whitlow brought to resolution before this practice had been suggested.—(See John Higginbottom on the

minute and discriminative attention, not only on account of its violence and tendency to an almost unlimited spread, but from its having been very generally confounded with an exanthem* or eruptive fever, which, in one or two of its species, it frequently accompanies, but of which it is then a mere symptom.

[One of the latest writers on erysipelas (or the erythema of the present author) considers it as merely a particular modification of cutaneous, or cutaneous and cellular inflammation. If (says he), we were to class these according to their natural affinities, we should place erysipelas between the exanthemata and phlegmon. It is less diffused than the former; not so circumscribed as the latter. The exanthemata are confined to the skin; erysipelas affects both skin and cellular structure; while phlegmon has its original seat in the latter; the skin being secondarily involved. Phlegmon is a more violent inflammation than erysipelas; but sloughing of the cellular membrane is more frequent in the latter than the former.]—(See *Lawrence on Erysipelas in Med. Chir. Trans.*, vol. xiv., p. 18.)

Erythema, from *ἔρυθρος*, "ruber," is a term of Hippocrates, who uses it as nearly as may be in the sense now offered; and for which many modern writers of our own country have not unaptly employed the vernacular term INFLAMMATORY BLUSH; since the redness has often very much the appearance of a blush, or glowing suffusion of the cutaneous capillaries. For ERYTHEMA, Celsus and Galen have unfortunately adopted the term *erysipelas*, whence Duretus, in his Latin version of Hippocrates, has used *suffusio erysipelatos*. And hence erysipelas has been made a very common synonyme of erythema by general writers, while the nosologists, with a few exceptions, have limited erysipelas to that species of exanthem or eruptive fever which is vernacularly known by the name of St. Anthony's Fire; and have revived erythema to express the local affection or peculiar inflammation before us, in which the pyrexia is mostly symptomatic.

Frequently, however, as these two disorders have been confounded, from an indiscriminate application of the same name to both, it will not be difficult to draw a distinctive line between

Application of Lunar Caustic to Wounds and Ulcers, 8vo., 1826.) When the disease is not immediately relieved by this plan, or other means tried to disperse the abscess, an early opening should be made for the discharge of the matter.—Ed.

* The doctrine of erysipelas being an exanthem, according to Dr. Cullen's definition of the last term, is rather inconsistent. It is correctly observed by Mr. Lawrence, that, although the leading characters of the exanthemata are thus expressed "morbis contagiosis, semel tantum in decursu vitæ aliquem afficientes," Cullen has arranged under this order erysipelas, which attacks the same individual repeatedly, and the contagious nature of which is, to say the least, very doubtful.—(See *Med. Chir. Trans.*, vol. xiv., p. 31.) As, however, Dr. Good's definition of exanthemata is "cutaneous eruptions essentially accompanied with fever," he does not fall into the same kind of contradiction as Cullen did.

them. Erythema bears the same analogy to phlegmon, as erysipelas does to smallpox. Phlegmon is local inflammation tending to suppuration; erythema, local inflammation tending to vesication: smallpox is an idiopathic fever producing a phlegmonous efflorescence. Smallpox is always contagious; erysipelas occasionally so; phlegmon and erythema have no such tendency.

The distinction then between erysipelas and erythema is clear; yet the confusion just noticed has been increased by some writers, who have not only used erysipelas in its popular, yet erroneous signification of erythema, but have also employed erythema in a new and unjustifiable sense; as occurs particularly in Dr. Willan's classification of Cutaneous Diseases; where, while erysipelas is made to embrace both erysipelas and erythema, as these terms have hitherto been commonly used, erythema is arbitrarily appropriated as the name of another collection of cutaneous erubescences of very different characters, and produced by very different causes; some of them primary, others symptomatic affections; some constitutional, and others local; occasionally smooth, papulous, tubercular, or nodose; most of which should be distributed under different divisions.

Thus introduced and explained, erythema, as a genus, will be found to comprise the seven following species, the first three of which are taken with little alteration from Mr. Hunter:—

- | | | |
|-------------|-----------------|---------------------------|
| 1. Erythema | Œdematous | Œdematous Erythema. |
| 2. ——— | Erysipelatosum. | Erysipelatous Erythema. |
| 3. ——— | Gangrenosum. | Gangrenous Erythema. |
| 4. ——— | Vesicularum. | Vesicular Erythema. |
| 5. ——— | Anatomicum. | Erythema from Dissection. |
| 6. ——— | Pernio. | Chilblain. |
| 7. ——— | Intertrigo. | Fret. |

Most of these depend upon a peculiar irritability of the constitution, or of the part in which the inflammation or erythema appears; and the common, though perhaps not the sole cause of such irritability, is debility or relaxation.

Galen, who justly distinguishes between suppurative, or, as he calls it, phlegmonous inflammation, erythematic (with him erysipelatos), and œdematous, ascribes the first, according to the old doctrine of temperaments, to a prevalence of the sanguineous diathesis; the second to that of the bilious; and the third to that of the phlegmatic or pituitous.—(*De Tumoribus, Præternat.*, tom. iii., xx.) That there is generally a peculiar habit in the last two, and often, as we have already observed, in the first, is so clear as to be indisputable; but it is by no means equally clear, that such peculiarity of habit is dependant upon the immediate cause Galen has adverted to. The temperaments of the Greek physicians, excepting when in excess, are not inconsistent with the condition of health; and hence, therefore, in connexion with the temperament, there is usually, in the last two inflam-

mations, a habit of debility or relaxation. And where this exists, the very same stimulus that, in a perfectly healthy frame, would produce a common adhesive or suppurative inflammation, under this state of the system changes the character of the inflammatory action, and urges on the ulcerative process from the first. It usually commences with great violence, and is peculiarly apt to spread; the surrounding parts being easily excited to act or sympathize in an action to which they are prone. Hence, continued sympathy is a common, though not a universal effect; for we sometimes meet with very considerable inflammations confined to the part irritated, notwithstanding that the irritated part evinces great violence of action. Mr. Hunter has illustrated this difference of effect by referring to a piece of paper under two different states, dry and damp. In dry paper, a blot of ink applied to it will not spread, and remains confined to the point of incidence; in wet paper it spreads easily, being attracted by the surrounding moisture, to which it has an affinity.

[The distinction proposed between erythema and erysipelas is well founded; the latter term being restricted by Cullen to a fever that is followed by the peculiar inflammation of the skin, commonly termed erysipelatos. By erythema, Dr. Good signifies merely the local affection of the skin, whether the consequence of fever or not. The only objection to so true a distinction is its interference with the common meaning of the word erysipelas, now more loosely employed in every medical publication, and at every medical school. Yet who will maintain that a fever, leading to a peculiar inflammation of the skin, ought to be confounded with other cases, in which either no fever may precede the local affection, or a fever of a very different kind from what precedes the efflorescence of erysipelas in Dr. Good's sense of the expression? The truth of the latter part of this remark will be illustrated in the history of erythema anatomicum. Why the author, in his definition of erythema, should have introduced the words "inflammation ulcerative," the editor can hardly understand; since erythema, or erysipelatos inflammation, frequently terminates without any ulceration, suppuration, or even vesications. The connexion which the disorder is represented by the author to have with debility as a cause, is another doctrine that does not meet with universal assent. The truth is, that the peculiar state of the constitution or part determining the kind of inflammation, is not known; but, as erythematous inflammation frequently occurs in young and robust persons, as well as the old and debilitated, nothing can be more certain, than that it is not essentially connected with weakness. Mr. Lawrence is quite at a loss to discover in this affection those marks of debility, which some have so much insisted on. Erysipelas, like any other inflammation, he observes, may occur in old and feeble persons, and the effects of the disease, when aggravated by injudicious treatment, or protracted from any cause, will soon weaken the most robust; but, however weak the patient, the local disturbance

is one of excitement; there is increased activity in the circulation of the part, clearly marked by all the symptoms. Indeed, speaking of the part, he is unable to recognise debility as the cause of any inflammation whatever, and, in reference to the seat of disease, he regards the expressions of passive and asthenic inflammation and venous congestion, as either unmeaning, or calculated to convey erroneous notions.—(See *Med. Chir. Trans.*, vol. xiv., p. 28.)]

SPECIES I.

ERYTHEMA ŒDEMATOSUM.

ŒDEMATOUS ERYTHEMA.

COLOUR SCARLET; SPREADING WIDELY AND DEEPLY THROUGH THE CELLULAR MEMBRANE, WHICH OFTEN IMPERFECTLY SUPPURATES, SLOUGHS, AND BECOMES GANGRENOUS.

This is the "œdematous inflammation" of Mr. Hunter, who observes that, when the extravasated fluid is water, it has very much the appearance of the adhesive inflammation, and probably resembles it more nearly than any other erythema, being of a scarlet colour, but much more diffused.

The skin, through the whole range of the intumescence, appears glabrous, and the redness vanishes upon a pressure of the finger, but returns as soon as the pressure is removed. The extravasated fluid is principally serum, and hence the swelling spreads further than the inflammation itself. It is very painful, or, rather, very sore: but has less of the sensation of throbbing than the adhesive inflammation. It is apparently limited to the surface, yet it probably goes much deeper; for the extravasated fluid is in too large a quantity to be furnished by the cells of the cutis alone: but as the swelling and the inflammation do not here keep pace with each other, as in the adhesive description, we have not the same guide to direct our judgment. Coincidentally with the remarks already offered, Mr. Hunter observes that "the difference between this and the adhesive inflammation arises, I conceive, from the principle of inflammation acting upon a dropsical disposition, which is always attended with weakness; whereas a greater degree of strength would have produced the adhesive inflammation under the same cause or irritation. And what makes me conceive this is, that, in many cases of anasarca legs, we have exactly this inflammation come on from distention, which adds to the extravasation of the serum, as well as in most cases of scarifications of œdematous parts to evacuate the water. When this inflammation takes place, it is much more lasting than the adhesive; and, I believe, seldom or never produces suppuration: but if it should run into this stage, it is more general, and the whole cellular membrane in the interstices of parts is apt to mortify and slough, producing very extensive abscesses, which are not circumscribed."—(*On Blood*, part ii., chap. ii., sect. vii., p. 269.)

There is no difficulty in determining why œdematous inflammation should rarely, if ever,

produce suppuration, and why it should be of longer continuance. Suppurative inflammation is, generally speaking, the process of a healthy part or habit taking place instinctively for the purpose of removing something that is dead, irritating, or otherwise mischievous, and filling up the space hereby produced with sound living matter. In œdematous inflammation, the part or habit is unhealthy and debilitated; and hence, while there is necessarily less tendency to suppuration, there is less power of recovery.

In some instances the disorder is migratory, of which Dr. Swediaur gives a singular case that had just occurred in his practice. The patient was a robust, sanguineous man of fifty-five years of age, who had for many years laboured under paroxysms of gout, which had returned after certain intervals, but who, at the time, had been free from attack for a longer term than usual. The œdema first suddenly showed itself in the eyelids, and disappeared on the second day, when he complained of pain and swelling in the fauces, with difficult deglutition. This was removed by astringent gargles, when the eyelids became again œdematous; then the neck, and in a few days, in succession, the fingers of the right hand; the fingers itched, became excoriated, and discharged an acrid humour, and the patient felt well. Some months afterward the same erythema returned, travelled in the same direction, and at last fixed on the feet, which in like manner inflamed, ulcerated, and healed, with a speedy return of general salubrity.—(*Nov. Nosol. Meth. Syst.*, vol. ii., p. 142.)

The general curative intention therefore may be expressed in a few words. It should consist in whatever has a fair promise of giving local or constitutional tone, or both. Hence the benefit of astringent epithems and lotions, whether formed of earths, acids, or metallic oxides, applied to the part affected; and of stimulants where the action is peculiarly weak, as camphire water, or a solution of the acetate of ammonia, with proof spirit proportioned to the degree of torpor. And hence, as internal medicines, bark, columbo, myrrh, iron, will often be found highly serviceable, in conjunction with a generous diet, pure air, and such exercise as may be taken without fatigue.

[When erythema œdematosum is joined with a general tendency to dropsy, the treatment should be chiefly directed against the latter disease. But, when the local affection is called œdematous merely on account of the copious effusion of serum in the part, and is not combined with a dropsical state of the constitution, some practitioners adopt antiphlogistic treatment, instead of the tonic stimulating plan. Thus, in the beginning of the case, venesection, the free use of leeches, low diet, &c., constitute the practice followed by many surgeons and physicians at Paris for the relief of œdematous erythema.*]

* Roche et Sanson, *Nouveaux Elém. de Pathologie*, Med. Chir., tom. i., p. 351. Rayer, *Traité des Maladies de la Peau*, tom. ii., pp. 221, 241; and Lawrence, in *Med. Chir. Trans.*, vol. xiv., p. 49.

SPECIES II.

ERYTHEMA ERYSIPIALATOSUM.
ERYSIPELATOUS ERYTHEMA.

COLOUR DEEPISTH RED; SUPERFICIAL; WITH A DETERMINED EDGE IN A SERPENTINE DIRECTION; THE PART WHICH HAS PASSED THROUGH THE ACTION HEALING AS THE PART NEXT ATTACKED BECOMES AFFECTED.

This is the "erysipelatos inflammation" of Mr. Hunter; and is evidently that which symptomatically accompanies the erysipelas as an exanthem, or eruptive fever. It is more commonly cutaneous, than situated in the deeper-seated parts; although, in some constitutions, almost every inflammation, wherever it takes place, will run deep as well as wide. The skin, however, appears to be most susceptible of its action; for it will spread over a prodigious surface of skin, while it rarely affects even the cellular membrane underneath; and in this respect especially, it differs from the preceding species. [This opinion, that erysipelatos inflammation rarely affects the cellular membrane, or goes more deeply than the skin, is now found to be incorrect. It is only in the slightest cases that the disorder is confined to the skin, and, in all others, an effusion soon takes place in the cellular texture, causing a soft swelling; and this may be considerable, with much tension and a shining surface, when a large part of the body, or an entire limb, is involved.—(Lawrence, vol. cit., p. 3).]—The extravasation, however, is less, than either in the oedematous or even the adhesive inflammation. It appears to support itself by continued sympathy; for it commonly begins at a point, and spreads in a migratory direction, as the part first attacked recovers. This cannot, therefore, be merely constitutional; for, if it were, the parts already inflamed could not recover, while the morbid condition of the constitution disposes the surrounding parts to the same action; but it affords an idea that, when the parts affected have once gone through the action, they lose the morbid disposition and become healthy. This property is not peculiar to the inflammation before us; the ring-worm and many other cutaneous affections have the same tendency.

Mr. Hunter observes, that this inflammation is more common in the summer than in the winter, especially in hospitals; and believes, that it takes place more frequently after wounds on the head than any where else. "I have often," says he, "seen it begin round a wound on the scalp, and extend over the whole head and face, the eyelids being very much swelled and the ears thickened; it has then advanced to the neck, shoulders, and body, creeping along both arms, and terminating at the fingers' ends: the part which attacks the body often descends to both thighs, passes down the legs, and terminates at the ends of the toes. And while this is going on, it is as expeditiously cured behind, and the skin peels off from the cured parts." Sometimes, however, it stops suddenly in its course, and assumes a milder character.

If it proceed deeper than the skin into the cellular membrane, it often suppurates, and at times occasions mortification in the cells by which the air is let loose; and it is this state of the disease that forms the *erysipelas phlegmonodes* of Galen (*Mat. Med.*, lib. xiv., cap. ii.), Van Swieten (*Comment.*, tom. ii., § 723), and many later writers, who have used erysipelas in the loose manner I have already pointed out, as synonymous with erythema. [In Mr. Lawrence's view of this subject, phlegmonous differs from simple erysipelas (*erythema erysipelatosum*) merely in the higher degree and deeper extent of the inflammation, which not only occupies the whole thickness of the skin and subjacent adipose and cellular tissue, but soon proceeds in the latter to supuration and sloughing, the skin itself being often involved secondarily in the mortification.]* The effect of this mixture of inflammation produces a strange feel, for it is neither that of fluctuation, nor of crepitation; and as there are no adhesions, the matter finds an easy passage into the common cellular membrane, increasing the same kind of supuration wherever it goes; and as mortification, and consequently putrefaction, follow speedily, the discharge becomes very offensive. As the parts loaded with effusion seldom ulcerate, they should be opened early; for the fluid either gets into the cellular membrane from the want of adhesions, or separates parts that are only attached, as the periosteum from the bone, or muscles from muscles; while the true suppurative inflammation, on the contrary, ulcerates briskly, and hence should be allowed to burst, or at least should not be opened early.

At the commencement of this inflammation, there is commonly some degree of fever, accompanied with prostration of strength and dejection of spirits, and especially with loss of appetite. But the fever soon subsides, while the inflammation pursues its course; yet since one source of irritation has thus departed, it is less violent, and sometimes assumes a chronic character.

As this, like the last, is a disease of weakness, the same general tonic plan will be calculated to oppose it; and where there is a tendency in the separated skin to crack, absorbent earths or powders should be scattered freely over the ulcerative or oozing parts, to imbibe the acrid fluid as it escapes, or the ulceration will soon become extensive; and the feeble and inflamed subjacent skin, hereby exposed to the stimulus of external agency, will grow gangrenous with great speed. Finely pounded starch is a useful powder for this purpose; as it combines a tonic and an astringent with an absorbent power; so, likewise, is a mixture of equal parts of starch and finely levigated calamine or rhubarb. The last I have sometimes thought peculiarly effectual in checking the irritation; as the second appears to be in preventing the

* *Med. Chir. Trans.*, vol. xiv., p. 9. The *phlegmon diffus* of Baron Dupuytren: the *diffuse inflammation of the cellular membrane* of Dr. Duncan.—(See *Edin. Med. Chir. Trans.*, vol. i.) This form of the disorder often commences and makes rapid advances in the subcutaneous cellular tissue.—*Ed.*

further spread of the inflamed outline that surrounds the separated cuticle.

This species of inflammation sometimes attacks infants from a very early period after birth; and, what is more singular, they have in a few instances been born with it. In such cases, it appears to be produced by some occasional cause, co-operating with an erythematic diathesis derived hereditarily. It generally assumes the mixed form of phlegmonous erythema, suppurates imperfectly as it takes its course through the cellular membrane, and is often succeeded by gangrene. Its progress is very rapid, from the relaxed state of the infantile fibre; and from the extrication of air, as soon as gangrene is produced, the tumefied surface has the mixed feel, already noticed, of fluctuation and crepitation. It commences usually about the genitals, works its way below towards the thighs and legs, and above towards the abdomen, and often excites on the peritoneum the same caseous or purulent secretion which is so apt to form on this membrane in puerperal fever. As there is no disposition to adhesion, the fluid spreads in every direction, wherever the ulceration makes a way for it; and hence it has often descended in great abundance into the tunica vaginalis and labia pudendi.

Stimulant epithems of ether, alcohol, and camphorated spirits, applied in the first stage of the disease to the parts affected, have been found the most beneficial practice: they act as counter-irritants, and take off the morbid excitement by the production of an artificial and more manageable inflammation. To these ought by all means to be added the use of the bark in any way in which it can be introduced, especially in that of injections, repeated several times a day.*

[Mr. Lawrence rejects the notion that the cause of erysipelas is debility, and adverts to various facts to prove, that it is a complaint of an inflammatory character. Hence, the antiphlogistic treatment is what he particularly recommends. "In contending, however, for the inflammatory nature of erysipelas, and for the propriety of treating it antiphlogistically," he says, "I do not mean to recommend, that measures equally active, and, in particular, that bleeding, whether general or local, are to be employed in all cases. In young persons, in

the robust, and those of full habit, in instances where the pulse is full and strong, or when there is headache and white tongue, in erysipelas of the head, attended with symptoms denoting affection of the sensorium, and more especially in the very beginning of the affection, venesection will be proper; and it may be necessary to bleed largely, and to repeat the evacuation, or to follow venesection to the local abstraction of blood. Under such circumstances, the other parts of the antiphlogistic plan must also be employed; that is, the alimentary canal should be cleared by an active purgative, which may be followed by salines and antimonials, with the occasional use of milder aperients; and low diet should be enjoined. Nothing can be more different from such a case, than that of an elderly person, with a small and feeble pulse, in the advanced stage of the disease. The interval between these extremes is filled by numerous gradations, requiring corresponding modifications of treatment. The antiphlogistic plan itself embraces a wide range in point of degree; from bloodletting, local and general, with purging, vomiting, the free use of mercury and antimony, and low diet, to the exhibition of a mild aperient, with some saline medicine. The treatment of erysipelas, like that of any other inflammation, must be modified according to the age, constitution, previous health, and habits of the patient, and the period of the complaint. In asserting, generally, that the antiphlogistic treatment is proper, I speak of the beginning of the disease, when the original and proper character of the affection is apparent; and I am decidedly of opinion, that, in some shape or degree, such treatment will always be beneficial in that stage. In many instances, active antiphlogistic measures are of the greatest service in lessening the severity both of the local and general symptoms. In others, the administration of calomel with aperients, and of diaphoretics with low diet, will be sufficient. When the affection occurs in old and debilitated subjects, the powers of life are soon seriously impaired, and our efforts must be directed rather towards supporting them, than combating the local affection. I have often seen such patients, labouring under erysipelas of the face in its advanced stage, with rapid and feeble pulse, dry and brown tongue, recovered under circumstances apparently desperate, by the free use of bark and wine."—(See *Med. Chir. Trans.*, vol. xiv., p. 41.) Nothing indeed can be more absurd, than to prescribe one plan, either antiphlogistic or stimulating and tonic, for every case, without any regard to the variation of circumstances.]

SPECIES III.

ERYTHEMA GANGRÆNOSUM. GANGRENOUS ERYTHEMA.

THE COLOUR DUSKY RED; SUPERFICIAL; CUTICLE SEPARATED FROM THE CUTIS BY A BLOODY SERUM; THE CUTIS, WHEN DENUDED, EXHIBITING DARK BROWN SPOTS, DISPOSED TO BLISTER

* This species of inflammation, which affects the genitals of children, seems analogous to that noticed by Burns in his Midwifery. Mr. Kinder Wood has also written on it.—(*Med. Chir. Trans.*, vol. vii.) "In this complaint," says Dr. Francis, "ulceration ensues within a few hours after vesication of the part; the ulcer becomes deep and foul; but mortification is rarely seen. In the treatment of it, bark and cordials internally, and stimulating applications externally, have proved serviceable." The late Dr. Richard Bayley and Dr. John Bard, of New-York, treated cases of this kind by tonics generally, and by the local application of the unguent. basil. nig. The pyroligneous acid, as a wash, may be mentioned as effectual.—(Sherrill, *Essay on Epidemics*, New-York, 1832.) We have used a solution of the chloride of soda also, with success.—D.

AND SLOUGH; OCCURRING CHIEFLY IN THE EXTREMITIES.

THE gangrenous erythema, like the two preceding species, is a frequent companion of debilitated or relaxed constitutions, but is mostly to be met with in advanced age, or weakly adolescence, or infancy; and particularly where, in old age, the constitution has been broken down by habits of intemperance and excess; the circulation is languid, and the blood even in the arteries assumes a venous appearance. The inflammatory stage is in these cases sometimes very slight, and the gangrene is ushered in with very little previous affection.

Either of the preceding species will pass readily into the present, in a warm, stagnant, and corrupt air; for the same reason that all hospital wounds run rapidly into the same state under the same circumstances.

Local applications are here of far less importance than an attention to the general condition of the constitution. Stimulants and perfect cleanliness are perhaps all that are demanded under the first head; while, under the second, pure air, and a steady course of tonic medicines and diet, adapted to the age and habits of the patient, are absolutely indispensable, and can alone furnish any hope of recovery.

How far this disease appertains to the *ignis sacer* of the Roman writers, will be seen under the ensuing species, which forms another subdivision of the same affection.

[Gangrenous erythema, or erysipelas, seems to the editor not to merit the rank of a distinct species, because it is an effect of several forms of erythema or erysipelas when they are violent, and it is not the exclusive character of any particular example of the disorder. Bad cases of phlegmonous erysipelas present us with the most severe specimens of gangrenous mischief resulting from the disease; the hope of preventing which mischief induced Messrs. Hutchison, Lawrence, and others, to have prompt recourse to numerous or extensive incisions in the part affected.]*

SPECIES IV.

ERYTHEMA VESICULARE.

VESICULAR ERYTHEMA.

COLOUR PALE RED; SURFACE ROUGHISH, AND COVERED WITH CROWDING MINUTE VESICLES,

* The experience which the editor has now had in the treatment of phlegmonous erysipelas, leads him to prefer numerous scarifications when the part is merely loaded with serum, and does not contain purulent matter or sloughs. He finds that from the small punctures or cuts, the quantity of fluid discharged will often be very considerable, and afford great relief. In a case which he is now attending, in Eagle-street, Red Lion Square, three pints of serous fluid flowed out of the small punctures in twenty-four hours. This practice is only necessary, however, when cold applications and antiphlogistic treatment fail to check the complaint. If matter form, a free and depending opening becomes immediately indicated. Cold lotions are much more effectual in arresting phlegmonous erysipelas than warm applications; a fact confirm-

FILLED WITH AN ACRID, OFTEN WITH A REDDISH FLUID; PROGRESSIVELY TRAILING INTO THE NEIGHBOURING SOUND PARTS.

THIS species admits of two varieties, which have been pointed out from the age of Celsus:—

- α Benignum. Benign vesicular erythema.
- β Corrosivum. Erosive vesicular erythema

IN THE FIRST, the redness and vesicles advance without a breach of the cuticle, as the part that has passed through the action is healing.

IN THE SECOND, the vesicles break in the part first affected, and the erosive fluid produces tracts of sanious ulceration as the redness advances.

Under the present and the preceding species is included the *ignis sacer* of the ancients; about which much has been written, but which has been seldom understood, and never hitherto received a clear methodic position. The author has taken some pains upon the subject, and trusts he will be able to establish the true boundary and character of a disease, not more frequently described by the physicians, than celebrated by the poets of antiquity.

The common error has consisted in making the *ignis sacer*, or holy fire, an exanthem or eruptive fever; an erysipelas or a pestis; or some other idiopathic fever of the same order. There is no doubt, indeed, that, like the erysipelatos erythema, it has at times been met with as an accompanying symptom in pestis; and, when we shall come to treat of this disease, a distinct notice will be taken of the variety which such an accompaniment produces, and of which the plague of Athens seems to furnish us with a tolerable example; but the *ignis sacer*, in its genuine and simple state, instead of being marked with a low eruptive fever, has often very little fever of any kind; certainly nothing more than symptomatic fever, and by Celsus is described as being best cured by an ephemeral, or any other fever which may give increased action to the system; hereby proving that this, like the entire group of erythemas, is a result of debility.

In ancient times, some diseases were supposed to be inflicted on mankind by the special interposition of the Divinity or of his ministers; and to these was assigned the name of *sacer*,

ed by Baron Dupuytren's experience, and, for many years, one that has influenced the editor's practice. The skin more frequently sloughs from phlegmonous erysipelas of the lower limbs, than from the same disorder on the head and face; a circumstance ascribed by Dupuytren to the great depth of the tibial and fibular arteries, and their considerable distance from the skin; while the temporal and occipital arteries lie directly under the integuments, to which they afford a very free supply of blood. Also, since the cellular tissue chiefly affected lies under the aponeurosis of the tendon of the occipitofrontalis muscle, a reason may be discerned why the disease should produce less injury of the vessels supplying the skin of the head. Baron Dupuytren, in the whole course of his experience, has seen but one example of sloughing of the scalp from erysipelas.—Ed.

or holy; though the peculiar crimes for which they were inflicted, or the names of the particular persons who in this manner first drew down the special vengeance of Heaven upon their atrocities, have not been communicated to us. The later term of Saint or Sanctus, as in St. Anthony's fire or St. Vitus's dance, are of parallel origin, and express corporal punishments first inflicted by the agents or supposed agents of the Deity, whose names they respectively bear. Ignis is a term expressive of the heat, redness, acrimony, and erosive power of a disease; and is hence applied to the present, in common with many other affections.

The best description of the *IGNIS SACER* that has descended to us from the Roman writers is that of Celsus. He represents it as a genus comprising two species; the first of which is precisely parallel with the species before us, and the second with the *erythema gangrænosum*, or the preceding; and, in order to prevent any doubt upon this subject, the definitions of both species are here given, as nearly as may be, in the words of Celsus himself:—"It has," says he, "two species; one (the vesicular erythema of the present system) is reddish, or a mixture of redness and paleness, rough, with approximating vesicles (*pustulæ*), none of which are larger than the rest, and which, for the most part, are very small. In these are almost always found a fluid (*pus*), and often a red colour with heat."—(*De Medicinâ*, lib. v., cap. xxviii., sect. iv.) Then follows his description of the two varieties just given; the benign and erosive, in the following words:—"sometimes it trails along, the part healing that was first diseased;" corresponding with the variety α of the present system; and "sometimes the part ulcerating, in consequence of which the vesicles (*pustulæ*) break, and the ulceration keeps spreading, and the fluid escapes;" alike corresponding with the variety β . Celsus then passes on to describe his second species, which answers to the character and almost to the words of *erythema gangrænosum*, or that we have just considered. "The other species," says he, "consists in an ulceration of the cuticle, without depth, broad, sublivid, but unequally so; and the middle heals, while the boundary lines advance; yet not unfrequently the part that seemed healed again becomes exulcerated; while the neighbouring parts, which are about to receive the disease, grow tumid and hard, and change from a blackish hue; the disease chiefly attacking the legs."

In this passage, the words fluid and vesicles are by Celsus named *pus* and *pustulæ*; but that he hereby meant vesicles, and an ichorous fluid, the $\phi\lambda\acute{o}\kappa\tau\alpha\iota\upsilon\alpha\iota$ of the Greeks, is clear; first, because Celsus thus explains the term in another section of the same chapter; and secondly, because in the *ignis sacer*, which, as we learn from Thucydides and Lucretius, was a symptom in the plague of Athens, the former has given us $\phi\lambda\acute{o}\kappa\tau\alpha\iota\upsilon\alpha\iota$, or vesicles, as the peculiar character of the eruption:—"Yet the body," says Thucydides, "was not outwardly very hot to the touch, nor pale; but reddish, livid, and

efflorescing with minute phlyctænæ (vesicles) and ulcers" (*Hist.*, ii., 50); which Lucretius has thus forcibly rendered:—

"Et simul ulceribus quasi inustus, omne rubore
Corpus, ut est, per membra SACER quom diditur
IGNIS."

"Wide-tinged with purple die, and brandish'd o'er
With trails of caustic ulcers, like the blaze
Strew'd by the HOLY FIRE."

It is perfectly clear then, I think, that the *IGNIS SACER* of the Roman writers was an erythema, chiefly vesicular, and sometimes gangrenous. It is also perfectly clear, that the present, like the preceding species of erythema, is the result of local or general debility, and requires warm and active local applications, and a tonic and bracing regimen. By later writers, however, the term is sometimes more generalized, and, like pestilence, is employed to denote other affections than the genuine *ignis sacer*, though making an approach to them.

Where the skin is slightly broken, and the acrid fluid oozes through the minute openings, the vesications should be frequently dusted, as already recommended under the second species, with chalk or starch; or where the latter is too harsh and drying, with a mixture of equal parts of starch and finely levigated calamine; carefully abstaining from all oleaginous or other applications that have a tendency to augment the relaxed state of the fibres.

I have observed that the vesicular erythema is found at times as a symptom in plague; it is also occasionally found in the one or other of its varieties, as a sequel, on the exhibition of mercury in irritable habits; and, under this form, has been occasionally denominated by authors *erythema mercuriale* and *hydrargyria*, as we shall have occasion to notice still further, when treating of syphilis.

SPECIES V.

ERYTHEMA ANATOMICUM.

ERYTHEMA FROM DISSECTION.

INFLAMMATION WITH LANCINATING PAINS ABOUT THE AXILLA, SHOOTING DOWN THE CHEST, USHERED BY SEVERE RIGOURS AND ANXIETY; SUCCEEDING RAPIDLY TO THE DISSECTION OF A FRESH CORPSE, WITH A PUNCTURE OR ABRASION ON THE HAND OF THE ANATOMIST; BLUSH A DEEP CRIMSON, WITH A SPONGY FULLNESS, CHIEFLY OVER THE PECTORAL MUSCLE: FEVER A TYPHUS.

In our opening remarks on the present order of INFLAMMATIONS, we adverted to the diffuse and ulcerative kind, which is often found to take place in the cellular membrane, though rarely limited to this texture, from a variety of apparently slight causes, under a peculiar condition of the organ locally affected, or of the idiosyncrasy, or of the habit or manner of life. These causes are very numerous, and in themselves of very different character, notwithstanding the similarity of effect which they often superinduce. Some of them are of a mechanical, others of an animal origin; some are general, others specific

irritants; but in every instance the cause, when first glanced at, is so seemingly minute, that nothing but an established experience of the fact, from a redundancy of repetitions, could induce us to predicate so serious and often fatal a result. Among the more common of these causes are venesection; the exposure of a pricked or pimpled finger to the fluids of a recently dead subject; the bite of a venomous serpent; the application of various secreted irritant or chymical acids to an abraded part of the cuticle; and a small, superficial, but jagged wound, made by a flesh-hook, or other mechanical instrument.

Now all these causes, with the exception of the bite of a venomous serpent or other animal, are perpetually taking place without any mischievous effect whatever. And hence it is obvious, that, unless there be some kind of aberration from the common law or powers of health in the part affected, or in the general frame of the individuals that occasionally suffer from the application of such causes, and thus evince an exception to the ordinary course of nature, there could be no mischievous effect at any time. Of the peculiarity of this aberration, or morbid susceptibility of impression, we know little or nothing. Intoxication seems to have been a predisponent in a few instances; but, as this has not uniformly acted, there must, even at the time, be a something independent of such an excitement, how much soever it may serve as an auxiliary.

Although the symptoms issuing from such causes brought into a state of activity evince, both in their local and constitutional march, a striking degree of resemblance, as well as of uniformity in their descent from case to case, yet they are often not without a considerable degree of anomaly and discrepance of character, with the exception of those which proceed from the apparent contagion of a recently dead body during dissection, or from the bite of the more venomous serpents. The former affection is peculiarly entitled to our attention, from the undeviating tenour of its progress, the frequency of its occurrence, and the wonted fatality of its termination; and an inquiry into its nature may possibly lead us to a somewhat better comprehension of the character of diffuse cellular inflammation from the venom of the more poisonous serpents. The writer has hence given it, for the first time, a distinct, and, as he believes, a deserved place in nosology, and trusts that the name he has assigned to it will meet with the approbation of the profession.

The effect itself has been long observed, and occasionally adverted to; sometimes, indeed, loosely described, though it has not, till of late, very minutely engaged the attention of pathologists. But the repeated cases that, within little more than the last two years, have occurred in England,* Scotland, and Ireland, and have been

separately reported by authorities of high reputation, have in the present day fixed the attention of the public upon the subject, and given it an interest that will, no doubt, lead to much clearer views than we are yet in possession of. The third volume alone of the *Dublin Hospital Reports* (p. 201), contains three cases of this kind, communicated by Dr. Colles; and the first volume of the *Transactions of the Medico-Chirurgical Society of Edinburgh* (pp. 492, 524, and 563) not less than eleven, communicated to or drawn up from personal observation, by Dr. Duncan, junior: in all of which the leading characters are the same; and particularly in the diffuse blush and spongy feel in the integuments of the side, and the typhous career of the accompanying fever: the chief discrepance being in the degree of pain or inflammatory action in the vicinity of the pricked or abraded part which formed the inlet to the disease.

But while the fact is thus generally admitted, the immediate cause has been very differently explained: some writers having ascribed the inflammation to simple irritation in a constitution or idiosyncrasy of peculiar excitement; others to the irritation of a putrescent fluid; and others again to a specific virus.

The weakest and most inadequate of all these hypotheses is the second, or that which supposes the inflammation to proceed from an absorption of some part of the fluids of the body in a state of PUTREFACTION. Yet it is the hypothesis still adopted by many pathologists of established name, and especially by M. Magendie, if we may judge from his account of the fate of Professor L  cler, who died, as he tells us, "in consequence of the absorption of putrid miasms, which took place by a slight abrasion on one of the fingers of the right hand."—(*Pr  cis El  mentaire de Physiologie*, 2 tom., 8vo., Paris, 1817.) It is an insuperable objection to this tenet, that the disease has occurred in almost every instance upon the dissection of a fresh body, and very rarely after putrefaction has taken place; frequently, indeed, when the examination has been made within twenty-four hours, and, in the case of Dr. Pett, within twelve hours after death. "All the cases," says Dr. Duncan, "which I have observed, or of which I have had accurate reports, except that of Mr. Whitlaw, and No. xvii., occurred after the examination of recent bodies, before they were interred."—(*Trans. Medico-Chir. Soc. Edin.*, vol. i., p. 565.) It is highly probable, indeed, that the process of putrefaction destroys the specific virus, and consequently takes off its effects;* and such is the expressed opinion of Dr. Colles (*Dublin Hospital Reports*, vol. iii., ut supra): and that in the few cases in which local or constitutional symptoms have followed the dissection of a putrid body, it has rather been from the action of the putrid matter, as a simple acuant on an irritable constitution,

* Case of Dr. Pett, communicated by B. Traversers, Esq. Case of Mr. Newby, by Dr. Nelson, *Medical and Phys. Journ.*, Feb., 1823. Id., Aug., 1823. Case of Mr. Rainer, by Dr. Barlow, *Edin. Medico-Chir. Trans.*, vol. i., p. 563.

* Garcilaso de la Vega, in his history of the civil wars of the Spaniards in the Indies, part 2, vol. i., chap. 42, observes, that all the Indians in the Windward Islands poison their arrows by dipping their points into dead bodies.—D.

than from any specific influence. Dr. Duncan's two cases of affection, when the body was putrescent, afford a striking confirmation of this opinion, instead of opposing it; for the first patient is described as being of a nervous, irritable temperament, and the second as being of scrofulous habit.

Under such and similar circumstances, even mechanical and chymical irritants, and diseased secretions of various kinds, though otherwise sufficiently innocuous, are often found to excite not only local but diffuse inflammation, and a sympathetic fever that has sometimes proved dangerous, and even fatal; the symptoms, indeed, being often a pretty close copy of those characterizing the disease before us. And hence many pathologists of the present day, chiefly from the difficulty of detecting a specific virus, have ascribed all the cases of anatomical erythema to the same cause of SIMPLE IRRITATION in a frame thus constituted.

But, in the first place, the disease before us has an essential difference from all the other sources of inflammation in the manner of its onset, and in the state of the affected part; while all the rest OPEN WITH LOCAL INFLAMMATION, originating at the point of injury; the inflammation spreading thence visibly towards the shoulder or axilla, and followed by fever and constitutional disturbance as the result of the local mischief; the anatomic erythema COMMENCES WITH FEVER AND CONSTITUTIONAL DISTURBANCE, while the inflammation first shows itself about the shoulder or axilla; the local point of injury remaining little if at all affected by inflammatory action. There is often, indeed, a severe and lancinating pain, which darts upwards from such point; but, except in a particular description of cases, which we shall notice presently, there is no inflammation worth noticing, even when the pain is altogether intolerable.

And, secondly, the plurality of individuals who have frequently been affected at the same time, as well as with precisely the same train of symptoms, and who have propagated the disease to their attendants, leads us, almost irresistibly, to the same conclusion of a specific source of impression as in other cases of propagable contagion. The same subject that gave rise to the complaint which terminated fatally in Dr. Dease, originated it also, though not to a fatal extent, in Mr. Egan.—(*Dublin Hospital Reports*, vol. iii.) The cases of Mr. Blyth and Mr. Young, narrated by Dr. Duncan (*Trans. Medico-Chir. Soc., Edin.*, vol. i.), were, in like manner, derived from a common dissection, as were those of Mr. Hercey, Mr. Hennen, and Dr. Dumbreck, communicated from the same authority; in each of which, also, one of the anatomists fell a sacrifice, while the others were fortunate enough to recover.

The following, forming another proof, from the pen of Dr. Duncan, is perhaps still more to the point. "Dr. Cumming, a medical practitioner in this city, was present 30th September, 1821, at the dissection of a young woman who died from puerperal fever. Took no share in

the dissection, except introducing a fresh thread into the needle which was employed in sewing the body, and was not aware of an abrasion, or having punctured himself in the act of threading. About eight hours thereafter, felt an uneasy sensation in the middle finger of the left hand, at the inner side of the flexure of the first joint; when, on examination, there was discovered an angry pimple. Passed a restless night; towards the morning, had a severe rigour, to which supervened symptoms of pyrexia." The disease became established, and, though its progress was less rapid and decisive than general, the patient expired on the eleventh day from the attack. The case, however, is here particularly selected, because it appears that a female who was employed to wash, in the evening after the above dissection, a towel that, in the course of it, had been used instead of a sponge, scratched her finger with a pin which was left in it, and received the same disorder, in a milder, indeed, though still a very alarming degree; but from which she ultimately recovered.

It is unnecessary to accumulate examples. Whatever be the difficulty of conceiving the existence of a specific virus generated shortly after death, and before putrefaction takes place, it is far more difficult to withhold our assent from such an explanation, or to account for such effects upon any other principle.

It may, perhaps, in a slight degree, assist the pathologist in his future inquiries into this obscure subject to observe, that we have ground for believing, that a new and active compound of some kind or other is constantly forming antecedently to the process of putrefaction, at the moment the living power, as well in plants as in animals, is ceasing to exist, and a play of affinities commences, which this power has hitherto restrained. In plants, this usually appears in the form of a saccharine principle, perhaps a saccharine acid; among mankind, in that of a phosphoric acid, and often, from its combination with other elements, of a phosphorescent light. This is particularly the case with those animals that have a peculiar power of emitting, and, perhaps, of secreting light while alive, as the glow-worm, the lantern-fly (*fulgora*), and the *cancer fulgens*, among insects; among shell-worms, the *phola*, *medusa phosphorea*, and various molluscs; and, among fishes, most that inhabit salt water.—(*Hulme, Experiments, &c., on the Light which is spontaneously emitted from various Bodies; Phil. Trans.*, 1800.) All these are found to pour forth a succession of light after their death, till putrefaction commences, but no longer. Yet something of the same kind seems also to take place in various other animals under certain circumstances;—perhaps in all. M. Cuvier tells us, that M. Percy, who, during twenty-five years of war, had under his care more than a million of wounded, and had often been obliged to dress wounds in the dark, had frequently observed a phosphorescent light to issue from them, especially when extensive and dangerous, and where the living power was at a very low ebb. And he found, also, that the best way of

rendering this emanation visible, is that of applying an aqueous fluid, as in the case of reviving the phosphorescent light of the recently dead animals we have just noticed. "In one instance," says he, "a vivid light, a true ignis-fatuus, existed for more than six days over the wound of an officer who had been dressed with compresses, wetted with pure water only."—(*Analyse des Travaux de l'Académie des Sciences de Paris pour 1819.*)

I pretend by no means to say, that the new and active, but virulent and contagious material, formed, and perhaps always in the human, and apparently in other animal bodies, on the cessation of the living principle, and when the laws of chymistry, hitherto held in subjection by the operation of this principle, now begin to assert their sway, is of either of the kinds I have thus adverted to; I have only endeavoured to draw the attention of the physiologist to the subject, by showing that some peculiar and extraordinary compounds, of a very diffusive and active kind, are assuredly formed on the immediate termination of life, and to urge him to a search after compounds that have not hitherto been explored.

Be the contagious material, however, what it may, it appears to pervade equally all the fluids of the decomposing body, whether natural or morbid; for the disease has followed where the punctured hand has been merely immersed in genuine pus (*Case, Lond., &c., Phys. Journ., Aug., 1823, p. 123*) that has flowed from an abscess of the stomach, or some other viscus, as well as where it has merely come in contact with the lubricating lymph of serous or mucous membranes; and, as already observed, where it has only touched a towel or a sponge, employed in wiping up the fluids or other materials that have required removal in the course of an examination, or even a thread wetted with the same and pressed through the eye of a needle.

Nor does the character of the contagious material appear to depend in any degree upon the nature of the disease of which the subject submitted to dissection has died. It has followed cases of dropsy, of pulmonary affection, of enteritis, of puerperal fever, of aneurism, and of Cæsarian section.—(*Duncan's Cases in Trans. Medico-Chir. Soc., Edin., ut supra; as also p. 566.*) So that the nature of the preceding disease has as little connexion with the virus as the process of putrefaction.

The ordinary progress of the complaint cannot be better described than by copying the sufferings of Professor Dease. His demonstration took place on a recent subject, on February 13, 1819, at one o'clock. He awoke early the ensuing morning with severe rigours, sickness, and acute pain in the left shoulder. On the next day, a slight fulness was observed above the clavicle along the left side of the neck, which could not bear the slightest pressure. On the day succeeding, a colourless swelling was noticed about the axilla, which first suggested the real nature of the complaint: and, on examining the hand, there was found

by Dr. Colles the mark of a slight scratch with a superincumbent vesicle. He appeared to improve a little for a day or two, though full, florid, and crimsoning erythema occupied the side in the region of the pectoral muscle, extending downwards. On the morning of the nineteenth he showed delirium, and a vesicle appeared on his forearm, which remained stationary to the last. By the next day the erythematous swelling had extended over the entire side of the body from a little below the axilla to the hip; and the swollen part became studded pretty thickly with indurated papulæ; the delirium being more confirmed. On the twenty-first, the inflammation completely involved the axilla, and, on its posterior edge, an abscess seemed to have formed, though there was no fluctuation. At this period, the opposite, or right arm, exhibited an intumescence on its anterior part, occupying about a hand's-breadth of the flexor muscles, which was punctured on the same evening, and discharged about a teaspoonful of serous fluid, but without relief; and, within an hour or two afterward, being the eighth day from the accession of the disease, he expired.

The pathognomonic blush that spreads over the region of the pectoral muscle has a peculiar feel, that is not easy to be described; it yields to pressure like a quagmire, or piece of sponge; and is hence called boggy by Mr. Lizars (*Trans. Medico-Chir. Soc., Edin., vol. i., p. 496*), and doughy by Dr. Colles.—(*Dublin Hosp. Reports, vol. iii., ut supra.*) In the case of Dr. Pett, it was found by Mr. Travers (*Lond. Med. and Phys. Journ., Feb., 1823, p. 176*) to crepitate, a secretion or extrication of air having apparently taken place. There is often a considerable degree of uneasiness in the punctured or abraded spot, which has proved an inlet to the virus, sometimes, indeed, amounting to an agonizing and intolerable pain, though without any visible show of inflammation, or too slight to be regarded. The accession of the fever is usually accompanied with great anxiety and dejection of spirits, and often an unwonted irritability of temper. The nervous and depressing character of the fever is, indeed, obvious from the first, and the patient rarely rallies into any degree of hope or composure, where it proceeds to a fatal termination.*

In very many cases, however, its issue is of a happier kind; and where this occurs, sometimes, about the eighth day, a gentle diaphoresis or diapnoë lubricates the harsh and burning skin, a sound and refreshing sleep succeeds, the pain and inflammation diminish, and the patient advances to recovery in a straight path. But, more generally, an effort is made to form lodgments of imperfect pus, bloody serum, or gangrenous ichor, often of all these combined, in particular parts of the affected side, most commonly indeed in the axilla; which swells into an enormous

* The late Prof. Godman has reported an interesting case of this affection, in the person of the late Mr. Adrian A. Kissam, which terminated fatally.—*Amer. Journ. of the Med. Sciences, vol. i., p. 315.*—D.

mous bag, and, if not opened by art, bursts spontaneously, and discharges the complicated and pent-up fluid to an amount of several pints; the whole of the cellular membrane on the affected side being broken down into the general mass, with numerous sloughs and skeins of fibres detached from the adjoining muscles and thrown out in loose bundles. The cure is long and doubtful in proportion to the range of the ulceration, and the extent of the gangrene: and the patient is often so much reduced as to be in danger of falling a sacrifice from hectic fever or some other secondary affection. But when he has reached this stage, he generally succeeds in the end, though the skin over the injured part is considerably shrivelled, from the loss of the cellular texture beneath, and often attached to the subjacent muscles.

Such is the progress of the disease when the contagion meets with a habit or constitution favourable to its mischievous action, and which yields at once to its influence. But, as in other contagions, so in the present, we perceive a striking diversity in this respect. The habit or idiosyncrasy of most anatomists, fortunately renders them altogether unsusceptive of its impression, and they escape from its arrest. And hence, in all probability, the reason why but few comparatively are ever affected with this fearful complaint, though handling dead bodies for years, and with hands chapped or punctured in various points.

There are others who seem to possess constitutionally a modified protection, though they cannot escape altogether; in whom the virus finds a less easy course of absorption, and, by being delayed in its progress towards the axilla, opens its assault at the point of contagion, becomes concentrated, and spreads its chief brunt in that quarter. In this case, the disease commences with local, instead of with constitutional symptoms, and the latter are even at last rather a sympathetic sequel, as in numerous cases of simple irritants, than a diacritical part of the disorder. The punctured hand or finger is not only vehemently painful, but swells and becomes considerably inflamed; the inflammation characterized by heat, redness, pain, and enlargement, gradually shoots up the forearm; and, if not checked in its progress, ascends to the shoulder, and fixes itself in the axilla, or spreads still further into the side of the chest. But the virulence is usually diluted as it widens; and though the constitution suffers much from symptomatic fever, the inflammatory action is often confined to the arm alone, where it seems to aim at forming a chain of abscesses from the hand to the elbow, and sometimes to the shoulder or axilla.

This distinction is so clearly marked and closely adhered to, that I have scarcely ever heard or read of a case that proved fatal, where the disease has opened with local inflammation, nor often where it has been accompanied with any great degree of danger: while, on the contrary, nothing can be more dangerous than the same disease, where the constitutional symptoms take the lead. And I gladly avail myself

of a confirmation of this remark by my distinguished friend, Mr. Travers, published since the preceding edition of the present work, in which it occurs in the same words:—"Inflammation is not necessary to the most virulent and fatal action of the poison; and, in general, I should be disposed to say of these cases, that the symptoms of local inflammation and constitutional irritation exist in an inverse ratio of severity."—(*Inquiry concerning Constitutional Irritation, &c.*, p. 203, 8vo., 1828.) In a few instances, a most offensive smell has been found to accompany the diaphoresis which occasionally breaks forth over the body. In the case of Mr. Whitlaw, Dr. Duncan describes it as "a profuse, dark-coloured, clammy sweat, of a smell so exceedingly fetid and disagreeable, that it could neither be borne by the patient himself nor by his attendants. It was in such abundance as not only to wet his body-clothes, but also the bedclothes, and stained them of a dark colour, so that they could with difficulty be washed white again. When the patient awoke out of this state of slumber, in which he had continued during the perspiration, he felt great relief of all the symptoms."—(*Trans. Medico-Chir. Soc., Edin.*, ut *suprà*, p. 505.) The diaphoresis was in fact critical; and, so far as I have seen, it never occurs but in those that recover; and usually, if not always, is an accompaniment of the disease where the local symptoms take the lead, and in a considerable degree concentrate the virus. It must not, therefore, be confounded with that cadaverous smell, which is sometimes emitted from the body a short time before death, and is a melancholy harbinger of that event.

The inflammation that most nearly resembles the erythema before us, is that produced by the bite of the more venomous serpents, and especially of the rattlesnake; and as, in all these cases, a specific virus is universally admitted, analogy, in addition to the reasons already urged, leads us to a like cause in the present instance. The chief difference is in the greater degree of virulence or malignity that characterizes the serpent's fang, and the greater rapidity of its mischief. A bite from the fang of the cobra de capello, or hooded snake, the *coluber naja* of Linnæus, generally destroys life in twenty-four hours, and from the fang of the rattlesnake (*crotalus horridus*, Lin.) in a shorter time, if no curative means be had recourse to.*

* This statement requires to be modified. The bites of venomous snakes are very unequal in their consequences, according to the season of the year and the climate; the empty or full state of the poison receptacles at the period when the reptiles bite; the constitution of the bitten person; the penetration of the fang into a vein; and other influential considerations. We have the authority of Professor Gibson, of the United States, in support of this statement. Instances occur, both among the Indians and the white people who inhabit the mountainous and thinly-settled parts of the American States, of almost instantaneous death from the bite of the rattlesnake. On the other hand, he says, it is certain that many persons wounded by this animal have sustained very

In both, the local and constitutional symptoms take place nearly simultaneously, and persevere in their double attack. The bitten limb swells instantaneously from the part affected, and the inflammation shoots with great speed up its entire length to the body; and, if it be the arm, associates the axilla in its malignant career; and, if life continue long enough, darts down the side over the pectoral muscle, and produces there the same kind of erythema as in the disease before us. The vital principle, however, is, from the first, exhausted suddenly, as though by a stroke of lightning; the blood ceases to flow in the smaller vessels of the swollen part; the superincumbent skin feels deadly cold; the action of the heart is so weak that the pulse is scarcely perceptible; the stomach so irritable that nothing can be retained on it; dejection and horror overpower the mind, and a low muttering delirium forms the closing scene.

Very powerful stimulants applied instantly may postpone the catastrophe, and sometimes, even in the bite of the rattlesnake, produce a cure; but if the tide of life be kept moving till the venom has exhausted its malignity, the debility is usually so extreme, that the unhappy sufferer too often falls a victim to the local mischief, when he has even triumphed over the constitutional assault.

A striking example of this occurred a few years ago in St. George's Hospital, in a patient whose progress the present writer watched with deep interest. He took notes on the occasion: but the account has been since given so much more minutely by Sir Everard Home, that he will chiefly copy from his statement.—(*Phil. Trans.*, 1810, p. 75.) The patient, by name Thomas Soper, twenty-six years of age, attempted, Oct. 17, 1809, to raise a rattlesnake, confined in a cage in a public show-room in Piccadilly, by irritating him with a footrule, but the snake continued quiet. The footrule was dropped into the cage, and the man had the rashness to introduce his hand to take it away. The serpent instantly seized upon it, and bit it in two places. The bites took place at half past two o'clock P. M.; and the wounded man instantly applied to a neighbouring chymist, who gave him a dose of jalap, as he considered him in a state of intoxication, from the incoherence of his language, which was probably the effect of great terror. The hand almost immediately began to swell, and he applied for aid at St. George's Hospital by three o'clock, or within an hour after the attack. The swelling had by this time extended half way up his forearm: the skin on the back of the hand was very tense, and the bitten part acutely painful. At four o'clock, the swelling had gained upon the elbow; and at half past four, the pain had extended to the axilla, and the swelling within a short distance of it: the skin was cold, the pulse beat a hundred strokes in a minute; the man complained of sickness, but his answers were in-

trivial injury.—(See Gibson's Institutes of Surgery.) The poisons of serpents are well known to be most powerful in hot weather, and the procreating season.—Ed.

coherent. Ammonia, camphire, and ether were freely administered internally; and the two former were also applied externally.

The symptoms continued to augment, with the exception that the patient was collected at times, and expressed a hope of recovery; but, for the most part, his mind was greatly dejected, and it was often difficult to keep him from fainting. The arm was quite cold; but the swelling extended to the shoulder, and down the side of the body, producing a fulness with evident extravasation of blood, as low as the loins, and giving a mottled appearance to the back on the right side. The surface of the swollen part was very extensively vesicated in the course of the present day (the 18th); there was a tremulous motion of the lips; the fainting fits were perpetually recurring; his limbs twitched; his stomach rejected what was introduced into it and the skin of the whole arm had a livid appearance similar to what is met with in a dead body. Brandy and opium were now given him instead of ammonia, but in the ensuing morning his pulse was scarcely perceptible; his extremities were cold, and he spoke in whispers. He was in this manner kept alive by nutritive and stimulant means; the constitutional symptoms appeared in five or six days to be diminishing, and the venom to have spent its force; inasmuch that the present writer made a minute on October 25th, that "he seems, upon the whole, to be recovering." He had not, however, strength enough left to cope with the extensive mortification which had taken place in the arm and axilla, and died November 4th, at half past four in the afternoon.*

In serpents whose venom is less virulent, a ligature tied a little above the bite, and continued for only an hour, will often prevent the action of absorption, and render the disease chiefly local; in consequence of which, as in the local modification of anatomic erythema, the patient escapes with a far less degree of danger. But the most active and malignant of all the serpentine poisons is that of the rattlesnake.

* It is difficult to add much to the important details furnished us concerning the influence of this poison by Sir Everard Home, as given in his history of the case of Thomas Soper.

Mr. Home mentions the intellectual powers of the patient to have been materially affected. Dr. Francis remarks (*Facts on Med. Jurisprudence*, N. Y. Med. and Phys. Journal, vol. ii.), "in company with the late James Inderwick, of the United States navy, I visited, in the year 1812, a young man, Mr. A—, of New-York, who was seriously bitten in the arm by a rattlesnake, that had been kept in confinement for a public show. The action of the poison, as in the case of Soper, began to manifest its effects within the first half hour, and its local changes, such as great swelling, pain, &c., were also similar to those stated by Sir Everard Home. But in the case of Mr. A—, the mind preserved its wonted functions throughout his whole illness. I have reason to believe, that the action of this poison is primarily through the medium of the sanguineous circulation. When the bite is inflicted in a large vein, its effects are more immediate, and its fatality more certain, than under other circumstances."—D.

All other serpents have an immunity against each other's bite; but the rattlesnake not only kills every other, and even its own kind, but, by being so far irritated as to inflict a personal wound, has been found to kill itself.

A highly stimulant diet, though most essential in the bite of the more poisonous serpents, does not seem to be of equal use in the erythema before us; nor, in the slighter cases, has any benefit been found from the use of a ligature. The excitant plan has been tried by some, and the antiphlogistic by others; but both have often failed, and a remedial mode of practice is still a desideratum.*

Considering the great benefit that results from fixing the inflammation in the hand and forearm, it appears reasonable that our first attempt should be to concentrate or recall it towards the punctured or abraded part; not by destroying the life of such part, as has too often been done by caustics, but by powerful and pungent irritants, as camphire, turpentine, or ammonia. Or, if within half an hour or an hour from the date of the injury, by the application of cupping-glasses; the great benefit of which practice, in preventing the absorption of poison from venomous animals, has been satisfactorily ascertained by Sir David Barry's experiments, as we have already had occasion to remark.—(*See his Experimental Researches on the Influence exercised by Atmospheric Pressure, &c.*, 8vo., 1826.) Our next object should be to counteract the inflammation that takes place in the axilla and in the region of the pectoral muscle, by a free use of leeches or cupping-glasses; while the constitutional symptoms should be opposed by opiates and sudorifics. We have already seen the high and critical advantage which has arisen from a general diaphoresis; and the present author has observed more benefit from a free use of Dover's powder acting in this manner and allaying the nervous and constitutional irritation, than from any other medicine whatever. In the meanwhile, the diet should be moderately stimulant, and the bowels must be kept duly open.

* The Guaco plant (*Bejuco de Guaco*) has long been considered by the natives of South America a specific for the bites of poisonous reptiles, and more particularly of the rattlesnake. A document published at Caracas, in 1832, and signed, "*Un Amigo de la Humanidad*," asserts, that it cures the bites of the most venomous serpents, and even of the viper; and Alibert, in his *New Elements of Materia Medica*, has stated the mode in which the negroes inoculate themselves with it. The attention of scientific men, however, has but recently been drawn to this medicinal plant, and the experiments as yet made with it, are not sufficiently numerous or accurate to enable one to form a correct opinion of its real value.

In the Jamaica (*W. I.*) *Phys. Jour.*, vol. i., p. 234, Mr. Higson, a gentleman well known for his botanical researches, and also for his travels in South America, has published a paper on this subject. He begins by remarking, that "the Guaco plant deserves the greatest attention, and its virtues should be made generally known." He then gives the details of two cases which came under his notice, in which the patients had been bitten by an ekkis, one of the most deadly of its species.

SPECIES VI. ERYTHEMA PERNIO. CHILBLAIN.

INFLAMMATION OF A CRIMSON COLOUR, SUFFUSED WITH BLUE; OBSTINATELY ITCHING; CHIEFLY AFFECTING THE EXTREMITIES DURING WINTER.

This species offers us the two following varieties:—

- | | |
|----------------------|---------------------------|
| α Simplex. | The cuticle remaining un- |
| Simple chilblain. | broken. |
| β Exulceratus. | Accompanied with ul- |
| Kibe. | ceration. |

The extremities principally affected by the chilblain are the hands and feet; but, in very cold climates, the nose, ears, and lips are affected also, and the living power is destroyed as completely as by combustion. So correctly has our great epic poet described the power of severe frost:—

"The parching air

Burns froze, and cold performs th' effect of fire."

That the pernio or chilblain belongs to the genus erythema is perfectly obvious, not only from its symptoms, but from the character of the age and constitution in which it is chiefly to be met with, and from the stimulant mode of treatment by which alone it is to be cured.

The proximate cause of chilblains is a diminution of the excitability or vital energy of the extreme vessels; and, as such diminution is most readily produced in children, or older persons of relaxed fibres, these are most subject to the disease. For, though we often meet with it also in strong and hardy boys, it will usually be found that the last, from the natural vigour and courage of their frames, have braved the cold and rigid reign of the winter season beyond the venture of their schoolfellows.

Local stimulants, then, are the only applications that will answer, and particularly those which serve at the same time to defend the weakened organ from the severity of the external air. Hence, oil-skin socks worn day and night are useful, and warm diachylon or Burgundy pitch spread upon leather still more so. For the same reason, embrocations of spirits of turpentine, opodeldoc, liquor ammoniæ acetatis, or equal parts of vinegar and spirits of wine, will usually be found serviceable. Linnæus recom-

These were treated by administering the expressed juice of the Guaco internally, and applying the bruised leaves of the same to the wound; and although they exhibited severe symptoms, as swelling and delirium, they recovered. He farther remarks, "I have been thus particular, hoping to dispel some of that skepticism that is so apt to accompany details savouring of the marvellous; but, on the continent south of us, thousands can vouch for the virtues of a plant, placed by Providence where it is most necessary."

Mr. Higson was unable to detect the flowers and fruit of this plant, but thinks he recognises its character in Humboldt and Bonpland's *Synopsis Plantarum Equinoctialium*, under the generic name Mikania, and species Guaco.—D.

mends bathing the part with diluted muriatic acid; and this has the advantage of being astringent as well as stimulant.* The weakened vessels should never be too much distended, and hence, though gentle warmth and stimulants are indispensable, great heat, and especially a near approach to a fire, and more particularly still when very cold, will always be found injurious. When the inflammation becomes ulcerated, or forms a kibe, warm and irritant dressings will alone succeed in effecting a cure; and, if fungous granulations should appear, which they are very apt to do in all sores accompanied with debility, they must be removed by a dressing of the unguentum hydrargyri nitrati, or some other mild escharotic.†

SPECIES VII.

ERYTHEMA INTERTRIGO.

FRET. EROSION OF THE SKIN.

COLOUR OF THE INFLAMED PART BRIGHT RED; CUTICLE ERODED; THE EXPOSED SKIN OZZING A LIMPID AND ACROMIONIOUS FLUID.

The fret, or erosion, which frequently takes place in different parts of the skin from an acrid secretion of the exhalants or sebaceous glands, and particularly behind the ears, about the groins, and around the anus, is usually accompanied with erythematic redness, or inflammatory blush; and hence is generally and correctly referred to the present place. It is an erythema with weak vascular action, and often considerable irritability in consequence of such weakness.

The most common example of this species is that which takes place behind the ears of children of a delicate habit, or who labour under irritation from teething, or from gross indulgence in luxuries. The discharge is often peculiarly offensive, and hence cannot proceed merely from defective absorption, for it would then be nothing more than saline without fetor. It cannot be checked too soon; for if it continue for a few weeks, or perhaps even less, it may acquire a habit, the suppression of which may run the risk of superinducing some worse disease than itself, as dyspepsy, diarrhoea, or convulsions. The organ affected should be kept well washed, to prevent the spread of the morbid secretion, and the discharge should be imbibed by dry and scorched rags applied to the part, or starch frequently dusted over it.—(J. P. Frank, *De Cur. Hom. Morb. Epit.*, tom. iv., p. 113, Mannh., 8vo., 1792.) But the irritability is here best subdued by the tonic and astringent

* One part of the tincture of cantharides, and six of soap liniment, equal parts of the liq. plumbi acet. and laudanum, and a mixture of tincture of myrrh and liq. plumbi acet., form common and useful applications to chilblains which have not broken, or assumed the ulcerated state.—Ed.

† The eminent operator Lisfranc treats erythema pernio by placing thereon perforated compresses spread with cerate, and covering these with a thick layer of lint, which must be constantly wet with a solution of the chloride of soda or lime.—See *Monographie des Dermatoses*, par Alibert, tome première, p. 41, Paris, 1832.—D.

powder of many of the metallic oxydes, particularly that of cerusse, which is one of the most valuable, as well as one of those in most common use.

GENUS VII.

EMPRESMA.

VISCERAL INFLAMMATION.

DERANGED FUNCTION OF A VISCERAL ORGAN, MEMBRANOUS OR PARENCHYMATOUS; WITH LOCAL PAIN; FEVER MOSTLY A CAUMA; INFLAMMATION MOSTLY ADHESIVE.

The genus of diseases upon which we now enter, consists of that numerous collection of visceral inflammations which, from the time of Boerhaave, have been generally distinguished by anatomical terms derived from the organ affected, with the Greek term *itis* added as a suffix, as cephalitis, gastritis, carditis, and many others. *Itis* is sufficiently significant of its purpose: it is immediately derived from *ἔπει*, which is itself a ramification from *ἐω*, and imports, not merely action, “putting or going forth,” which is the strict and simple meaning of *ἐω*, but action in its fullest urgency, “violent or impetuous action.” As a suffix, therefore, we shall retain it in its common use, and proscribe it, to prevent confusion, from the few compounds, or proscribe the compounds themselves, in which this common use is departed from; as rachitis, hydro-rachitis, ascites, and tympanitis, none of which convey any idea of violent or impetuous action, and some of which are peculiarly marked by a contrary state.

This application of a common term in composition to so large a body of visceral inflammations, and the general use of the term for so long a period as that throughout which it has been employed, is a sufficient proof, that practitioners have discovered between these inflammations other features of resemblance than the general symptoms of inflammatory disorder. In the prosecution of the subject, we shall find that this is the fact; and I have already observed, in the opening remarks upon the present order, that, with a very few exceptions, the inflammation in all the diseases is of the adhesive kind, and the fever a cauma. With a view, therefore, of simplifying, as far as simplicity may be of real use, the present system will, for the first time, comprise the whole of these under one genus, here distinguished by the name of EMPRESMA, or “internal inflammations;” a term, in its simple form, employed both by Hippocrates and Galen, and which it seems necessary to revive for the present purpose.

Many of the organs included under the genus before us, and which we shall presently follow up in their respective order, sympathize with each other, and most of them with the stomach. The necessary consequence of which is, that the constitution is disturbed generally, though in very different degrees, according to the organ affected; or, in Mr. Hunter's opinion, according to the different degree of its connexion with the stomach.

If the heart, the lungs, or the brain be in-

flamed, whether primarily or secondarily, as by sympathy, the stomach is peculiarly influenced, probably from the essential importance of these organs to life itself (as all the vital organs, or those essential to life, maintain a very close degree of affinity); and the disease originating in any of these has, in consequence, a more violent effect upon the constitution than the same quantity of inflammation would have if it were not in a vital part, or in one with which the vital parts do not sympathize. The pulse, in such cases, is much quicker and smaller than when inflammation takes place in a common part, as a muscle, cellular membrane, or the skin. The progress, moreover, when the attack is so violent as to prove fatal, is, generally speaking, far more rapid than in other parts; so that, at its very beginning, it has the same effect upon the constitution, as a farther advance of an inflammation in other organs that is equally sure of proving fatal in its result. The debility commences early, because the inflammation itself is immediately interfering with actions essential to life; and, as already observed, the sympathy between these organs is peculiarly close, inasmuch as so almost to make any single action common to the whole.—(*Hunter, on Blood, &c.*, p. 325.)

In inflammation of the brain, the pulse varies, perhaps, more than in inflammation in any other part; and we must rather depend upon other symptoms than upon the state of the pulse. It is sometimes quick, sometimes slow, sometimes depressed, sometimes full, according as the disease is characterized by the acute pain, delirium, stupor, or other concomitants.

When inflammation is seated in the heart, its action becomes extremely agitated and irregular. When in the lungs, the heart, possibly from sympathy, does not seem to allow of a free diastole.

If the stomach be inflamed, the patient feels an oppression and dejection through all the stages of the disease. The vital energy, or simple animal life, seems to be impaired and lessened in the same manner as sensation is lessened when the brain is injured. The pulse is generally low and quick; the pain obtuse, but urgent and overwhelming; so that the patient can hardly bear up under it.

If the intestines be affected, the symptoms are nearly of the same kind, especially if the inflammation be in the upper part of the canal; but, if it be seated in the colon, the patient is more roused, and the pulse is fuller than when the stomach itself is inflamed.

If the uterus be the organ attacked, the pulse is extremely quick and low: if one of the testicles, the pain is depressing, and the pulse quick without much strength. With the uterus, the testicles, and the intestines, the stomach peculiarly sympathizes; often, indeed, as much as if itself were primarily affected. If we contrast these species of inflammations with those that attack parts not very essential to life, but with such a degree of violence as to produce universal sympathy and affect the vital functions, we shall find that, in the latter, the pulse is fuller and stronger than common; and the blood is pushed further into the extreme ar-

teries. The attack usually commences with rigour; the patient then becomes somewhat roused, because the action of the part is roused, and the effects on the constitution are not yet such as to impede the operations of the vital organs. Much, however, will still depend upon the nature of the parts, whether active, as muscles, or inactive, as tendons; as also upon the situation of the same description of part, and especially upon the character of the constitution; for, if the last be extremely irritable and weak, as in many women who lead sedentary lives, the pulse may be as quick, hard, and small, even at the commencement of the inflammation, as in inflammation of the vital parts. The blood, moreover, may be sily, but will be loose and flat on the surface. It is singular to observe how very rarely the pancreas is subject to inflammation, or even to disorders of any kind. "The pancreas," observes Dr. Baillie (*Lect. and Obs. on Medicine*, 1825), "is upon the whole less liable to disease than any other important gland in the body. I do not recollect that, in private practice, I have met with one case in which there was satisfactory evidence of the pancreas being diseased; and I have only known of a solitary example of it during the thirteen years in which I was physician of St. George's Hospital." [Now, however, that morbid anatomy is more extensively and zealously cultivated than it was thirty years ago, examples of diseased pancreas are more frequently met with. On the whole, however, the pancreas, like the salivary glands, to which it is analogous, is, comparatively speaking, seldom diseased. This subject is noticed in a preceding part of this volume.]

Having premised these general remarks, we are the better prepared for examining the relations which the numerous species belonging to the present genus bear to each other, and satisfy ourselves with a more summary account of several of them than would otherwise be necessary.

These species are as follow:—

1. Empresma Cephalitis. Inflammation of the Brain.
2. ——— Otitis. ——— of the Ear.
3. ——— Parotitis. Mumps.
4. ——— Paristhin-itis. Quinsy.
5. ——— Laryngitis. Inflammation of the Larynx.
6. ——— Bronchlem-itis. Croup.
7. ——— Pneumoni-tis. Peripneumony.
8. ——— Pleuritis. Pleurisy.
9. ——— Carditis. Inflammation of the Heart.
10. ——— Peritonitis. ——— of the Peritoneum.
11. ——— Gastritis. ——— of the Stomach.
12. ——— Enteritis. ——— of the Bowels.
13. ——— Hepatitis. ——— of the Liver.

SPECIES I.

EMPRESMA CEPHALITIS.

INFLAMMATION OF THE BRAIN.

PAIN IN THE HEAD; AVERSION TO LIGHT; FACE MORE OR LESS FLUSHED; CAUMA.

THE pathology of cephalitis, or inflammation of the brain, is, in some degree, obscure and difficult, from the difference which occurs in several of its secondary or concomitant symptoms; occasioned partly, perhaps, by the difference of its exciting cause, partly by the particular portion of the organ that is primarily or chiefly affected, and partly by circumstances which seem to baffle all research. From this occasional difference of symptoms some nosologists have endeavoured to establish as many distinct affections, and have hence multiplied a single specific disease into a considerable number of distinct species, and even genera, and treated of it under a fearful host of distinct names: and hence the disease before us has been described, not only under the term cephalitis, but under those of phrenitis, paraphrenitis, phrenismus, sideratio, siriasis, sphacelismus, typhomania, calentura, and a great many others, which have burdened the medical vocabulary, and perplexed the medical student.

The disease may commence in the meninges, or membranes of the brain, or in the substance or parenchyma of this organ. [In its activity, it varies from the highest degree of acute to the lowest degree of chronic or scrofulous inflammation, and with numerous modifications, by which the different forms pass into one another by almost insensible gradations. It may terminate by serous effusion; by the deposition of false membrane; or by a peculiar softening of the cerebral substance.—(See *Abercrombie's Path. and Pract. Researches on Dis. of the Brain*, p. 5, 8vo., Edin., 1828.)] If it were to confine itself strictly to the part first affected, instead of spreading from one part to another, there would perhaps be no great difficulty in determining from the symptoms before us its direct and actual seat; for while membranous and muscular inflammation, before the access of gangrene, is accompanied with an acute and rousing pain, great heat, and a pulse considerably and permanently quickened, parenchymatous inflammation is rather distinguished by a heavy and often a stupifying pain, a slight increase of heat, and a pulse irregularly quickened, sometimes sinking even below its natural standard.—(*Hunter, on Blood, &c.*, p. 288, 289.)

Now both these conditions are occasionally

VOL. I.—G g

found in different cases of cephalitis; and we may hence infer, that in the one instance, the disease is seated chiefly, if not altogether, in the meninges, and, in the other, in some part of the substance of the brain itself, thus presenting to us the two following varieties:—

- | | |
|---------------------------|--|
| α Meningica. | Pain in the head acute; Phrensy. |
| Brain fever. | intolerance of light and sound; cheeks permanently flushed; eyes red; watchfulness; delirium; pulse rapid.* |
| β Profunda. | Pain in the head obtuse; Deep-seated inflammation of the brain. |
| Acute dropsy of the head. | cheeks irregularly flushed; pulse irregularly frequent; eyes oblique; sleep heavy, but unquiet; and occasionally interrupted by screams. Chiefly common to children. |

The above clear and distinctive marks, however, by which the two varieties are separated from each other in exact cases, are not often to be met with; as each, for reasons already given, is apt to assume something of the character of the other.† And hence they have hitherto

* Cruveilhier infers from some cases which he has published, that what he terms “la meningite sous-arachnoïdienne de la convexité du cerveau,” has for its pathognomonic character a stupor gradually increasing to complete coma; and he is of opinion that headache, exaltation of sensibility, delirium, and convulsions, are frequently entirely absent.—(*Anat. Pathol.*, 6me livr.) When this affection occurs towards the base of the skull, accompanied by acute dropsy of the ventricles, vomiting is set down by this pathologist as usually one of the first and most predominant symptoms, so as often to raise suspicion that the patient's disorder is in the stomach.—Ed.

† The following remarks by Dr. Quain are judicious and interesting:—“An examination,” says he, “of the structure of the brain, and of the peculiarities of the circulation in it, would also lead to the inference, that if the meninges be the seat of inflammation, the contiguous cerebral substance must participate in some degree, in the irritative influence. In other organs, the vessels, after entering them by trunks and branches of various sizes, branch out and ramify in their interior, until they become capillary in their spongy and areolar tissue. But in the brain a different arrangement takes place; the vessels, after entering at the base of the skull, communicate freely with one another, and then branch out upon the surface of the brain, ramifying in an extended web of cellular tissue (pia mater); in this way they become reduced to so great a degree of tenuity before they enter the substance of the organ, that it may be said to be surrounded by a vascular atmosphere, from which its supplies are derived. Hence it is, that as the meninges and the contiguous cerebral substance are supplied from the same source, each will, more or less, become affected by any inflammatory action set up in the other. M. Bayle, in his Thesis, gives six cases of what he considers chronic arachnitis, and in all of them the arachnoid membrane was thickened, opaque, and resisting, and there was found some serous effusion; but in five of these cases, portions of the cerebral substance were adherent to the membranes, and so much softened

escaped the attention of almost all our nosologists, even of those who have subdivided inflammation of the brain into the greatest number of distinct genera or species of disease; while Vogel expressly declares, that all the most acknowledged symptoms of inflammation of the brain are equivocal, not only as to a distinction of one morbid part from another, but as indicative of inflammation in any part; and Dr. Cullen asserts, in a note subjoined to his *generic* definition (for he advances the disease to the rank of a genus, and a genus too without a species or a specific character), that there are no symptoms capable at all times of distinguishing, with certainty, inflammation of the brain from inflammation of its meninges. On which account, he deviates from the more complicated arrangements of Sauvages, Linnéus, and Sagar, and includes several of their genera in his own definition, which runs in more general terms as follows:—"pyrexia severe; pain of the head; redness of the face and eyes; intolerance of light and sound; watchfulness; fierce delirium, or typhomania."

There is so much correctness in this remark of Dr. Cullen's, notwithstanding the error of his arrangement, that the present author yielded to it in the first edition of his Nosology, and introduced cephalitis, not indeed as a naked genus without a specific character, but as a single species without enucleating its varieties; or, in other words, without treating of deep-seated inflammation, constituting acute internal dropsy of the brain, separately from inflammation of the head generally. It may, perhaps, be doubted, whether acute dropsy of the brain ought to be regarded as an idiopathic inflammation at all, and consequently whether the present is the proper place for it; but the reasons which will immediately be advanced will, I trust, settle this point completely. And as, upon a closer attention to the subject, notwithstanding Dr. Cullen's remark, I am induced to think that there are cases in which parenchymatous or deep-seated inflammation may be distinguished from meningitis, I have so far deviated from the first arrangement as to give these distinctions under the form of the above varieties.

as to be brought away with the latter, when an effort was made to detach them: in five of them, the pia mater was injected, thickened, and infiltrated with serous fluid. M.M. Martinet and Parent, in their elaborate monograph on arachnitis, give the results of their examination of 116 cases, published with the expressed design of establishing the diagnosis and pathology of arachnitis. But though these are classed as inflammations of a serous membrane, we find, that in a considerable number of them, the inflammation had extended to the cerebral substance, the vessels of the pia mater being at the same time injected, and its substance thickened and covered with a serous or sero-purulent effusion; so that, judging from the *post-mortem* appearances, they were, in fact, mixed cases; and in strictness, we must refer the symptoms, or physiological indications presented during life, to the lesion of the cerebral substance, rather than to that of the meninges.*—Dr. Quain, in *Cyclop. of Pract. Med.*, art. INFLAMMATION OF THE BRAIN.—ED.

I admit, nevertheless, with Dr. Cullen, that there are no symptoms capable at all times of distinguishing, with certainty, inflammation of the substance of the brain from inflammation of its meninges; and only contend, that the distinction may be drawn in certain cases in which the disease is simple, and the characters strong and unmixed; and strikingly indicative of membranous or parenchymatous inflammation, according to the general rules just laid down upon this subject.*

It is possible, indeed, that meningeal inflammation may occasionally be still more limited, and exist chiefly or altogether in one of the membranes alone, as the arachnoid; whence some pathologists have set down ARACHNITIS as a subvariety of the meningeal form: but, as such minute derivations can never be supported by pathognomonic symptoms, nor lead to any practical utility, I cannot but prefer the example of Professor Frank, and, indeed, of most of the Italian pathologists, in rejecting them, to that of Pinel and other French writers,† in introducing or retaining them.

[Dr. Abercrombie, who uses the term *meningitis* to express inflammation of the arachnoid or pia mater, or both, as distinct from inflammation of the dura mater, finds that it is not characterized by any uniformity of symptoms. In some cases, it comes on with headache, vomiting, fever, and impatience of light, but more commonly with a sudden and long-continued paroxysm of convulsions, sometimes preceded by headache and vomiting, sometimes without any warning. In some examples, the convulsion passes immediately into coma, which afterward alternates only with a repetition of the convulsion, until death. In other cases there is a recovery from the first convulsion, and the patient appears to be doing well; but afterward falls into coma, with or without a recurrence of the convulsion; while, in certain other instances, no convulsion occurs till a late period of the disease.]

On the other hand, inflammation of the substance of the hemispheres is said to be attended with symptoms which also vary considerably, according to the extent of the disease, and the particular part of the brain which is the seat of it. In some cases, headache is followed by

* According to Bayle, delirium and progressive paralysis are the invariable accompaniments of chronic meningitis. The delirium is at first partial; it is a monomania, with weakness of intellect; but, after a time, it passes on to the maniacal excitement, and finally subsides into confirmed idiocy. The paralysis does not amount to a total privation of motion and sensation in any particular part; it is at first slight, but gradually increases, and extends to the whole muscular system, rendering the gait feeble and vacillating, and ultimately destroying the power of motion. The diminution of sensation is not proportioned to that of motion. Spasmodic movements, with contraction and rigidity of the limbs, sooner or later set in; and, finally, epileptic attacks, which terminate in fatal apoplexy.—ED.

† Recherches sur l'Inflammation de l'Arachnoïde, &c., Par P. Duchatelet, M. D., &c., et L. Martinet, M. D., 8vo., Paris 1821.

high delirium, and this by coma. In others, there is a sudden attack of convulsion. A frequent form of the disease is characterized by headache, followed by convulsion of one or more limbs: these afterward becoming paralytic. The disease may be fatal in the inflammatory stage: that of ramollissement, simple or combined with partial suppuration; that of undefined suppuration; that of encysted abscess; of that or ulceration of the surface of the brain.*]

I believe that a simple and unrestricted appearance of inflammation is more frequently to be traced in meningic, than in profound or parenchymatous cephalitis; or, in other words, that, in primary inflammation of the substance of the brain, the meninges are more disposed to partake of the affection, either by continuous action or sympathy, than the substance of the brain is in primary inflammation of meninges. And hence, those nosologists that describe but a single species or *genus* of this disease, as it has been often though incorrectly denominated, like Vogel, Cullen, and Parr, lean chiefly to the meningic variety, and define it by characters of great vehemence or acuteness, so as in reality to limit themselves to this variety alone. Yet, as the symptoms do not always, nor even most frequently, mount up to this aggravation, in consequence of the disease more commonly originating, or being more commonly seated, in the substance of the brain itself than in its membranes, they have all been dissatisfied with their respective definitions; and, instead of enlarging or modifying their terms to meet the distinctive phenomena as they vary according to the seat of the disease, have endeavoured to apologize for their own inaccuracy, by representing these phenomena as irreducible and anomalous.

The first variety, therefore, exists in the judgment and even in the description of all writers, who, where they have not entered into more minute subdivisions, have given it as the general character of the complaint.

The existence of the second variety, or, in other words, the propriety of regarding what has hitherto been denominated acute or internal

hydrocephalus as a variety of cephalitis, requires to be examined somewhat more at length.

The absurdity of the usual arrangement of internal hydrocephalus, and of contemplating it as belonging to the ordinary family of dropsics, with which it has scarcely a common symptom, has long been felt by pathologists, and is directly noticed both by Sauvages and Cullen. But the question is, if we remove it from its usual situation, where are we to place it? If we do not regard it as a dropsy, in what light are we to contemplate it at all? And how are we to regulate our treatment of it? The Professor of Montpellier tells us, that, according to its symptoms, it is to be ranked in the coinotose, spasmodic, or some other tribe of diseases: distinctly importing that, in his own opinion, he could not refer it to any single division in his very extensive classification. Dr. Cullen's reply is, that it is an evident and idiopathic species of *apoplexia*, and ought to take its place under that genus; and he has hence distinguished it by the appellation of *apoplexia hydrocephatica*, and in this manner assigned it "a local habitation and a name." In reference to this assignment he observes, however, that, in a nosological work, it is difficult to collate exactly diseases that, in their progress, assume a changeable form, and hence to allot a perfectly fitting place to hydrocephalic apoplexy. "Yet I prefer," says he, "placing this disease under the head of apoplexy to placing it under that of hydrocephalus (dropsy of the head); first, as it differs extremely from the symptoms of sensible (external) dropsy of the head; and next, as in its proximate cause, and at length in its symptoms, it bears to apoplexy as near a relation as possible."

Dr. Cullen evidently regarded the effusion or dropsy in the ventricles of the brain as a mere effect of the disease, rather than as the disease itself; yet the drowsiness, or heavy sleep, or whatever else there is akin to apoplexy, and which he contemplated as the proximate cause of the disease, and consequently as the disease itself, is a still more remote effect than even the effusion, for it is probably the mere result of such effusion. In truth, it is only necessary to

* See Abercrombie's *Pathol. Pract. Researches on Diseases of the Brain*, pp. 50, 70. This eminent pathologist candidly owns, "that our knowledge is not sufficiently matured to enable us to say with confidence what symptoms indicate inflammation of the substance of the brain, as distinguished from that of its membranes." Yet, as Dr. Quain has pointed out, there are circumstances in which we can indicate, with sufficient precision, the symptoms of cerebritis, as distinguished from any that can, in strictness, be referred to meningitis; for instance, when the inflammation is isolated, and does not reach the membranes, as where it is seated in the thalamus, or corpus striatum. But if the inflammation occur at the circumference of the organ, where the membranes and cerebral substance are in contact, and both are supplied by the same vessels, then, though the inflammation may at the outset be seated in the meninges, it will speedily extend, more or less, to the cerebral substance, and, by complicating the lesion, confuse the diagnosis.—(Dr. Quain, in *Cyclop. of Pract. Med.*, art. INFLAMMATION OF

THE BRAIN.) It is an observation made by the same physician, that if we note the symptoms commonly ascribed to inflammation of the arachnoid membrane, we shall find that several of them must really depend upon a disturbance of the functions of the cerebro-spinal mass, and not of its investments; as, for instance, delirium, spasm, and rigidity of the muscles, convulsions, vomiting, stupor, coma, contraction or dilatation of the pupils, strabismus, &c. In the great majority of superficial inflammations, it appears to Dr. Quain that there is a mixed lesion, and all that discrepancy which their progress and symptoms present is explicable, not merely by the extent and degree of the inflammation, or by peculiar idiosyncrasy, but by the fact that, in some of them, the inflammatory action is, for the most part, expended on the membranes; that, in others, the reverse obtains; while, in a third group, it seems as if concentrated on the vessels of the pia mater, the arachnoid on the one hand, and the brain on the other, being but slightly affected.—Ed.

run over Dr. Cullen's specific definition of this disease, to see how very little it has in common with apoplexy. This definition is as follows:—"Apoplexy arising gradually; affecting infants, and the age below puberty, first with lassitude, feverishness (*febriculâ*), and pain of the head; afterward with a slower pulse, dilatation of the pupil, and somnolency." The definition includes two stages of disease, if not two distinct diseases, a primary and secondary: and it is only in the second stage or secondary disease, the mere result of the first, that it bears any analogy to apoplexy.

The first and leading symptoms are evidently those of pyrexia, which is, therefore, the fundamental part of the disease; and had not Dr. Cullen been in some degree influenced by system, he would probably have coloured these symptoms a little more highly, as he might have done without any departure from the truth. And hence, while Dr. Parr, Dr. Young, and a few others, have adhered to Dr. Cullen's view of the subject, the great body of pathologists have been dissatisfied with it, and have correctly carried internal hydrocephalus over to the class of pyrexias, and regarded it as a fever or an inflammation. Thus, in Dr. Macbride's table, it occurs as a nervous fever, under the title of *febris continua, nervosa, hydrocephalica*: and more simply under that of *febris hydrocephalica*, in Professor Daniel's edition of *Sauvages*; while Dr. Quin of Dublin, Dr. Withering, Dr. Rush, Dr. Golis, Professor Martini, and a host of other writers of authority, have contemplated and treated it as an inflammation—an inflammation of the brain—and consequently a cephalitis, in the language of Dr. Coindet, *Céphalite interne hydrocéphalique* (*Mémoire sur l'Hydrocéphale*, par J. F. Coindet, M. D., Geneva, 1818); in that of Dr. Golis, *wasserschlag* (*Prakt. Abhandl. über die vorzüglichsten Krankheiten des kindlichen Alters*, band. i., Wien, 1815), or water-stroke, from its violence; the fever being regarded as a mild and somewhat irregular cauma, and the effusion into the ventricles of the brain as a mere effect of the inflammation.

This is not the only instance, indeed, in which cauma assumes a mild character. In various other species of *empresma* it is often found to do the same, of which the reader will find an interesting example under the species *laryngitis*, a few pages further on: and of which every practitioner is meeting with daily instances in *pneumonitis*, and especially in inflammation of the *parenchyma* of the lungs producing suppuration. The general organ of the brain, however, seems to have less irritability than almost every other organ when in a state of health, and we often find it to be little irritable in a state of lesion; since nothing is more common than for a bullet, or the broken point of a knife, sword, or other weapon, to be forcibly driven into it, and buried there for weeks, months, or years (*Gooch's Cases*; *Hoegg. Diss. Observ. Medico-Chir.*, Jen., 1762), in one instance eleven years (*Majanel, Journ. de Med.*, tom. xli., p. 65; *Id.*, tom. xx., p. 553), not only without

danger, but sometimes with little inconvenience.

In the third number of the *Medico-Chirurgical Journal* there is an excellent paper upon the subject before us, by Dr. Porter of Bristol, which commences with a very correct pathological view of the disease, minutely coinciding with the present arrangement, and confirming this view by a variety of strongly-marked and well-selected cases. And I am glad to avail myself of Dr. Porter's authority in following up this second variety of cephalitis into a distinct and extended illustration.

[The view adopted by the foregoing authorities and by Dr. Good, receives important corroboration from the statements of that distinguished pathologist, Dr. Abercrombie, who has observed (*On Diseases of the Brain*, p. 19; also, *Dr. Mills, in Trans. of Assoc. of King's and Queen's Coll. of Physicians*, vol. v., p. 353), that, in the earlier investigations of this class of diseases, too much importance was perhaps attached to the effusion, as if it alone constituted the disease called acute hydrocephalus. The symptoms were ascribed to the compressing influence of the effused fluid, and the practice was directed chiefly or entirely to the promotion of its absorption. It is now, says Dr. Abercrombie, very generally admitted, that the effusion in acute hydrocephalus is to be considered as one of the terminations of inflammatory action within the head, though there are certainly other causes from which the serous effusion may arise. Dr. Mills proposes to call the acute species, arising from inflammatory action, *hydro-cephalitis*.]

In a few words, both varieties not only evince symptoms of inflammation during the progress of the disease, but anatomical proofs of the same upon dissection after the disease has terminated fatally; in the meningeal subdivision, the complaint commencing in and being ordinarily confined to the meninges or membranes of the brain, the bloodvessels chiefly affected with inflammatory action being the meningeal branches of the external carotid; and, in the deep-seated subdivision, the complaint commencing in, and being ordinarily confined to, the posterior part of the brain, the bloodvessels chiefly affected being minute branches of the basilar artery. It is nevertheless possible, and appears often to become a fact, from the anastomoses that are occasionally found between different arteries of the brain, from the continuous spread of morbid action from neighbouring sympathy, or from some unknown cause, that either variety may pass still deeper or wider into the substance of the brain, and make an approach towards the other; and hence the mixed, anomalous, and even contradictory symptoms, by which the specific character is sometimes distinguished (*J. P. Frank, De Cur. Hom. Morb. Epil.*, tom. ii., p. 48); a striking example of which, but too long to be quoted, is to be found in the *Edinb. Medical Commentaries*.—(Vol. ix., p. 164.)

"In three cases," says Dr. Sagar, "I have found suppuration of the brain after death; in each of which the patient during the progress of

thedisease breathed sonorously, but without stertor."—(*Syst. Morb. Sympt.*, Cl. XI., Ord. III., Gen. XII.) Whether, in the case of effusion between the membranes, the fluid be confined, where the disease commences in the meninges, to the space between the dura mater and the arachnoid tunic, and where it commences in a contiguous part of the brain, to that between the arachnoid tunic and the pia mater, as asserted by Dr. Porter, I have not been able to determine.

We may hence explain why the symptoms of irritation and oppression should so much vary, as we find they do, in different cases; why there is sometimes no delirium, and at other times a considerable degree; why the delirium is sometimes furious and impetuous, constituting the *delirium ferox* of medical writers; why, in other instances, it is mute or muttering, designated by the phrase *delirium mite*; why there should occasionally be examples of that comatose or heavy stupor to which the Greeks gave the name of typhomania; and why the pain and pyretic symptoms should vary from great acuteness to a mere disquieting headache and slight increased action: as also why, in a few cases, there should not only be found suppuration, but examples of that mollification, or softening of the brain, the *Ramollissement de cerveau* of M. Rouchoux (*Dict. de Méd.*, tom. ii., Paris, 1822) and other French writers, which is more frequently traced in apoplectic subjects, and of which we shall have to treat when discussing the disease of apoplexy.

Except in a few cases, in which it is brought on by the abuse of strong liquors, and, in warm climates, by exposure to the intense heat of the sun (*Abercrombie*, op. cit., p. 6), PHRENSY is not often found as an idiopathic complaint, though it is a frequent attendant upon other diseases, as synochus, worms, various exanthems, trichoma, hydrophobia, injuries of the brain, and severe grief. [The diagnosis of inflammatory affection of the brain, as laid down by Dr. Abercrombie, seems faithful and correct. His account, however, refers to inflammation of the brain, in its several modifications and consequences, and not merely to acute cephalitis. In the head: violent headache, with throbbing and giddiness, sense of weight and fulness, stupor, a great propensity to sleep. In many obscure and insidious cases, a constant feeling of giddiness is the only remarkable symptom. In the eye: impatience of light, unusual contraction or dilatation of the pupil, double vision, squinting, blindness, distortion of the eyes outwards, paralysis of the muscles of the eyelids, objects seen that do not exist, long-sightedness suddenly changed into ordinary vision. In the ear: transient attacks of deafness, great noise in the ears, or unusual acuteness of hearing. In the speech: indistinct or difficult articulation, unusual quickness or slowness of speech. In the pulse: slowness and remarkable variations in frequency. In the mind: high delirium, transient fits of incoherence, peculiar confusion of thought, and forgetfulness on particular topics. In the muscles: paralytic and convul-

sive affections. In the urine: frequently a remarkable diminution of the secretion, often joined with a frequent desire to void it.*

In this important diagnosis, as Dr. Abercrombie justly remarks (*Op. cit.*, p. 17), minute attention to the correspondence of the symptoms is of more consequence than any particular symptom. Thus, the peculiar oppression which accompanies a high degree of fever, is not an unfavourable symptom; but the same degree of oppression occurring without fever, or with a very slight fever, would denote a head affection of much danger. A degree of headache and delirium, accompanying a high fever, would only be symptomatic; but accompanying slight fever, would indicate a dangerous affection of the brain.] Cephalitis sometimes makes a near approach to mania; but is easily distinguished by the nature of the exciting cause, where this can be ascertained, the abruptness of the attack, and the violence of the fever; added to which there is in phrensy, for the most part, though not always, a hurry and confusion of the mental powers, a weakness and unsteadiness of mind, which is rarely or perhaps never to be met with in genuine mania. It sometimes, however, runs into mania, of which Stoll has given a singular instance in a chronic case that continued for nine weeks before it assumed this change.—(*Rat. Med.*, sect. iii., p. 179.)

[From circumstances noticed by Dr. Abercrombie it appears probable, that, in this form of the disease, the inflammation is primarily seated in the membranes of the brain. Another affection of frequent occurrence, referred by Dr. Abercrombie to this head, is characterized by a peculiar aberration of mind, without any complaint of pain. There is a remarkable restlessness, quickness, and impatience of manner, obstinate watchfulness, and incessant rapid talking, the patient rambling from one subject to another, but often without any actual hallucination; he knows persons about him, and answers distinctly questions put to him. The pulse is rapid, but other symptoms of fever are absent. The disease is sometimes mistaken for mania, and set down as not dangerous, though often rapidly fatal. On dissection, the chief appearance is a highly vascular state of

* The undisturbed state of respiration, in the great majority of cases of simple cerebral inflammation, seems to admit of explanation by Sir Charles Bell's discoveries respecting the origin and functions of the respiratory system of nerves. Large portions of the brain may be destroyed, and extensive regions of the body deprived of sense and motion; but, as long as that portion of the medulla which gives origin to the nerves of respiration continues free from irritation and inflammation, the functions of respiration and circulation proceed without interruption. When, however, the general inflammation or irritation extends to the medulla, as happens in the paroxysms of convulsions which sometimes occur in cerebritis, the respiration then becomes extremely hurried.—See Dr. Crawford's *Obs.* in *Cyclop. of Pract. Med.*, art. INFLAMMATION OF THE BRAIN.—EDITOR.

the pia mater, without any actual result of inflammation.

A second modification of inflammation of the brain, particularly described by Dr. Abercrombie, is that which comes on with a sudden attack of convulsion, followed by palsy, and putting on the appearance rather of an apoplectic, than of an inflammatory affection. It is generally connected with inflammation of a portion of the cerebral substance, but may also occur in combination with inflammation of the membranes. This modification may also take place in a more chronic manner, in which it continues for months. In such cases it is generally distinguished by headache, often confined to one side of the head; loss of memory; affections of various organs, as the eye, the ear, or the tongue; convulsive affections; palsy of one limb or one side of the body; terminating in coma and death. On dissection, *ramollissement* or suppurating of a part of the brain is generally met with; but sometimes the part is of a dark colour, and rather firmer than the surrounding parts.—(Op. cit., pp. 7 and 17.)

A third modification, noticed by the same physician, most commonly affects children, but sometimes adults. It is usually preceded for a day or two by languor and peevishness, which are followed by fever, sometimes ushered in by severe shivering. The patient complains of acute pains in some part of the head, with flushing of the face, and impatience of light. In many cases, there is frequent vomiting. The pain frequently extends along the neck, and is sometimes complained of in the arms and other parts of the body. The pupil is usually contracted; the eye is morbidly sensible, and sometimes suffused; the tongue generally white; the sleep is disturbed by starting and frightful dreams; the bowels are mostly confined; but frequently they are natural, and sometimes loose. After some days, slight delirium begins, or a peculiar forgetfulness shows itself, the patient using one word instead of another, misnaming persons and things, &c. These symptoms are followed by a tendency to sleep, soon changing to coma. While these symptoms are going on, the pulse, which was at first frequent, usually falls to the natural standard, or below it; the pain becomes less violent; the eye loses its acute sensibility, becoming dull and vacant, often with squinting and double vision; and these are often succeeded by dilated pupil and blindness, even before the patient falls into coma. The pulse having continued slow for a day or two, sometimes only for a few hours, begins to rise again, and attains extreme frequency, and occasionally that of two hundred in a minute. Through the whole course of the disease, according to Dr. Abercrombie, it is extremely unequal in frequency, varying perhaps every minute, and every time it is counted. This remarkable inequality, he says, is not observed in other diseases, except from some temporary cause; and is, in all affections of the head, a symptom deserving much attention. The patient is now perfectly comatose, sometimes with paralysis, sometimes with

convulsions; and, after a few days more, the disease proves fatal. The falling of the pulse, while the child continues in a state approaching to coma, is often the first symptom indicating the alarming nature of the disease.

A fourth form of the disease, depicted by Dr. Abercrombie, proceeds with slight headache and febrile disorder, with remissions and aggravations for several days, ere the case assumes any decided character. The headache, though not severe, is now remarked to be greater than is correspondent to the fever; and while the pulse falls, and the appetite improves, the headache continues. After a few more days, the pulse sinks even to the natural standard, while the headache is increased, with an evident tendency to stupor. This instantly marks a head affection of the most dangerous character, and the patient now lies for several days in a state of considerable stupor, sometimes with convulsions, often with squinting and double vision. The pulse then begins to rise again; some amendment seems to take place; but a relapse into perfect coma soon follows, and death takes place in three or four days.

A fifth variety, pointed out by the same practical writers, begins with violent headache, but without fever. The pulse is about the natural standard, or even as low as 60. In some cases, the face is flushed; in others, rather pale. The eye may be natural, or it may be impatient of light, with contracted pupil. There is a look of much oppression, and sometimes there is vomiting. Delirium frequently appears at an early period, and in five or six days passes into fatal coma, the pulse having continued from 70 to 80 through the whole course of the disease. In other cases, the pulse is at first above the natural standard, afterward falls to 60 or 50; and at last rises to 120 or 130. In some cases vision is not affected; in others, squinting and double vision occur; and sometimes these symptoms, after lasting a day or two, cease, yet the disease goes on to its fatal termination. In every case there is more or less delirium, though often slight and transient; and frequently the patient lies in a dozing state, and talks incoherently, but is capable of being roused so as to converse sensibly. This condition, says Dr. Abercrombie (Op. cit., p. 6-13), when not accompanied by fever, is always characteristic of a dangerous affection of the brain.]

The remote causes of cephalitis are those of inflammation in general applied to the organ affected; such as sudden exposure to cold after great heat; cold liquors incautiously drunk in the same state; inebriation, and especially from spirits; exposure of the naked head to the rays of a vertical sun; violent passions of the mind; obstructed menstruation; accidental injuries; suppressed eruptions of various kinds (*Frank*, ut *suprà*, tom. ii., p. 51); and several kinds of poison.

From some of these causes, the inflammation assumes a chronic character; is slow in its progress, and obscure in its symptoms. The symptoms, moreover, however connected with a morbid consent in other organs, generally

point to the brain as the seat of lesion; and consist of cerebral compression or acute pain in the head, irregularity in the pulse, and some kind of paralysis. M. Lallemand, who has industriously collected a multitude of anomalous cases of this kind, observes, that where the inflammation runs into suppuration, an effort is usually made by nature to form a sac or barrier for its limitation; but that even this effort is often in vain, and still adds to the fatal issue, as the new membrane frequently becomes thickened, and creates a fresh source of irritation.—(*Récherches Anatomico-Pathologiques sur l'Encéphale et ses Dépendances; Lettre quatrième*, 8vo., Paris, 1823.)

[According to the valuable researches of Dr. Abercrombie, the disease may be fatal: 1st, in the inflammatory stage; 2dly, from serous effusion; 3dly, from deposition of false membrane; 4thly, from suppuration; 5thly, from peculiar disorganization, or softening of the brain, or its conversion into a soft pulpy mass, retaining its natural colour, and without the appearance or smell of pus—the *ramollissement* of French writers; 6thly, the terminations in the chronic form are, thickening of the membranes, contraction and obliteration of the sinuses, caries of the bones, &c.]

The cure of phrensy must be attempted in the same manner as that of inflammation in general, or rather as the cure of inflammation by resolution; for resolution is the only means by which a cure can be effected in this case. Copious and repeated bleedings must here therefore hold the first place, and the nearer the blood is drawn from the affected organ, the better chance it gives us of success. The temporal arteries and the jugular veins have hence been recommended as the most effectual vessels to open; but for various reasons it is better to begin with drawing blood liberally from the arm, and afterward by a free application of leeches to the temples. The head should be shaven as soon as possible, and kept moist with napkins wrapped round it dipped in cold vinegar, or equal parts of water and the neutralized solution of ammonia; or, which is still better, with ice-water: all which is preferable to blistering, which is too apt to increase the morbid excitement; and the practice has the authority of Hippocrates, who was in the habit of applying cold epithems, not only in inflammation of the brain, but even of the abdominal viscera.—(*Περὶ Νοσῶν*, p. 484.) The effect of blistering in the early stages is looked upon by Dr. Abercrombie (*Op. cit.*, p. 156), as rather ambiguous. When it is employed, he recommends it to be on the back of the head and neck, where it will not interfere with the more powerful remedy, the application of cold. After the first violence of the disease has been subdued, however, he approves of successive blisters to various parts of the head and upper part of the spine.] The bowels should be thoroughly evacuated, and even stimulated, at first by calomel alone, or mixed with jalap, and afterward kept open by cooling saline aperients; nitre should be given in moderate quantities, repeated as frequently as the stom-

ach will bear; and it is often considerably assisted by the tincture or infusion of digitalis. The chamber should be cool and airy; and no more light be admitted than the eyes can endure without inconvenience.

[In cases which assume a more chronic character, Dr. Abercrombie (*Op. cit.*, p. 156) represents the abstraction of blood as having less control over them. In all forms of the disease, he says, active purging is the remedy from which we find the most satisfactory results; and though bleeding is never to be neglected in the earlier stages of the disease, his experience is, that more recoveries from head affections of the most alarming aspect take place under the use of very strong purging, than under any other mode of treatment. He deems croton-oil the most convenient medicine for the purpose.]

I have said that furious delirium, though generally laid down as a pathognomonic of this variety of cephalitis, does not always occur; and in a very strongly-marked case in which I was consulted several years ago, the mental powers were not much interfered with.

PROFOUND or DEEP-SEATED CEPHALITIS, or, as it is more commonly called, ACUTE or INTERNAL HYDROCEPHALUS, so far as examinations after death may be depended upon, is almost always accompanied with effusion into the ventricles of the brain; on which account, indeed, the name of HYDROCEPHALUS has been applied to it, though most incorrectly; for I cannot but agree with Dr. Porter, that it has no other symptom in common with chronic or idiopathic HYDROPS CEREBRI, and that such a generalization has been a cause not only of much confusion in nosology, but of much mischief in practice: and hence Dr. Coindet proposes, while he retains HYDROCEPHALUS for the latter, as already observed, to distinguish the former by the name of HYDRENCEPHALUS.

This disease is sometimes found in adults, but mostly in young subjects, and chiefly from early infancy to seven years of age, particularly in those of a fair complexion. After seven years the disease is comparatively rare.

[Dr. Mills has recorded the cases and dissections of twenty patients who fell victims to acute hydrocephalus. Of these, twelve died before they attained the age of six; seven between their sixth and eighth year; and one at the age of twelve.]—(*Trans. of the College of Physicians*, vol. v., p. 434, *Dubl.*, 1828.)

The symptoms commence obscurely, and are those of irritation produced by worms: as irregularity, and especially costiveness in the bowels; listlessness; impatience; knitting the brows into a frown; heaviness of the head, which organ the patient is always desirous of reposing in a chair or some other place; irregular fever; and occasionally violent and deep-seated pain in the sensory, shooting from temple to temple, or across the forehead; frequently accompanied with sickness. Sprightliness, vivacity, and good-temper, sink into dullness; the brightness of the eye becomes dim, and the colour of the cheek vanishes; the child walks unfirmly, as though stepping over a threshold

and often staggers as if drunk. The pulse is irregularly quick; the sleep unquiet and interrupted by screams; and the eye has a look peculiarly oblique or squinting. These three last symptoms are usually regarded as pathognomonic. The eye, however, instead of taking an oblique direction, is sometimes turned upwards: but either change is the result of spasmodic action; the pupil is often at first contracted, but at length unalterably dilated.—(*Chcayne, Essay on Hydrocephalus.*) The pyretic symptoms appear chiefly in the evening, but sometimes at other periods; for, in this respect, there is a strange and unaccountable anomaly; and as the disease advances, they increase. The head is hot to the hand, though without any flush; a severe pain is felt in the forehead, sometimes shooting back to the nape of the neck, or alternating with pains in the limbs, or with colicky gripings, and the stimulus of light becomes highly painful. Shortly after which, many of the symptoms are apt to assume deceitfully for a few hours, perhaps a day or two, a milder character; but the pulse evinces less power, the limbs become emaciated, stupor supervenes, occasional convulsions, more or less general, follow, and death very speedily closes the scene.

So imposing is the apparent improvement at times, that Dr. Gölis candidly tells us (*Praktische Abhandlungen, &c.*), in two instances he dropped his unfavourable prognosis, and thought the little patients on the point of recovery. But a relapse after thirty-six hours in the one, and forty-eight hours in the other, took place, and was speedily followed by death.

I have thus given a brief sketch of the symptoms that principally mark the progress of this disease in all their versatility; and it is this versatility that has produced the chief differences of opinion concerning it.

The first symptoms are unquestionably rather those of irritation than of compression, as is obvious from their resemblance to those of inflammation. The venous system in children, indeed, and especially the veins of the head, are not disposed to plethora, which is rather a characteristic feature of advanced years; nor does the small quantity of water which is often found in the ventricle, seem adequate to the violence of the effect; and we have hence very strong grounds for supposing that the collection of water is only a secondary disease, dependant upon some previous idiopathic affection in some part of the brain; and that affection, as Dr. Rush has long ago very ably shown, an inflammation. It has indeed been observed, in opposition to this opinion, that acute hydrocephalus is less frequently to be met with in strong and vigorous, than in weak and sickly children, dropsy being here, as in other species, far more commonly an effect of debility; while it is in strong and vigorous children alone that we have reason to expect inflammatory action in the brain, as in any other organ. Bleeding, it is admitted, has been serviceable at times; but we are told that it has often been unproductive of any benefit whatever; and that it is

possible to account for its occasional utility by other means than its taking off inflammatory action, as by simple removal or diminution of venous congestion. Yet we have already observed that venous congestion is not commonly a disease of infancy, but of later life; that the first symptoms are those of irritation; that post-obit examinations have very generally shown an inflamed state of the arteries; and that the fluid accumulated is not sufficient in many instances of itself to account for the symptoms by which the disease is characterized.

[Many facts on record exhibit a large quantity of fluid in the brain, without any alarming symptom having resulted from it. Morgagni found eight ounces in a man who died suddenly of suffocation in an advanced stage of pneumonia; and Dr. Heberden found the same quantity in a man who sunk rapidly, after having been weakened by a febrile attack, without any symptom of an affection of the brain. It is, therefore, as Dr. Abercrombie justly remarks (*Op. cit.*, p. 147), not the mere presence of a certain quantity of fluid in the brain that gives rise to the symptoms of hydrocephalus; all of which, on the other hand, have been known to occur and terminate fatally without any effusion. The conclusion deduced from these facts by Dr. Abercrombie is, that the prominent symptoms in these cases are not the result of effusion, but of that disease of the brain, of which the effusion is one of the terminations.]

In the progress of the complaint, there is often a very singular irregularity in the quickness of the pulse, which seems to be always varying and untrue to itself; insomuch that, if we count it several times in succession, we may chance to find it now eighty strokes, now a hundred, now a hundred and twenty or thirty strokes, and, immediately afterward, not more than eighty or ninety in a minute.

[Some physicians are much more confident than others of being always able to detect the existence of the disease. The most characteristic symptoms of its first stage, as pointed out by Dr. Mills, are, a peculiar expression of countenance, indicative of oppression, pain, and despondency; frequent sighing; a disposition to retirement; a heat, weight, pain, or heaviness of the head, or all these combined; intolerance of light; waywardness and fretfulness; a low irregular fever; frequent nausea or retching; an irregular state of the appetite and bowels; and the continuance of the disease, notwithstanding the employment of aperient medicines.]

The diagnosis of the second stage Dr. Mills considers less difficult. The heavy sigh, the deep moan, the wild scream, the preternatural dilatation or contraction of the pupils, imperfect or lost vision, delirium, difficult deglutition, paralysis of one hand, arm, or leg, of the eyelids, and of the sphincters; the head and neck permanently bent back; a slow intermitting or a rapid pulse; frequent vomiting and convulsions, are symptoms which Dr. Mills represents as characteristic of the stage of effusion.

On the other hand, Dr. Abercrombie does not recognise any certainty in the diagnosis, and

has published various facts which tend to prove that none of the symptoms can be depended upon as a certain indication of effusion. Slowness of the pulse, followed by frequency, squinting, double vision, dilated pupil, paralytic symptoms, and perfect coma, he says, have been noticed without any effusion. He further shows that all these symptoms may exist in connexion with a state of the brain which is simply inflammatory.]

The duration of the disease is equally uncertain; commonly, perhaps, it runs on from three to six weeks before it proves fatal; but it will sometimes destroy life in a fortnight, or even a week. Dr. Coindet has occasionally known the patient sink in two or three days. [According to Dr. Mills, acute hydrocephalus, which is the most frequent, commonly lasts from seven to twenty-eight days; chronic, from one to six months; though occasionally protracted to one, two, three, or even sixteen years.

According to Dr. Abercrombie's researches (*Op. cit.*, p. 21), the seat of effusion varies in different cases. It is found in the ventricles under the arachnoid, between the arachnoid and dura mater; and there is every reason to believe that it also takes place between the dura mater and the bone, though the fluid effused in this situation escapes when the head is opened. It is occasionally met with in the cavity between the layers of the septum lucidum. Cases are recorded in which the effusion was confined to one of the lateral ventricles; a state which Dr. Abercrombie has never seen, and which must have depended upon an obliteration of the communication between the two ventricles. Nosologists divide hydrocephalus into internal and external, according as the fluid is contained in the ventricles, or between the brain and its membranes. This distinction is generally adopted: its correctness, however, is doubted by Dr. Duncan, jun. In many cases of chronic internal hydrocephalus, the ventricles, he observes, are so much distended, and the parietes so much thinned, that the head becomes translucent as a hydrocele, and the hemispheres form a mere membranous bag, which is generally ruptured in opening the head. The water is then supposed to lie in direct contact with the membranes, and between them and the brain; the remaining parts of the basis of which are supposed to be the whole brain compressed by the water external to it, while the thinned upper portions of the hemispheres are altogether overlooked, or supposed to be an exudation of coagulable lymph.—(*Edin. Med. Chir. Trans.*, vol. i., p. 221.) That such mistakes may have happened, seems, indeed, highly probable, though authorities are so numerous and weighty in support of the reality of external hydrocephalus, that its existence can hardly be disputed.]

We have already observed that the substance of the brain has more generally evinced proofs of inflammation and other mischief than the membranes; though not unfrequently the increased vascularity and turgescence have extended from the parenchyma to the surface. As the existence of effused fluid is not neces-

sary to the disease, it varies considerably in quantity when it is found, from a few drachms to eight or ten ounces or more; as a mean measure, however, it may be stated at five or six ounces. Most modern pathologists concur with Malpighi and Haller in holding that it is incoagulable; but Pechlin, Lapeyronie, and a few authorities of the present day, have denied this. [Dr. Abercrombie describes it as sometimes limpid, sometimes bloody, and sometimes turbid, containing shreds of flaky matter. In certain cases it is seen in the ventricles, exhibiting all the sensible qualities of pus. Generally, however, it seems to contain but a very small proportion of animal matter; and, in Dr. Marcet's experiments, a thousand grains yielded less than two grains of animal matter. In other cases, however, it is coagulable.] The disease is often connected with a scrofulous habit, and has sometimes formed a fatal metastasis to phthisis. [From the investigations of Dr. Mills, it appears that the disease often attacks the healthy children of healthy parents, but occurs more frequently in the puny or scrofulous, or in children whose parents are scrofulous, debilitated, or worn out by intemperance. There were appearances of scrofula in twenty-two of the patients examined by him. In two, the brain was scrofulous; in three, the lungs; in four, the liver; in eight, the mesenteric glands; in four, the spleen; and, in five, the cervical glands. Of the patients who recovered, six had no visible marks of scrofula, and the parents of twenty-six seemed also free from it.]

The mode of practice, in consequence of the above discrepancy of opinion, has been extremely undecided: while many practitioners are so despondent as to fear that every plan is equally unavailing. It has fallen to the author's lot, however, to see several patients recover, both in infancy and verging towards adult age, who had all the characteristics of the disease, and were unquestionably labouring under it.

[This is a point on which the sentiments of Dr. Abercrombie differ from those of the author of the present work. The former admits that many cases have recovered which exhibited all the usual symptoms of hydrocephalus. Yet, if certain principles which he has endeavoured to establish be correct, and which have been already noticed in the foregoing pages, there is no certain test of effusion in the brain; and all the symptoms usually attending it exist in connexion with an inflammatory condition of the brain; which, if allowed to go on, would probably lead to effusion, but which, if treated with decision in its early stage, may be treated with success. Whether the fluid can be absorbed, or the disease cured after effusion, must remain a conjecture; but from the facts that Dr. Abercrombie has adduced, he inclines to the belief, that in ordinary cases, the removal of the fluid, if it were to take place, would be no improvement of the patient, because there would still remain the deep-seated disease of the central parts of the brain which accompanies the effusion in a large proportion of cases, and which, we have seen, may be fatal without any effu-

sion, yet with all the usual symptoms of hydrocephalus. It is a valuable observation made by Dr. Abercrombie (p. 149), that the ground of prognosis in particular cases, depends, perhaps, in a great measure, upon the activity of the symptoms. The more they approach the character of active inflammation, the greater the prospect of cutting them short; and the more they partake of the characters of low scrofulous inflammation, the less it will be. In every instance, the period for active practice is short, the irremediable mischief being probably done at an early period of the disease.]

Contemplating it as a variety of cephalitis, the author has uniformly pursued the general plan recommended under the preceding variety, and to this practice he can only ascribe whatever degree of success he has been fortunate enough to meet with.

Blood should be drawn freely from the nape of the neck by cupping or leeches: the head should be shaven, and napkins dipped in ice-water, or vinegar and water, be applied to the posterior part of it, and be changed every hour or half hour. The bowels should be freely purged with calomel, or calomel and jalap;* and the jalap should be toasted to render it less disposed to excite sickness: an easy diaphoresis should, if possible, be excited and maintained on the skin; the chamber should be large and well ventilated: and, whenever it may be right to stimulate the head, epithems of neutralized ammonia should be preferred to blistering. The value of digitalis is doubtful; when used early it has seemed serviceable, but it should be avoided in the second stage of the disease; unless, indeed, it be employed, as by Dr. Gölis, to smooth the passage to death, by diminishing the violence of the convulsions that usually precede it. In later life than infancy, where it has been necessary to draw blood repeatedly, I have occasionally prescribed opening the temporal artery with great success: for a small quantity, as six or eight ounces of blood drawn in this way, will often answer the purpose of double or treble the quantity abstracted from the arm. In a young lady of nineteen, labouring under very prominent symptoms of this disease, I found the violent and deep-seated pain in the head cease instantly; and the pulse sink from seventy to forty-four, as soon as only a tea-cupful of blood had been taken away in this manner.

Mercury, employed both externally and internally, in a quantity sufficient to excite a pytalism, has also been used in many instances with great success, both among adults and infants, but particularly among the latter. Dr. Percival gives the history of a child of his own, aged three years and a quarter, in which a perfect cure was obtained by this and nothing else. In forty-eight hours signs of amendment appeared, and in six days the child was well; during which time thirteen grains of calomel had been

taken, and seven scruples of strong mercurial ointment had been rubbed into the legs. Dr. Dobson of Liverpool employed quicksilver in the same double plan, and asserts that he found it equally useful, and most strikingly so in the following case. Four children of the same family had evinced this disorder in succession; three had fallen victims to it under a different treatment: one, between three and four years old, was subjected to the mercurial plan of calomel and inunction. In forty-eight hours a pytalism was excited, the symptoms abated, and the child recovered.—(*Edin. Med. Com.*, vol. vi., p. 224.) Dr. Gölis prefers the internal to the external use of mercury, as far more active and to be depended upon. He gives it in free doses, and observes, "that an infant of a year old and under will bear a much larger proportion without diarrhoea or griping, than those of four, five, six, or even eight years of age." And hence to the former he often prescribes eight or ten grains in the course of twenty-four hours. If diarrhoea or griping be produced, it should be remitted. With Gölis, pytalism has proved a rare effect.

In adults, the ordinary proportion is ten grains of calomel, and a drachm of strong mercurial ointment every night. Under this treatment, various cases of success are recorded in the *Edinburgh Medical Journal*.

[After depletion, Dr. Mills exhibits calomel with opium, but at first in small doses; and recommends blisters, or the antimonial ointment, to be applied to the head or its vicinity. He has also given nauseating doses of tartar emetic with decided benefit.]

SPECIES II.

EMPRESMA OTITIS.

EARACHE. IMPOSTEME IN THE EAR.
SEVERE PAIN IN THE EAR; TENDERNES UPON PRESSURE; DEAFNESS, OR CONFUSION OF SOUNDS.

This is usually a distressing rather than a dangerous disease; but the fever is sometimes violent, and delirium, and even death has been a consequence. It is often produced by cold, and is hence frequently a local catarrh;* and is still more commonly, perhaps, occasioned by some exotic substance which has accidentally entered into the ear, as a small piece of ragged bone (*Hagendorn*, cent. i., obs. 64), a cherry-stone (*Fabric. Hildan.*, cent. iii., obs. 4), a worm, an insect, or the larva of an insect, as of an ant, a fly, or a cricket; of all which we have a variety of curious histories in medical journals.—(*Stalpart Van der Wiel. Maget. Journ. de Med.*, tom. lxiv.; *Moehring*, obs. 21; *Samml. Medicinischen Wahrnehmungen*, b. viii., p. 37.) In these instances, the disease is confined to the external ear: but from many of the ordinary sources of inflammation, it often exists within the tympanal cavity; whence, too, the inflammatory action has extended to the brain,

* Statement of the early symptoms which lead to the disease termed Water on the Brain. By G. D. Yates, M. D., Svo., 1823.

* It often ensues after severe cases of scarlatina, measles, and some other diseases.—D.

or affected it by sympathy.* In this case, the membranes and lining of the inner organ are coated with coagulable lymph, pus, or both; while even the temporal bone of the affected side has become carious. An instance of this last kind is related by Dr. Powell. The patient was a young gentleman of sixteen, who had been attacked with otitis once or twice before. The pain was intense, but the pulse never exceeded seventy-two: yet the disease proved fatal. The intellect was at no time disturbed.†

The disease, therefore, offers two distinct modifications, and is so far correctly arranged by M. Itard.

α External.

External Imposteme.

External ear highly irritable, lining membrane, when examined by a bright light, red and tumid.

β Internal.

Internal Imposteme.

Hemicrania, sense of weight in the head; roughness about the mouth of the Eustachian tube: tonsils often enlarged.

A hissing or tingling sound accompanies both varieties; but is most painful in the latter. M. Itard‡ believes both to proceed chiefly from cold, and to possess much of the nature of a catarrh: but in dividing them into two distinct sub-species, a catarrhal and purulent, he ramifies very unnecessarily; for, let the exciting cause be what it may, the purulent is only a subsequent state to the preceding.

The EXTERNAL OTITIS generally suppurates in a short time, and then more completely forms what is vulgarly called an IMPOSTEME or IMPOSTHUME in the head, a term corrupted from *aposteme*; the discharge, which is usually yellowish, puriform, fetid, and somewhat bloody, flows from the external auditory passage in a greater or less abundance, according to the extent of the inflammation. It commonly diminishes in about a fortnight or three weeks; when the fluid becomes thicker, and to the eye, and even the smell, caseous. It then ceases, and is succeeded by a copious ceruminous secretion,

* Case of Inflammation and Abscess of the Brain, attended with Disease of the Ear. By John O'Brien, M. D., Trans. King's and Queen's Coll., Dublin, vol. ii., p. 309, 8vo., 1824; Parkinson, in London Med. Repository, March, 1817.

† Med. Trans., vol. v., art. xvi., p. 212.—The frequent connexion of inflammation of the dura mater with affections of the ear, and of the petrous portion of the temporal bone, has been of late admirably illustrated by Dr. Abercrombie.—See his Pathological and Practical Researches on Diseases of the Brain, p. 32, &c. 8vo., Edin., 1828. In the Museum of the University of London is a temporal bone, in the petrous portion of which an abscess formed, and the matter from which, after perforating the diseased bone, extended itself gradually down in the loose cellular membrane of the neck to the upper part of the chest. The disease proved fatal by bringing on inflammatory mischief in the neighbouring part of the dura mater.—Ep.

‡ Traité des Mal. de l'Oreille et de l'Audition. Par J. M. G. Itard, M. D., &c., 2 tom., Paris, 1821.

which passes off without any injury to the sense of hearing.

This is the ordinary course; but it sometimes runs into a chronic state, and especially where there is a morbid diathesis from struma, syphilis, or variola; and, under such circumstances, it becomes often tedious and unmanageable, and is accompanied with a thickening of the tympanal membrane, and an obtuseness of hearing. In some cases, however, the *otorrhœa* or chronic state takes the lead. This is mostly the effect of cold, and is, in fact, an otitic catarrh. The discharge from the ear is at first, perhaps, not attended to, and, from particular circumstances, occasionally ceases for a time; but only to show itself in any accidental excitement with renewed violence. The discharge differs in different individuals in its consistence, colour, and the peculiarity of its smell, though the last is always offensive; it is at first mucous, then purulent, and at length consists of a thin sanies; in which last case, connected with the specific fetor that issues from a carious bone, there can be little difficulty in determining that some of the small bones of the ear, or even the temporal bone itself, are affected; which, indeed, are at times thrown out in minute fragments. M. Lallemand, who has ably treated upon this subject, observes, that "the morbid secretion is apt to alternate with attacks of rheumatism in other organs, catarrhus vesicæ, leucorrhœa, and various other complaints."* The most dangerous metastasis is that to the membranes or substance of the brain; which M. Lallemand conceives occasionally produces death so soon, that no trace of such a transfer is to be ascertained on dissection.

The general remedies for inflammation are here to be resorted to; and particularly warm, narcotic fomentations, and a dry atmosphere. Blisters behind the ears have often afforded relief; and for the same reason stimulant errhines and sialogogues: which, by evacuating the mucous follicles of the Schneiderian membrane, and the salivary glands, produce an influence on all the neighbouring parts, and often on the whole of the vessels of the head. And hence headaches, ophthalmias, and pains in the ear, are in many instances equally relieved by these applications, and were often employed by Dr. Cullen for this purpose.—(*Mat. Med.*, vol. i., p. 436-442.) When the case is chronic, setons or some other protracted drain should never be neglected.

When worms or larvæ of insects are the irritating cause, a few drops of oil of almonds introduced into the ear will readily suffocate them.

The INTERNAL OTITIS inflammation or imposteme of the tympanal cavity, may commence either in the lining membrane, or in the membranes which cover and connect the minute bones, or even in the mastoid cells; it is soon, however, apt to spread from its primary seat to

* Recherches Anatomico-pathologiques sur l'Encéphale et ses Dependances Lettre quatrième, 8vo., Paris, 1823.

every adjoining part, so as to implicate every division or recess of the cavity of the tympanum; and, unless the inflammatory action is soon mastered,* suppuration must necessarily ensue, and it rarely happens that the tympanal bones are not involved in this severer process. In some cases in which their articulations or other connecting mediums are destroyed, they drop away as soon as the tympanal membrane becomes so far ulcerated as to allow them a passage. Occasionally, however, a kind of adhesive inflammation, either between the articulating membranes, or the bones where the former are destroyed, may effect an ankylosis, and render them quite immoveable.†

How far, under these circumstances, the organ of hearing may be destroyed, must depend upon the extent of the disease, and the parts that have been actually involved in it. If that portion of the organization which merely assists in conveying the sound has been alone affected, the hearing will not necessarily or altogether be destroyed; and hence the malleus and incus, or two outer bones, are sometimes lost, while the sense of hearing is still preserved in a sufficient degree of perfection for ordinary purposes; the sonorous vibrations being afterward conveyed through the tympanum, as usual, along its parietes to the stapes, and by the vestibular fenestra to the labyrinth. But if these last have participated in the ulcerative process, and especially if the stapes be detached with the other

bones, the vestibule laid open, the sac eroded, and the water which it contains have escaped, the destruction has extended to the sentient, as well as to the conveying part of the general organ, and the loss of hearing will be irreparable on the side on which the mischief has occurred.—(*Edin. Med. and Surg. Journ.*, No. lxxiv., p. 92.)

SPECIES III.

EMPRESMA PAROTITIS.

MUMPS.

PAINFUL UNSUPPURATIVE TUMOUR OF THE PAROTID GLANDS, OFTEN EXTENDING TO THE MAXILLARY; CONSPICUOUS EXTERNALLY; FREQUENTLY ACCOMPANIED WITH SWELLING OF THE TESTES IN MALES, AND OF THE BREASTS IN FEMALES.

THE parotid glands are subject to a troublesome, and sometimes a fatal phlegmon, which we have already noticed under the name of PHLEGMONE *parotidæ*. The inflammation before us is altogether of a different kind; it is more extensive, more painful, and rarely tends to suppuration. In our own country it is vernacularly called MUMPS, in Scotland BRANKS, and in France OREILLONS, and OURLES.

The tumour, though sometimes confined to one side of the neck, more usually appears on both; it is at first moveable, but soon becomes diffused to a considerable extent. It increases till the fourth day, and often involves the maxillary glands in the inflammation; is evidently contagious, and often epidemic. After the fourth day, it gradually declines; and, for the most part, there is but little pyrexia, or need for medical aid; a brisk purgative or two, and avoidance of cold, being all that is called for.* The sympathetic action of the testes and the mammae is most conspicuous towards the decline of the inflammation. And, in many instances, it is by no means an unfavourable sign; for it has been occasionally found, that where sympathy has not been manifested, or the glandular swelling has been suddenly repelled,† the symptomatic fever has been greatly exacerbated, delirium has ensued, and even death has closed the scene.

* The patient's diet should not be stimulating, and exposure to cold ought to be avoided. The common plan of covering the swelling with flannel, sprinkled with hartshorn, or camphorated spirit, is by no means a bad one. Parotitis, in a subacute form, occasionally takes place on the decline of fevers, or follows exanthematous diseases, as measles, smallpox, and scarlet fever, or occurs as an effect of scrofula. It is only in the form of mumps that the disease is supposed to be contagious.—ED.

† In consequence of the well-known fact, that the inflammation in parotitis is strongly disposed to a metastasis from its original seat to other organs, cold applications should be avoided, and this not only with respect to the swelling of the parotid gland itself, but to any secondary inflammations in the breast or testicles. Leeches and warm poultices and fomentations may be safely employed, when the degree of inflammation requires them.—ED.

* The means recommended by Dr. Burne (*Cyclop. of Pract. Medicine*, art. OTALGIA and OTITIS), are one general bleeding, to the extent of from ten to twenty ounces; the repeated and free use of leeches; blistering the nape of the neck, and an active purge with calomel, jalap, &c., followed up by the exhibition of one or two grains of calomel, and a quarter of a grain of tartarized antimony, every two hours through the first day, and every three or four hours during the second, after which the antimony is omitted, and the calomel continued according to circumstances. If suppuration occur, fomentations and poultices are to be employed, and ammonia and opium prescribed. There may be cases, in which the confined state of the matter will require the membrana tympani to be punctured.—ED.

† Of the five openings leading to and from the tympanum three are closed, the fenestra ovalis and fenestra rotunda by their proper membranes, and the large opening to the external meatus by the membrana tympani; while the other two are open, the one leading to the Eustachian tube, the other to the mastoid cells, which cells, forming a cul-de-sac, leave the Eustachian tube the only open channel of communication with the tympanum from without. Hence, in inflammation of this cavity, it and the mastoid cells become filled with the usual product of inflammation of a mucous membrane, which has no means of escape, because the Eustachian tube itself is generally involved in the inflammation, and closed. In this manner the delicate texture of the ear is exposed to the pressure and other bad effects resulting from the confinement of matter; and hence arise ulcerative perforation of the membrana tympani, puriform discharge from the meatus externus, destruction of the organ by caries, and eventually cerebral abscess, and death.—See art. OTITIS, by Dr. Burne, in *Cyclop. of Pract. Med.*—ED.

When there is any danger of such a result, the swelling should, if possible, be brought back, or sustained by stimulant cataplasms or blisters. Dr. Hamilton has in several cases observed this sympathetic influence operating alternately; and mentions more than one instance, in which, after a very considerable enlargement of the testicle, upon the cessation of the disease, this organ entirely wasted away, inasmuch that the tunica vaginalis became an empty bag.*

In advanced life, parotitis is sometimes apt to run into a chronic form, accompanied with very mischievous symptoms; in which state it is denominated a malignant parotid. This is more especially apt to take place in females when menstruation is on the point of ceasing, and the general action of the system labours under some disturbance. The tumour should, if possible, be dispersed by leeches and cooling repellants: for if it proceeds to suppuration, to which it tends, though very slowly, the ulcer rarely heals; usually degenerating into a foul offensive sore, that sinks deeper and spreads wider, resisting all medical treatment, and at length undermines the constitution, and destroys the patient. Vomits frequently repeated, have in this case been found highly serviceable; and those of the antimonial preparations are to be preferred to ipecacuanha. They maintain a longer action, and determine more effectually to the surface, or rather to the excrements generally. [Dr. Neumann, of Neustadt in Silesia, employed the hydriodate of potass with great success as an external application in empresma parotitis, which prevailed epidemically in that town in June, 1823. Among the poor classes, who were treated in the ordinary way, the disease was very tedious, and generally ended in suppuration. Among the higher ranks, the treatment consisted in the exhibition of an emetic, and covering the tumour with a plaster, composed of eight parts of mercurial ointment, and one part of the hydriodate of potass; and the common result was a complete cure in three or four days. In the cases so treated, Dr. Neumann never observed any metastasis to other organs, and he is disposed to impute this to an erythematic redness, which always appeared on the first or second day, and remained from eight to twelve days.†] In a case in which a diseased condition of the parotid gland formed only part of an enormous tumour in a patient aged forty, Mr. Carmichael removed the whole by the knife, and the patient recovered, with a slight partial paral-

ysis of one of the muscles on the affected side.* (The parotid gland, when affected with cancer or sarcoma, has also been successfully removed by Bécлар, Lisfranc, Professor Naegele of Heidelberg, and others.† When, however, the whole of the gland is diseased, its deep extension at the base of the skull makes the removal of every portion of it impracticable. In one example, in which the disease created a serious impediment to deglutition, and had made such progress that the effectual removal of the whole of it seemed impossible, Dr. Fricke of Hamburg tied the carotid artery. The result was a partial diminution of the tumour, and an improvement in the power of swallowing; but abscesses afterward formed in the swelling, and the patient fell a victim to constitutional disturbance.‡]

SPECIES IV.

EMPRESMA PARISTHMITIS.

QUINSY.

REDNESS AND SWELLING OF THE FAUCES; WITH PAINFUL AND IMPEDED DEGLUTITION.

This is the squinsy or squinancy of our old writers; the cynanche or angina of medical books. Paristhmia, from *παρά* and *ίσθμῶς*, literally *morbus faucium*, or *throat-affection*, is the term employed by Hippocrates, and is only varied to paristhmitis, in the present system, in consonance with the general termination of all the species belonging to the genus before us. The term was used among the Greeks, as on the present occasion, in a specific sense; though the later Greek physicians gave different names to its different varieties; and hence we meet with cynanche, synanche, and parasyanche; the common signification of all which is *angina* or strangulation, while the prefixes *cy-* *sy-* and *parasy-* are of doubtful meaning, as I have further observed in the preliminary dissertation to the Nosology. Aëtius attempted to justify *cynanche*, but Cælius Aurelianus and Paulus used *synanche*, after Celsus. The Latins employed *angina* in the same extent as Hippocrates did *paristhmia*; quinsy is used in a parallel latitude among ourselves. Sauvages conjectures, and there is some ground for the opinion, that the synanche of the Greeks was the common quinsy of the present day, the *paristhmitis tonsillaris* of the system before us; their parasyanche, the quinsy of the pharynx, *paristhmitis pharyngea*; and their cynanche, croup, or *empresma bronchlemitis*.

* Edin. Trans., 1773. Numerous individuals pass through life without even having had parotitis, while a few have it oftener than once. It is most frequent in children, in whom it is often regarded as a sign of their being about to shoot up in their growth. The hypothesis that strumous children are more liable to it than others, does not agree with the editor's observations. Sometimes it is endemic in schools, particular towns or villages, public institutions, ships, &c.—Ed.

† See Rust's Mag. für die Gesammte Heilkunde, 1826; and Edinburgh Medical Journal, No. xciii., p. 452.

* Trans. of the King's and Queen's College, Dublin, vol. ii., p. 101, 8vo., 1824.

† As early as 1808, Dr. Samuel White, of Hudson, N. Y., published an account of his extirpation of the parotid gland. Bécлар's operation was performed in 1823. Cases of the same have been recorded by Dr. McLellan of Philadelphia, Dr. Mott of New-York, Dr. Bushe, and others. See a Dictionary of Practical Surgery, by S. Cooper, with numerous notes and additions, by David M. Reese, M. D., published by Harper and Brothers, New-York, 1834.—D.

Quinsy presents itself to us under four varieties: the common inflammatory sore throat; the ulcerated, or malignant; the sore throat that peculiarly attacks the pharynx; and inflammation of the œsophagus.

- α Tonsillaris. Swelling of the mucous membrane of the fauces, and especially of the tonsils; redness florid; fever a cauma.
 - β Maligna. Redness crimson; with ulcerations covered with mucous and spreading sloughs, of an ash or whitish hue; fever a typhus. Frequently epidemic, generally contagious. Found often as a symptom in rosalia, or scarlet fever.
 - γ Pharyngæa. Redness florid, and especially at the lower part of the fauces; deglutition extremely painful and difficult; fever a cauma.
 - δ Œsophagi. The impediment to deglutition felt below the pharynx, with a circumscribed pain, and rejection of food when it reaches the seat of obstruction.
- Common Quinsy. Inflammatory sore throat.
- Ulcerated, or Malignant sore throat.
- Pharyngic quinsy.
- Quinsy of the œsophagus.

In the FIRST VARIETY, or COMMON QUINSY, the swallowing is, for the most part, greatly impeded; and the speech, and sometimes even the respiration, rendered highly troublesome; the mucus is excreted sparingly, and consequently there is a considerable clamminess in the mouth; and the pain sometimes spreads to the ears. The disease is never contagious, and, though violent while it lasts, is comparatively of short duration. It terminates by resolution or suppuration, hardly ever by gangrene; though a few sloughy spots sometimes appear upon the fauces.

The usual cause is cold; and it is hence found most frequently in spring and autumn, when vicissitudes of heat and cold are most common. It is supposed to affect particularly the young and the sanguine; but, in my own practice, it has occurred as often at other ages and in other temperaments. When it has been reproduced several times within short intervals of each other, it is apt to establish a peculiar diathesis or habit, so as to be excited readily, and by very slight occasional causes.

If attacked by a medical process early, much benefit has been derived from astringent and acid gargles, and vapours inhaled by any simple machine for this purpose.* Blisters to the throat, or behind the ear, ought also to form a part of the curative plan; and, if bleeding be had recourse to, it should be by scarification, or

leeches applied to the tonsils or fauces. An early use of leeches I have often found highly successful, and can distinctly corroborate Dr. Crampton's remark, that leeches fix far more readily on moist internal surfaces than on the skin. Dr. Crampton, by way of caution, passes a thread of silk through the lower half of the body of the leech (*Dublin Hospital Reports*, vol. iii., p. 229), but I have never found this necessary. Cooling purgatives, and a low regimen, should also enter into the general plan of treatment. If suppuration cannot hereby be prevented, the better way will be to expedite this termination by the steam of warm water, or water impregnated with the leaves of rosemary or chamomile; and, where the fluctuation is clear to the touch, if the abscess do not of its own accord break readily, it ought by all means to be opened with the lancet.

In a few instances the suppuration has pointed and broken externally, and the termination has been favourable.—(*Schenck*, lib. ii., obs. 36.) And occasionally, from the extent and violence of the inflammation, there has been so much danger of suffocation that it has been found necessary to make an opening into the trachea (*Ballonius*, i., p. 182; *Fernire, Journ. de Méd.*, tom. lxii.): which has been done sometimes as high as the larynx, and sometimes considerably lower; and, under both kinds of operation, the patient has recovered.—(*Pienus, Chir. Tract.*, iv., v., c. 1; *Musgrave, Phil. Transact.*, No. 258.)

In the MALIGNANT or SECOND VARIETY, the inflammation passes at once into the ulcerative stage, and is consequently characterized by the symptoms stated in the definition: the sloughing often takes place rapidly, and spreads widely, and the fever is a typhus. This variety is frequently epidemic, generally contagious, and found often as an alarming symptom in rosalia, or scarlet fever. In its idiopathic form it is usually ushered in with a sense of stiffness in the neck, accompanied with some hoarseness of the voice, and occasionally with symptoms of a coryza. It is in effect a quinsy taking an erythematic or erysipelatous, instead of a phlegmonous turn, in consequence of the peculiar temperament of the atmosphere, or of the patient, or of some unknown cause.

The sloughs at first appear whitish or cinereous, but soon become brown and often black, and spread over the whole of the fauces and mouth, into the nostrils, and often down the œsophagus; the ulceration has, also, sometimes passed up the Eustachian tubes, and affected the ears. And, as the sloughs appear to carry contagion with them, on being swallowed they have communicated the disease through the entire range of the alimentary canal.

The danger is hence very great if the ulceration cannot be checked, and it is peculiarly so

* One of the best local applications in the early stage of this form of paristhmitis is the nitrate of silver, a strong solution of which should be applied with a camel's hair pencil, to the inflamed tonsil and the parts adjacent. A more active treatment than that proposed by Dr. Good, will,

however, often be required in these cases, and then our most prominent remedy is general bloodletting. We have employed also, with advantage, scarification of the tonsils, as recommended by Dr. Kopp, of Hanau.—D.

to children and adults of relaxed and delicate frames. The disease makes its appearance most commonly in the autumn, though it has appeared in every season.

The erythematic character is sometimes very striking, the intumescence spreading widely, yet limiting itself to the cellular tissue. Even externally the throat is swollen, hard, and tender; while such is the constriction within, that deglutition is impossible, and there is great danger of suffocation. Dr. G. Gregory has given a well-marked instance of this modification in a young woman in whom it terminated fatally on the sixth day, and has referred to other cases of a similar kind, and mostly with a similar result, from Dr. Kirkland, Dr. Wells, and Mr. James. From its being chiefly seated in the cellular membrane, Dr. Gregory has given it the name of *cynanche cellularis*.—(*Med. and Phys. Journ.*, vol. xlviii., p. 287.)

Dr. Cullen regards the eruption of scarlet fever as a pathognomonic symptom of this disease: but this is to confound two complaints that are very clearly distinct, as we shall have further occasion to observe, when discussing rosalia, or scarlet fever. It is at present sufficient to remark that, even in the opinion of Dr. Cullen himself, quinsy is not essential to scarlet fever, or, in other words, does not always accompany it; and that, on the other hand, a scarlet eruption is not essential to the malignant quinsy, or does not always accompany it, though he contends that it does almost always.—(*Præctice of Physic*, part i., book iii., chap. iv., sect. dcli.)

The malignant or ulcerated sore throat may be without a scarlet eruption, or with it; if the former, it is an idiopathic affection, and constitutes a variety of paristhmitis or cynanche. If the latter, it is a symptomatic affection, and constitutes a variety of rosalia or scarlatina.

Cleanliness, pure air, and a free ventilation, are here of the utmost importance; and, as the contagion is often very active, the nurses should be cautious to remove speedily the sloughs and foul mucus that are washed or wiped from the mouth.

The general treatment will necessarily be the same as that we have already pointed out for typhus. Emetics are often employed with great advantage at the commencement of the complaint; and the bowels should be gently opened, but not irritated with drastic purges.

Here, also, as a means of abstracting blood locally, leeches have been often found of peculiar advantage when timely applied (See *Dr. Crampton, on the Application of Leeches to Internal Surfaces*, *Dubl. Rep.*, vol. iii.): and the throat should be soon afterward gargled with port wine made still more stimulant by spices or other aromatics; or with a strong decoction of bark, rhatany, or catechu, very sharply acidulated with mineral acids, the aromatic or pungent Cayenne vinegar, or charged with an addition of Cayenne pepper in substance. Gargles of the mineral, and even the metallic astringents, have also been tried, but, in general, they want poignancy. Lunar caustic, in the propor-

tion of one part to a thousand parts of water, has sometimes been found useful (*Journ. de Méd.*, Nov., 1789), as has the tincture of capsicum with infusion of roses, in the proportion of an ounce of the former to seven or eight ounces of the latter.

A strong decoction of mezereon root may also advantageously form the basis of a gargle; though even this will be improved by an addition of capsicum or Cayenne pepper (*Collin. Med. Comment.*, ii. 27; *Stephen, Med. Comment.*, Edin., v.), or the aromatic or mineral acids. The stimulus of mezereon is less acrid than that of Cayenne pepper, but it is more permanent, and acts more immediately on the fauces. [Gargles, containing the chlorurets of lime and soda, have been particularly useful in the present disease.] In conjunction with these, camphire and ammonia have often been found beneficial, when externally applied in the form of a liniment.—(*Rumsey, Lond. Med. Journ.*, x.) Both may be used internally; and the latter will be found, as Dr. Peart has well observed (*Practical Information on the Malignant Sore Throat, &c.*), one of the best stimulants we can employ, in doses of half a scruple of the subcarbonate every three or four hours. Bark and wine should also be taken jointly, and in as large a quantity as the system will bear. Even sleep is less necessary than both these: nor should the patient be suffered to rest for a period of three hours at a time without fresh doses of both, though we wake him for the purpose. Time, indeed, is here every thing: if we make no progress in the first thirty-six hours, we may tremble for the event. Women, unaccustomed to wine, have taken it successfully under this disease, in the proportion of two bottles a day, for more than a fortnight.*

* The therapeutical indications in the malignant form of paristhmitis, as stated by American physicians, vary much. Many rely principally on the employment of powerful stimulants externally and internally; with others, the application of leeches near the part affected, and sometimes general bloodletting, are considered expedient. No remark from us is necessary as to the utility of blisters, and other counter-irritants, which should be applied early. The utility of lunar caustic, but in a solution much stronger than that prescribed by Dr. Good, and gargles made with the chlorurets of lime and soda, and with diluted pyroligneous acid, have found strong advocates with us. A century ago, mercurial remedies were recommended in the treatment of the malignant throat distemper, by Dr. Wm. Douglass, of Boston. This author's description of the disorder, as it prevailed epidemically in several parts of New-England, in 1735-6, contains conclusive testimony as to its formidable character, and mercury was used on the principle "*similia similibus curantur*," or, to quote his own words, "as any affection of the throat does frequently produce a natural ptyalism, mercurials, used with discretion, are a kind of specific in such like ulcers and ulcercula; among all mercurial preparations, calomel answered best; turbitb proves generally too strong a revulsion."—(*Pract. Hist. of a new Epid. Eruptive Miliary Fever, &c.*, Boston, 1736; and N. E. *Journ. of Med. and Surg.*, vol. xiv., p. 1.) So

QUINSY OF THE PHARYNX is, properly speaking, that which commences in this organ. It is met with but rarely; nor is it, when it does occur, a case of serious importance. It is distinguished by the florid redness of the inflammation, especially at the lower part of the fauces, and by the nature of the fever, which is a *cauma*. The pain, indeed, extends sometimes behind the sternum, but is only felt in swallowing. The breathing is not affected. A cure is easily induced by swallowing slowly nitrous and mucilaginous medicines, and taking off the phlogotic diathesis, where it prevails, by bleeding and brisk purgatives.

QUINSY OF THE ŒSOPHAGUS, the *cynanche œsophagitis* of Professor Frank (*De Cur. Hom. Morb. Epit.*, tom. ii., p. 104, 8vo., Mannh., 1792), is more deeply seated than the preceding, though the inflammatory blush often extends to the fauces. The food will in consequence pass forward to the seat of obstruction, but no further; and, by irritating the inflamed part, produces a painful effort to vomit, which continues till, by a severe struggle, which occasionally reaches to the back-bone, the ingulfed morsel is dislodged, and thrown back into the mouth.

M. Bretonneau, in a recent work of great value, has given instances in which the inflammation before us, instead of leading to ulceration, shows a tendency to the production of concrete and membranous exfoliations, precisely like those of croup; into which disease it occasionally passes by an extension of the inflammatory action from the fauces or tonsils to the glottis. To this modification he has given the name of *angina diphtheritica*, or croupal sore-throat: and wherever it exists its treatment is to be that of this last disease.—(*Des Inflammations Spéciales du Tissu Muqueux, &c.*, Par P. Bretonneau, Paris, 8vo., 1826.)

SPECIES V.

EMPRESMA LARYNGITIS.

INFLAMMATION OF THE LARYNX.

PAIN ABOUT THE LARYNX; EPIGLOTTIS SWOLLEN AND ERECT; BREATHING SHRILL AND SUFFOCATIVE; GREAT ANXIETY; DEGLUTITION IMPEDED; FEVER A CAUMA.

It is doubtful whether this severe and dangerous complaint has ever been described till of late years. It seems to have been known to Dr. Mead, whose general account coincides with a disease noticed by Hippocrates. It is minutely and accurately detailed by Dr. Home, in his *Principia*; and is the subject of several

early as 1751–2, the late venerable Dr. Holyoke, of Salem (Mass.), informs us, that he was in the habit of prescribing mercurials. Dr. Ogden, of Jamaica (L. I.), in his letters on the malignant sore-throat distemper, dated Oct., 1769, and Sept. 14, 1774, warmly enjoined the mercurial practice; and he assures us, that he administered the *mercurius dulcis* freely in the sore-throat disease, both in children and adults, about twenty years before the date of his first publication. "Perhaps it is most safe to divide the merit of this bold and adventurous practice between Dr. Douglass and Dr. Ogden; the authority of the latter, however, had

excellent papers in the Transactions of the Medico-Chirurgical Society, particularly by Dr. Farre, Sir Gilbert Blane, Dr. Roberts, and Dr. E. Percival. It is particularly and accurately described by Professor Frank.—(Ut *suprà*, tom. ii., p. 105.) The disease, as will be perceived by the definition, bears a considerable resemblance in many of its symptoms to croup; is highly acute, and destroys by suffocation in a day or two, unless very actively opposed. Frequently, indeed, it destroys much sooner.* Brassavoli mentions a case that proved fatal in ten hours (*Comment. ad Hippocr. de Rat. Viet. Acut.*, lib. iv.); and Schenck another, in which suffocation and instant death were produced by a fit of vomiting, the spasmodic action having extended to the stomach or its auxiliary muscles.—(*Obs. 29, ex Trincavellio*, lib. ii.) Of three cases described by Dr. Baillie, each proved fatal; two of them on the third day, and one on the fourth. The patients had all been previously subject to inflammation of the throat, and were between forty and sixty years of age.—(*Wardrop's edition of Baillie's Works*, vol. 2. p. 54.)

It is produced by cold or the usual causes of quinsy, but has been often excited by too much exertion of the organ in singing, or public speaking.

The disease makes its approach with the common symptoms of inflammatory fever, as chilliness succeeded by heat; the voice becomes hoarse and indistinct; the breathing laborious, with a painful sense of constriction in the throat; the fauces present a Modena-red colour, and are considerably swollen and turgid, the swelling extending to the face and eyes, the latter not unfrequently protruding, as in cases of strangling; though occasionally the inflammation is confined to the larynx, and no peculiar appearance is to be traced on the tonsils, uvula, or velum palati (See *Mr. Coekburn's Case*, *Edin. Med. and Surg. Journ.*, Apr., 1823); the pulse is quick, and the tongue furred; and every attempt to swallow is accompanied with great distress; the muscles of deglutition, and even those of the chest, being thrown into severe spasms, threatening the patient with instant death from suffocation, and making him call out for air and an opening of the windows.

It is distinguished from croup by the existence of a perpetual and voluntary hawking, rather than a forcible and involuntary cough, as though to clear the passage by expectoration. It is also distinguished from it by the nature of the expectation, which is a viscid mucus, rather

great weight in extending the mercurial treatment in sore-throat affection, and in other diseases of an acute nature."—(Thacher's *Am. Med. Biography*, life of Ogden.) It was deemed suitable in this place to substantiate the claims of American physicians to this novel method of practice, however bold it has been pronounced by some.—D.

* "I have seen it," says Armstrong (Lect. on the Morbid Anatomy, Nature, and Treatment of Acute Chronic Diseases, London, 1831, p. 268), "in one case terminate fatally in seven hours from its commencement; in another case it ran its course in eight hours."—D.

than a coagulable and membrane-like exudation. The two diseases differ, moreover, in their proximate causes as considerably as in their symptoms. Laryngitis consists in a *suppurative* inflammation of the membranes of the larynx, extending backward to the membrane common to itself and the œsophagus, between which pus is often found lodged; while croup or bronchlemlitis is a *peculiar* inflammation of the trachea, extending through the bronchial vessels, and exciting, on their internal surface, the secretion just noticed of a concrete filmy material, which threatens suffocation by filling up the opening of the rima glottidis. [How far this last statement agrees with the facts revealed by morbid anatomy, will be considered under the next species.*]

In the treatment of this distressing malady, our object should be to take off the inflammation by the most active means. For this purpose, eighteen ounces of blood should be instantly drawn from the arm, and eight or ten from the throat by leeches; and the bowels should be thoroughly purged by calomel and jalap, or some other active cathartic. In connexion with this process, many writers advise the application of blisters, and the use of relaxant inhalations. But, in preference to both, I would recommend gargles of ice-water acidulated, and epithems of pounded ice applied externally. Professor Frank recommends, as in bronchlemlitis, a free use of calomel, in the proportion of five grains at a dose to infants of two years old, two or three times a day, or three grains every three hours, till fifteen grains have been taken. If this plan do not speedily answer, no time is to be lost, and bronchotomy must be had recourse to. But whether the opening should be made in the larynx or below it, must be left to the judgment of the surgeon.

In a few instances, however, this disease seems to commence with comparatively little violence, and to run easily into a chronic form.

[A disease, well deserving of the name of

chronic laryngitis, has been faithfully described by Mr. Lawrence. The patients died of suffocation; but the progress of the complaint was slower than in the more acute modification of the disease, noticed by Drs. Farre, Percival, and Baillie.—(See *Med. Chir. Trans.*, vols. iii. and iv., and *Trans., of a Soc. for the Imp. of Med. Knowl.*, vol. iii.) The symptoms were not acute, nor did the inspection of the parts disclose any marks of active inflammation. The membrane covering the chordæ vocales was thickened, so as to close the glottis; and a similar thickening extended to a small distance from these parts, accompanied with an œdematous effusion into the cellular substance under the membrane. The epiglottis did not partake of the disorder. In one or two instances, this thickened state of the membrane was the only change of structure observed; but in others, it was attended either with ulceration of the surface near the glottis, appearing as if it had been formed by an abscess which had burst; or with a partial death of one or more of the cartilages of the larynx; viz., the arytenoid, thyroid, or cricoid. The rest of the air-passages, and the lungs, were healthy. In most cases, Mr. Lawrence is an advocate for the early performance of bronchotomy.—(*Med.-Chir. Trans.*, vol. vi., p. 221, &c.) The prospect of success will of course very much depend upon the state of the lungs, and the disease being free from any other serious complication.]

In the *angina laryngea œdematosa* of M. G. L. Bayle, the expulsion is glairy, rather than membranous. In the course of the chronic inflammation by which the disease is marked, and which produces the effusion, a few tubercles or caruncles are formed, that render inspiration suffocative, yet interfere but little with expiration. A cough, as may be expected, is sometimes a concomitant.

This form of inflammation has generally been found to take place in debilitated habits, or after

* The following passage from an article on laryngitis, written by Dr. Cheyne, merits attention:—"We acquire," says he, "a juster view of laryngitis, by contrasting that disease with croup. They are both truly inflammatory diseases, but in that point alone do they resemble each other. Croup is a disease occurring before puberty, generally affecting not merely the larynx, but the whole of the bronchial membrane; ending in an effusion of lymph on the free surface of the membrane; to be cured, probably, in ninety-nine cases of a hundred, by emetics and bleeding timely employed; and it is a disease in which a surgical operation will only add to the danger, to which, in its second stage, the patient is exposed. Laryngitis, on the other hand, is a disease which rarely occurs before puberty; is confined to the upper extremity of the windpipe; ends in a serous effusion into the cellular tissue beneath the mucous membrane; will probably terminate unfavourably, in a great majority of cases, under any method of treatment, in which emetics aggravate the danger, and bleeding is often a doubtful remedy, and in which, when the patient is *in extremis*, bronchotomy will afford the only reasonable hope of safety.—(*Cyclop. of Pract. Med.*) It seems questionable, however, whether this contrast may not, in one

VOL. I.—H h

respect, go rather too far; for the editor, some time ago, presented a specimen of laryngitis to the London University, taken from a person who died of scarlet fever; and in this instance, there was a thick layer of lymph effused, not only on the lining of the larynx, but on that of the trachea. In the foregoing quotation, the facility of curing croup has probably been overrated. With respect to the doubtful good effects, of bleeding in laryngitis, this observation seems to be intended only for particular cases, because Dr. Cheyne has adduced abundant proof of the benefit often derived from the free use of the lancet in this disorder. At the same time, he refers to instances in which bleeding had pernicious effects. We may, says he, with comparative safety, bleed while the complexion is good, or, in other words, as long as the quantity of atmospheric air admitted into the lungs is sufficient to produce that chymical change, by which venous blood, in passing from the right ventricle into the right auricle, is converted into arterial; but when the blood is no longer arterialized; when the face and lips become livid, the expression anxious, the eyes protruded and watery, Dr. Cheyne sets down bleeding as injurious. Under such circumstances, either laryngotomy or tracheotomy is indicated.—Ed.

an exhausting fever, or some other complaint. If the patient recover, it is usually in about three weeks: for the most part, however, no remedial plan succeeded at La Charité, and the disease terminated fatally in about a month or six weeks. Tracheotomy was often tried, but rarely with success. On dissection, some degree of ulceration, or purulent discharge, was commonly traced.—(*Mém. sur l'Œdème de la Glotte, ou Angine Laryngée Œdémateuse; Nouveau Journ. de Med.*, Janv., 1819.) It ought to be observed, that Dr. M. Hall, Mr. F. White (*Dublin Hospital Reports*, vol. iv., p. 561), Mr. Liston (*Edin. Med. and Surg. Journ.*, No. lxxvii., p. 568), and others, have since succeeded with tracheotomy in several instances in our own country. If the inflammatory action commence below the larynx, it is called *tracheitis* by Professor Frank (*De Cur. Hom. Morb.*, tom. ii., p. 107); yet the pain and struggle are here considerably less than in proper laryngitis, though they sometimes resemble the signs of sternalgia, or angina pectoris.*

* Several American writers have contributed to our knowledge of this affection, as Prof. James Jackson of Boston, Dr. Dick of Virginia, Drs. Bliss and Peixotto of New-York, &c. The most valuable monography is that by Dr. J. B. Beck, of New-York.—(*N. Y. Med. and Phys. Journal*, vol. iii., p. 397.) This author has traced the disease in the writings of Cœlius Aurelianus, Celsus, Tulpus, Riverius, Morgagni, Lommius, Boerhaave, and Lieutaud. Dr. Beck regards laryngitis as purely local in its origin, affecting males rather than females, probably on account of the greater development of the larynx in the former, and as generally attacking adults; in the few cases recorded of its occurrence among children, it has been caused by the application to the part of a powerful stimulus, as steam, &c. The disease of which General Washington died, is justly considered by Dr. Beck to have been laryngitis. In the treatment of this disorder, Dr. B. thinks the indications of cure are “first to arrest, if possible, the progress of inflammation, and thus prevent effusion; and if we should fail in this object, in the second place, by means of an artificial opening in the trachea, to enable the patient to breathe, until the obstructions in the larynx may be removed, either by the process of absorption or by the aid of medicine. Our means for accomplishing the first are bloodletting, emetics, cathartics, blisters, and mercury. The second requires the operation of tracheotomy.” Bloodletting should be pursued freely, without regard to the absolute quantity which may be drawn, but to the effect produced on the system. This effect is syncope. Emetics relieve, not merely by their relaxing effects on the system, but by the copious secretions they produce from the mouth and fauces. Purgatives aid by lowering the general tone of the system. Blisters, to be useful, should be applied early, and to the chest, abdomen, or inside of the thighs. In regard to mercury, he says, “that after the use of depletion and emetics, there is no article within the knowledge of our art which can be trusted to, with such just confidence for accomplishing a cure, as calomel.” Dr. Beck thinks it important that the operation of tracheotomy should not be deferred till the last stages of the disease, and till the patient is already sinking, and that it should be tried in all cases where other means have proved ineffectual.—D.

SPECIES VI.

EMPRESMA BRONCHLEMMITIS.
CROUP.

BREATHING PERMANENTLY LABORIOUS AND SUFFOCATIVE; SHORT DRY COUGH; EXPECTORATION CONCRETE AND MEMBRANOUS; FEVER A CAUMA.

IN the first edition of the present work, as also in that of his volume on Nosology, the author was induced to follow M. Swediaur, Dr. Young, and various other authorities, in denominating this disease BRONCHITIS; but as the same term is used in a very different sense by various other writers, importing inflammation of the bronchiæ generally, though a sense hardly called for, as, except in the present instance, such affection is usually a symptom of catarrh, or some form of pneumonitis, he has been induced to change the name of bronchitis for that of BRONCHLEMMITIS, which, as importing MEMBRANOUS or MEMBRANE-LIKE inflammation of the bronchiæ, from *λίμνα*, “a sheath or membrane,” as in neurilemma, a sheath or membrane of the nerves, is expressly descriptive of that concrete or tubular effusion which peculiarly characterizes the complaint. In a valuable treatise published by M. Bretonneau, of Tours, since the second edition of the present work, it has been described under the name of *Diphtheritis*, from *διφθέρω*, *pellis*, *exuvium*.*

[According to Laennec, Ballonius, in 1576, made the first mention of the disease.† The best informed critics, however, now incline to the opinion, that croup was not unknown to physicians of more ancient times. The particular merit to which Ballonius may rightly aspire, is that of having first distinctly described the effusion of coagulable lymph, or the false membrane in the larynx and trachea.‡ Laennec himself admits, that we owe the first good description of croup to Ghisi.—(*Martin Ghisi, Lettere Mediche*, Cremona, 1749.) Dr. Home's “Inquiry,” which, as Dr. Forbes observes, was the first systematic account of croup in this country, was published in 1765.]§

* Des Inflammations spéciales du Tissu Muqueux, et en particulier de la Diphthérie, ou Inflammation pelliculaire, connue sous le nom de Croup, &c. Par P. Bretonneau, médecin en chef de l'Hôpital de Tours, 8vo., Paris, 1826.

† A learned paper, entitled, “Observations tending to ascertain whether the ancients were acquainted with croup,” may be seen in the *Am. Journ. of Med. Science*, vol. iii., p. 56. It is written by Dr. John R. Cox, of Philadelphia, and its object is to prove that the disease was known to Hippocrates, Galen, and many other writers, who existed anterior to those referred to by Michaelis, Cheyne, &c.—D.

‡ Ballonii Op. Omm. Med., tom. i., p. 132. Venet., 1734. Also Rubini, Riflessioni sulla Malattia denominata Crup, p. 200; and Forbes's *Trans. of Laennec on Diseases of the Chest*, p. 118, note, 2d edit.

§ For a complete bibliographical history of croup, Dr. Forbes refers to Michaelis, *De Angina Polyposa*, Argent., 1740. Rubini, *Riflessioni sulla Malattia comunemente denominata Crup*, Parma, 1813; and Bretonneau, *De la Diphthérie, ou Inflammation Pelliculaire*, Paris, 1826. These au-

This disease appears in the present day to exist in most parts of the world, and in the American states is called *hives*, supposed by my distinguished friend Dr. Hosack to be a corruption of the term *heaves*, and probably so named from the heaving or violent efforts of the muscles of the chest and abdomen which take place in breathing during its course.

The writers on croup have given but one form of it, except what has been erroneously called spasmodic croup, a disease of a different kind, which has already been described under the name of *LARYNGISMUS STRIDULUS*. Properly speaking, however, there are two forms, an acute and chronic, under which the present species shows itself, and which may thus be distinguished as varieties:—

- a Acuta.** Sense of suffocation keen, and constrictive; chiefly seated in the larynx; respiration sonorous; voice harsh; cough ringing; great restlessness; terminating in a few days.
- Acute croup.**
- β Chronica.** Sense of suffocation obtuse and heavy; chiefly seated in the chest; cough severe, but intermitting; lasting some weeks or months.
- Chronic croup.**
- Bronchial polypos.**

The disease, in both varieties, usually commences with the common symptoms of a cough or catarrh; but essentially consists in a peculiar inflammation, that spreads through different parts, or even the whole range, of the wind-pipe, from the larynx to the minutest ramifications of the bronchiæ. In this extensive sense, the tube was called *bronchus* by the ancients; and I have hence preferred the term *bronchlemmatitis* to that of *trachlemmatitis*, or membranous inflammation of the trachea, as such a term would imply a limitation of the inflammatory action to the upper part of the bronchus alone, to which it is not confined in either of the forms before us.

The FIRST VARIETY, importing the common or ACUTE CROUP, the suffocatio stridula of Dr. Home, though it extends thus widely, usually commences in the larger parts of the tube; during which a peculiar effusion is secreted, that readily assumes a membranous form,* and sometimes lines, not only the trachea above its bifurcation, but also its minutest branches, though the larger parts of the tube are first affected. When chymically examined, the secre-

tion appears to consist chiefly, if not entirely, of the gluten, or coagulable lymph of the blood, diluted with its serosity, and copiously combined with that peculiar substance of the blood, detected by the labours of modern chymistry, which, from its essential tendency to concreate into a fibrous, and even a membranous texture, has received the name of fibrin.

By what means the raucous secretions throw forth this peculiar effusion in the present disease, we know not. It is said by some writers to be secreted on no other occasion, and by no other organ; but this is unquestionably a mistake. There are few practitioners, perhaps, of accurate observation, who have not found it discharged at times from the intestinal canal; of which I have already given examples under *DIARRHŒA tubularis*; in which, as in croup, there is an inflammatory affection of the morbid organ, and a spasmodic constriction of the passage.*

[Croup, says Professor Laennec, is an inflammation of the mucous membrane of the air-passages, with exudation of coagulable lymph, which, becoming concrete at the very moment of its formation, lines the inner surface of this membrane to a greater or less extent. When this false membrane is removed, the subjacent tunic is found of a deep vivid red colour, occasionally livid and somewhat thickened. This colour is commonly very uniform over the whole space, covered by the false membrane, but is also not unfrequently unequal, and occasionally is even altogether wanting.—(*Hufeland's Journ.*, b. vi., p. 559.) In the greater number of cases, the degree of redness and swelling is less, than in many instances of dry catarrh. We cannot, therefore, attribute the plasticity of the secretion in croup, the distinctive feature between it and the mucous catarrh, simply to a higher degree of inflammation; but rather to the peculiar nature of that inflammation. The false membrane corresponds exactly to the form of the canals which it invests. Its thickness is usually somewhat greater in the larynx and trachea than in the bronchiæ, and varies from less than half a line to a line. Its consistence is about that of boiled white of egg; but this generally diminishes towards its extremities. It is of a white colour, sometimes with a shade of yellow, and is almost entirely opaque.

Some days, or even hours, after its formation, it begins gradually to be detached from the mucous coat, to which it had been closely adherent, and, after being broken into fragments by the cough, is sometimes expectorated. The separation is effected by a more liquid secretion, which, becoming in its turn also concrete, constitutes a second false membrane. This process may be repeated several times in succession; but, in general, each successive formation

thors prove, by extracts, that the croup was known to several ancient physicians, particularly Hippocrates and Aretæus; although its precise anatomical characters were not so, owing to the imperfect state of pathological anatomy.—See Laennec on Diseases of the Chest, &c., trans. by Forbes, note, p. 118, 2d edit.—Ed.

* An excellent plate of this membranous formation, resembling a morbid specimen in the cabinet of Dr. J. W. Francis, of New-York, may be seen in the *Am. Med. and Phil. Reg.*, vol. ii., p. 41.—D.

* Inflamed mucous membranes, generally speaking, are more disposed to pour out a purulent, or muco-purulent fluid, than coagulable lymph; but, when the inflammation is violent or peculiar, as it is in croup, the latter substance will be effused.—Ed.

is less consistent than the preceding. The croupy membrane is most commonly restricted to the larynx and upper part of the trachea; but, in other cases, it extends over a great portion, or even the whole, of the bronchial ramifications. Sometimes, the disease is confined to the bronchiæ and their ramifications. More commonly, as has been shown by Bretonneau, the inflammation commences on the tonsils or the pharynx, and from thence spreads, at the same time, downwards to the larynx, and upwards to the nostrils. The affection usually stops at the œsophagus, but occasionally the false membrane extends to the stomach. In children, the disease almost always begins in the bronchiæ, or larynx, and very rarely extends beyond the glottis; while, in adults, it more frequently originates on the tonsils or pharynx. M. Bretonneau has also shown that what may be called plastic angina, has been frequently mistaken for malignant sore throat. While, however, Dr. Forbes admits the correctness of the statement, that what has often been considered as a gangrenous affection of the throat is merely an inflammation of the same kind as that of croup, and characterized by the formation of a membranous exudation of a peculiar kind, he does not assent to the proposition, that simple croup, or croup unaccompanied by any pharyngeal affection, does not exist as a separate disease.]*

Dr. Cullen asserts that acute croup seldom attacks infants till after they have been weaned, and that there is no instance of its occurring in children above twelve years of age. As a general rule this remark holds, but the disorder is by no means unfrequent in infants at the breast, of which I had one example not long ago: and it has been found occasionally in persons considerably above twelve years of age.† Those who have once had it are more susceptible of it than before; though the susceptibility gradually wears off as they grow older. It is found equally in midland regions and on the coast, but, perhaps, more frequently in low, marshy grounds than in drier uplands. [Our author believed that there is no unequivocal instance of its being contagious, though it is occasionally epidemic: and Dr. Elliotson has never seen a case in which the circumstances satisfied him that it originated from contagion.—(*Med. Lect. at Lond. Univ., vid. Med. Gaz.* for 1832-3, p. 66.) Some modern practitioners, however, among whom are Lobstein (*Mem. de la Société Méd. d'Emulation*, vol. viii.) and Bretonneau (*De la Diphtérie*, 8vo., Paris, 1826), mention

contagion as one of the causes of croup. A fact recorded by the latter physician, and quoted by M. Guersent (*Nouveau Dict. de Médecine*, art. ANGINE COENNEUSE), is considered by M. Louis to be perfectly conclusive on the point. In another instance, related by M. Lobstein, a young girl who had not been exposed to the same atmospheric influence as her sister, already ill with croup, was attacked by it after having been playing with her at the time when her disease was completely developed. Dissection after death left no doubt of the nature of the disease. Other facts, tending to prove the contagious nature of croup, are adverted to by M. Louis. Professor Laennec also refers to a case showing the danger of respiring the patient's breath too closely.—(*Op. cit.*, p. 125.) The asthenic croup, described by Bretonneau as occurring in the hospitals of France, and often joined with malignant angina, is certainly contagious.]

Acute bronchlemmitis commences usually in the evening, with a slight cough, hoarseness, and sneezing, as though the patient had caught cold, and was about to suffer from a catarrh. And to these, in a day or two, succeed a peculiar shrillness and singing of the voice, as if the sound were sent through a brazen tube. "At the same time," says Dr. Cullen, who has well described the progress of the disease, "there is a sense of pain about the larynx, some difficulty of respiration, with a whizzing sound in inspiration, as if the passage of the air were straitened. The cough which attends it is sometimes dry; and, if any thing be spit up, it is a matter of a purulent appearance, and sometimes films resembling portions of a membrane. Together with these symptoms, there is a frequency of pulse, a restlessness, and an uneasy sense of heat. When the internal fauces are viewed, they are sometimes without any appearance of inflammation; but frequently a redness, and even swelling, appear; and sometimes, in the fauces, there is an appearance of matter like that rejected by coughing. With the symptoms now described, and particularly with great difficulty of breathing, and a sense of strangling in the fauces, the patient is sometimes suddenly cut off."—(*Pract. of Phys.*, cccxxiv.) To which I may add, that the countenance exhibits great distress; the head and face are covered with perspiration from the violence of the struggle; the lips and cheeks are alternately pale and livid.

Dr. Cheyne, who has written one of the best treatises on croup in the English language, has adverted to the following changes, as indicating the different stages of the disease and the degrees of danger.

1st, There is a ringing, croupy cough (to which many children are liable upon taking cold, more particularly those who have had an attack of croup), attended with little or no change in the breathing or sound of the voice.

2d, The unusual shrill, croupy cough, with difficult breathing; the necessary supply of air being with difficulty inspired, from the obstruction of the passage. The voice is altered, bro-

* See Laennec on Diseases of the Chest, p. 119, 2d edit., transl. by Forbes; also, M. Bretonneau sur la Diphtérie, Paris, 1826; and P. Ch. A. Louis, Mém. et Recherches Anat. Pathol., p. 242, &c., Paris, 1826.

† Du Croup, considéré chez l'adulte, in Mém. et Recherches Anat. Pathol., Par M. Louis, p. 203, &c., Paris, 1826. According to Dr. Cheyne, the disease may occur at any period, from the second or third month after birth to puberty; and he believes, with Professor Home, that the younger children are when weaned, the more liable are they to croup. After puberty it rarely occurs.—Cyclop. of Pract. Med., art. Croup.

ken, both hoarse and puling. The difficult breathing in croup has been compared to the sound of air passing through thick muslin: it rather appears, says Dr. Cheyne, like the sound of a piston forced up a dry pump. It varies considerably, however; for it is either like the sound to which it has just now been compared, dry and hissing, audible in different degrees; or, when the swelling and spasm of the larynx are greater, it is crowing, and sometimes creaking and suffocative. Under this extremity of difficult breathing, children are said to have perished.

3d, The cough and voice are stridulous; the respiration is difficult, laborious, creaking, sometimes suffocative, varying in the degree of difficulty and laboriousness.

4th, The voice is whispering and low; the cough less frequent, and not audible at the opposite side of the room. There is the act of coughing without the sound; the respiration increasing in difficulty and quickness, laborious and interrupted.

1. According to Dr. Cheyne, the first is a state which is rather the forerunner of an alarming attack of croup. It is often without danger. It points out the children, who, when exposed to the usual excitements, are most liable to croup.

2. When, with the croupy cough, the breathing continues difficult, the serious attack has commenced, and the child is in danger. In this state, the skin is warm, the tongue white, the pulse full and quick, and the countenance much flushed. The usual mucous secretion is interrupted; the patient, if not an infant, is timid and apprehensive; and the eyes are heavy, watery, and bloodshot. The degree of danger is now to be estimated by the breathing.

3. This state denotes the second stage of croup, or that of effusion, which, according to Dr. Cheyne, is generally hopeless. The countenance is still flushed; but with marks of defective circulation. The lungs no longer purify the blood. There is a purple redness in the cheeks, eyes, and nails. The complexion is often mottled, or the flush on the cheeks is circumscribed. The pulse is smaller and very quick. There is sometimes an expectoration of mucus, mixed with flakes of puriform matter. The urine has a sediment in it. The eyes are prominent and bloodshot; the pupil is dilated, and the iris pale. When the breathing is most violent jactitation occurs, and lethargy when it is least disturbed.

4. This is the morbid state. The trachea is coated with effusion. The face is leaden, and the eye filmy. The extremities are cold and swelled. The muscular power is exhausted, and the child nearly insensible.—(*Cheyne's Pathology of the Larynx and Bronchia*, 8vo., Edinburgh, 1809.)

The editor deems the following observations, made by Professor Laennec on the symptoms of croup, well deserving of attention. If we except the expectoration of membranous fragments, or the appearance of false membrane in the fauces, not one of the symptoms is pa-

thognomonic. The croupy voice, or sound, independently of its not being always well marked, does not occur until after the disease has made great progress. The cough, he says, is similar, or nearly so, in other diseases, particularly in certain cases of whooping-cough, in which the *sonorous inspirations* sometimes perfectly resemble the crowing of a cock. Laennec had of late only met with one case of croup sufficiently severe to be recognised from the beginning. It was soon more fully characterized by the expectoration of fragments of false membrane, moulded on bronchiæ of different diameters. In this case, which occurred in a child six years old, the stethoscope detected, during the whole course of the disease, no other respiratory sound but that of a *dry respiration*, evidently tubular or bronchial, unmixed with any of that crepitous dilatation of the pulmonary cells so strongly marked in infancy. This sign, coinciding with a natural resonance of the chest, will suffice, if it is constant, to indicate croup affecting the bronchiæ; since it exists in no other case, except sometimes, and in a much less degree, in dilatation of the bronchiæ; a chronic affection, generally of very partial extent, and not liable to be confounded with croup.]—(*Laennec*, op. cit., p. 124.)

The essence of croup consists in the secretion of the viscid and concrete lymph, which is perpetually endangering suffocation. Dr. Cullen does not dwell sufficiently upon this symptom; but ascribes the danger principally to spasmodic action, and represents the accompanying fever, which, on his hypothesis, is also a spasmodic action, to be very considerable; but spasm was with him, as we have already seen, a favourite doctrine, and his judgment was often warped by it. Dr. Marcus, who regards all fevers as inflammation of some organ or other, and as entirely seated in the arterial system, regards croup also as a local inflammation alone, utterly independent of spasm, which neither exists here nor in fevers of any kind; and attributes the danger to this symptom solely: which is the more extraordinary, as he regarded croup to be a disease identic with whooping-cough, in which the spasm or convulsion is the most prominent symptom. [Croup, even when most partial, is almost always attended with great constitutional disturbance. In the majority of cases, the symptomatic fever is acute, and very severe; the action of the heart being frequently irregular. In some cases, particularly such as occur in hospitals, it is observed by Laennec, that the pulse is but little accelerated, the skin rough and dirty, the debility extreme, and the breath fetid, even where no gangrenous specks exist in the throat. This variety is denominated *asthenic* by Guersent and Bretonneau, and is that which is found sometimes to accompany malignant sore throat.]—(*Laennec*, op. cit., p. 123.) The locality of the disease, as well as the peculiar character of the inflammation, sufficiently distinguish it from catarrh, in which there is also some inflammation of the mucous membrane of the trachea, though of a common kind, and rarely limited to this organ. In children,

however, it frequently treads close upon catarrh, measles, hooping-cough, and any other disease that has debilitated the powers of the lungs: for, as Dr. Michaelis observes, whatever tends to weaken or produce any degree of irritation in the lungs, so as to occasion a preternatural secretion into that organ, may be considered as a predisposing cause of croup.* Professor Dupuy, of the Veterinary School at Alfort, gives an instance of its having been communicated in a village, in which it was epidemic, to a dog, brought under his care from a mistaken idea that the dog was suffering from hydrophobia. During the progress of the disease this animal had the shrill, ringing voice of children labouring under it; and speedily died of suffocation. On opening the body, a false membrane was found in the larynx, of a reddish colour, which extended to the bronchiæ; and the lungs were filled with an abundant serous effusion.—(*Bibl. Méd.*, Août, 1822.)

[M. Louis has published some highly interesting observations on the croup of adult persons, and ably pointed out both its agreements with, and difference from, the same disease in children. In the latter subjects it resembles at first a slight cold, speedily followed by pains in the forepart of the neck, and usually preceded by sore throat. The cough soon becomes violent, recurring in paroxysms: there is a hissing sound in the breathing; with dyspnoea; the croupal voice, &c. On the contrary, in adult patients, there is more or less soreness of the throat at the very commencement of the attack, accompanied with heat, difficulty of deglutition, and little or no cough. The inflamed tonsils and pharynx soon become covered with coagulable lymph, and then pain begins to be experienced in the larynx and trachea, speedily followed by dyspnoea, anxiety, change of the voice, but rarely with suffocative paroxysms, even in the last hours of existence. M. Louis, however, regards this description as only generally applicable, since, in many cases lately recorded, children are represented to have had a soreness of the throat as one of the earliest symptoms; and, according to M. Guersent, croup frequently begins in this way in infants at the breast. In the croup of adults, the nasal fossæ, the pharynx, the velum palati, the uvula, the tonsils,

the larynx, the trachea, and sometimes the bronchiæ, were found, on dissection, covered with coagulable lymph, or a false membrane, the consistence and thickness of which diminished according to the order in which the parts are here specified.]—(*Mém. et Rech. Anat. Path.* pp. 239–242, &c.)

The cure demands prompt and active remedies; and must depend, not so much upon searching into and correcting the remote cause, or even counteracting the spasm, as in counteracting the inflammation, preventing the further effusion of lymph, and promoting the loosening and discharge of that which already invests and obstructs the larynx and trachea.

There is in the patient a perpetual effort to remove this solid secretion by coughing; but the cough is for the most part dry and ineffectual, and nothing more than a little flaky mucus is excreted. Very copious bleeding* at the commencement of the attack, by breaking down abruptly the inflammatory action, has sometimes carried off the disease at once. This M. Fieliz and Dr. Cheyne recommend from the jugular veins (*Fieliz, Richter's Chir. Bibl.*, b. viii., p. 531), and M. Ghisi by topical scarifications; but, in infancy, leeches will usually be found to answer best; and, in adults, their repeated application may be useful after general bleeding. Emetics have afterward been tried, but with doubtful success: sinapisms and blisters, with as little.

[It deserves to be mentioned, however, that all these means are spoken favourably of by Professor Laennec (*Op. cit.*, p. 126–7) and Dr. John Forbes; and that emetics are the remedy in which Dr. Cheyne has most confidence. When an attack of croup is apprehended, the latter physician prescribes an emetic, the warm bath, a dose of jalap and calomel, and dilution. When the first stage is formed, he has recourse to an emetic, the bath, a mercurial purge, venesection, a blister over the sternum, calomel in doses of one, two, or three grains every hour, diluents, and the antiphlogistic regimen. In the second stage, emetics are his chief remedies; and he has recourse to cordials when the strength flags.] The inhalation of warm vapour, recommended by Dr. Home, can rarely be practised, from the extreme restlessness of the little patient; and the remedy principally relied upon in the present day, and which certainly seems in many instances to have operated like a charm, is large and repeated doses of calomel; of this, not less than five or six grains are commonly given to very young children, and continued every two or three hours till there is a discharge of a green bilious matter, which seems to be the criterion of its having

* On the coast of the Frith of Forth the disease is said to be endemic; and it is also alleged to prevail to a great extent on the coasts of Ireland, in the winter and spring seasons. These facts are noticed by Dr. Cheyne (*Cyclop. of Pract. Med.*, art. CROUP), who ascribes one principal exciting cause of croup to the influence of large bodies of water in the vicinity of any place, where the disease is remarkably frequent. On this principle, croup ought to be endemic on every part of the seacoast: no doubt there must be other circumstances concerned. The exciting cause is undoubtedly, in almost every instance, cold and wet; and hence its greater frequency in spring and winter than in other seasons. It is more common in northern than southern latitudes, and sometimes epidemic. An age under twelve years might be regarded as a predisposing cause of the disease.—ED.

* Michaelis, *Richter's Chir. Bibl.*, b. v., p. 739. Dr. Elliottson recommends bleeding from the arm or jugular vein, and the application of leeches to the throat. He would follow up general by local bleeding; and, after promoting the hemorrhage from the leech-bites with a poultice, would put on a blister.—(*Lect. at Lond. Univ.*, as published in *Med. Gaz.* for 1832–33, p. 66.) A proposal has been made to apply ice in a bladder to the throat, after the leech-bites have bled well.—ED.

taken effect, and not only excites a salutary counteraction, but prevents the further secretion of thick lymph. [The mercurial practice, joined with the antiphlogistic, is that of which the editor's observations lead him to entertain the highest opinion. The free and quick exhibition of calomel was first proposed by Dr. Rush, and afterward recommended by Dr. Hamilton. It has the sanction of Professor Elliotson, who pronounces it to be a better practice than that of giving emetics.] Relaxants, as antimony and ipecacuanha, should be employed during the action of the calomel: and as soon as this has answered, sedatives, as opium or hyoscyamus, may be united with the relaxants: but, above all, the hydro-cyanic acid, as already recommended in whooping-cough, and to the same extent. If this plan should not succeed, Dr. Michaelis recommends tracheotomy; and has so little apprehension of its being attended with danger, that he advises it to be had recourse to soon after the attack, as affording a convenient opportunity of bringing away the preternatural membrane which serves as a lining to the trachea.—(*De Angina Polyposa*, &c., ut *suprà*.) But this advice is given with more courage than judgment. Whenever the operation is performed, it should be after every other remedy has failed, and not before any other has been attempted. [When the exudation extends through the trachea, and ramifications of the bronchiæ, as the pathological observations of Laennec, Louis, and many other writers, prove to be frequently, though not always the case, there will be but little hope of benefit from such an operation.—(*Boyer, Traité des Mal. Chir.*, &c., tom. vii., Paris, 1821.) Dr. Cheyne also long ago showed, that the operation cannot be necessary for the purpose of letting air into the trachea; for in patients who died of the disease, he found a pervious canal one fourth of an inch in diameter.* He considered the operation as equally unfitted for the removal of the membrane; for, from its extent, tenacity, and adhesions, this is almost always impracticable; and even if it could be extracted, respiration would be but little improved, as the ramifications of the trachea and bronchial cells would still remain obstructed.†

The question relating to this operation is intimately connected with another point; namely,

* In the dissections of four patients who died of this disease, as recorded by Dr. James Jackson of Boston, the mucous membrane of the larynx was inflamed, but there was no false membrane or lining of coagulable lymph. and the trachea was pervious.—See N. E. Journ. of Med. and Surg., vol. i., p. 383.—D.

† See Cheyne's Pathology of the Larynx and Bronchia, Edin., 1809. Dr. Elliotson has tried bronchotomy without success; yet, after the failure of bleeding, mercury, blisters, cold applications, and even emetics (in which last he does not seem to put great confidence), he conceives that, if the patient's friends consented, after being told of the very slender chance of bronchotomy proving useful, such chance ought to be taken.—Lect. at Lond. Univ., as published in Med. Gaz. for 1832-33, p. 67.—Ed.

how far the fatal result of croup may be really owing to the obstruction of the glottis with coagulable lymph. If, says M. Louis, the false membrane lessen the air-passages of a child more than those of an adult, it is seldom in a degree sufficient to produce a mechanical impediment to the free circulation of air; and as death frequently occurs in children after the false membranes have been expectorated, this result is no longer ascribable, at least in all cases, to the mechanical impediment to the entrance of air into the lungs. The cases and dissections recorded by M. Louis, prove how rarely this impediment exists in the adult, in whom death takes place notwithstanding the breadth of the larynx; and he inclines to the opinion, that too much stress has been laid upon the mechanical obstruction of the air-passages, as an explanation of the cause of death in children: he imputes more effect to the spasm of the glottis and trachea; an explanation which he conceives is equally applicable to the adult and the young subject. But he observes, that it ought not to be forgotten, that the spasmodic symptoms never occur until the larynx has been lined with coagulable lymph, and hence this lymph, and the inflammation of which it is the production, are, in the opinion of M. Louis, always the primary cause of the spasm. He also adverts to various dissections by himself, M. Lobstein, and M. Vieusseux, from which it appears that the lungs and other organs do not exhibit after death the appearances commonly found in cases of asphyxia. At the same time, he conceives that the deficiency of respiration has a share in producing the fatal termination, but that the functions of the heart and lungs cease simultaneously, so as to make a difference from asphyxia, strictly so called.—(*Op. cit.*, p. 245.) The course of the disease, according to the view taken of it by Dr. Cheyne, is increased action, effusion, laborious respiration, circulation of blood with venous colour, sensorial debility, and death.]

Dr. Harden, of St. Petersburg, has of late, after every other remedy had failed, ventured upon cold affusion. He first tried it, in a fit of despair, upon a child of his own, eighteen months old. The child was placed in a bathing-tub, with its belly on a cushion of hay; and a pail of water, 12° Reaumur, was then poured quickly from the head along the spine. The symptoms, after the first affusion, soon diminished; the operation was repeated at intervals, ten times, and the child recovered. He has since employed it with like success in the first stage of the disease; and Dr. Miller, another physician of St. Petersburg, is said to have been, still more lately, as fortunate as himself.—(*Extr. of a Letter from D. Von dem Busch, of Bremen, to Dr. Eberle, of Phila.*, Jan. 6, 1822.)

Under the genus LARYNGISMUS, belonging to the second order of the preceding class, I have observed, that the spasmodic affection there described, from its inducing a sense of suffocation, and possessing various other symptoms resembling those of croup, has often been mistaken for this last complaint, and been denominated spasmodic croup; though without the pathog-

nomonic sign of a membrane-like exudation, and for the most part without any inflammation whatever. It attacks children suddenly, most frequently in the night, and is apt to return in paroxysms, with short intervals of ease; while the real acute croup has no intervals, but continues its alarming course, till it destroys the patient, or yields to the means made use of. During the action of the spasm, in the former case, however, there is a considerable hoarseness and shrillness in the voice, and, from the struggle, a profuse perspiration about the head and face. Violent as these symptoms are, they commonly yield to a brisk antimonial emetic: after the operation of which the patient commonly falls into a sound sleep, and awakes with little remains of the complaint.

THE SECOND OR CHRONIC VARIETY OF BRONCH-LEMMITIS I have introduced chiefly on the high authority of Dr. Warren, who calls it, as I have already observed, a bronchial polypus; a term which may lead to mistakes; and which, in its application to any other part of the body, does not import the febrile action which exists as a characteristic of this disease. A concrete parenchymatous material, obstructing the bronchial vessels, coughed up in smaller or larger masses, sometimes easily and without any attachment to the sides of the bronchial tubes, and sometimes so extensively insinuated by radicles or radiating vessels as to produce a fatal hemorrhage on their being thrown up with violence, has been noticed from a very early period in the history of medicine to the present day. Bartholine, Tulpius, Ruysch, Gretz, and Morgagni, have all been appealed to as giving examples of this affection; and it is very possible that even Hippocrates may allude to something of the kind (*De Morb. Popular.*, lib. vii., sect. xli.) in the case of Phericides, who, he tells us, was accustomed to bring up from his lungs, in a fit of coughing, γαλακτώδεια, "white milky concretions;" and at length, before he died, ολον ἐκ μύξης μυκτῶν, ξυνεστηκῶν, λευκῶν, φλέγματι περιεχόμενα, "firm mucus-like excrescences, surrounded with white phlegm." But the complaint does not seem to have been distinctly described till Dr. Warren's history of it.—(*Med. Trans.*, vol. i., art. xvi.) The case by which he chiefly illustrates it, is that of a young lady, eight years of age, of a strumous habit, who was suddenly attacked with difficulty of breathing, attended with a short, dry, and almost incessant cough; but without any pain in the side or chest. The symptoms diminished in the ensuing night, and the complaint appears to have been productive of little inconvenience for six weeks; when it returned with additional severity, with costive bowels, a white but moist tongue, and a pulse too quick to be counted. Bleeding, purgatives, and the oxymel of squills relieved her, but the breathing was still laborious; she had wasting night-sweats, and the pulse beat from a hundred to a hundred and twenty strokes in a minute for the ensuing twelve days; at the close of which period she awoke suddenly in the night, and was almost choked in bringing up, by coughing, what Dr. Warren calls "a large poly-

pous concretion." It came up without either blood or mucus, and instantly gave her great relief. For two months afterward, she seldom passed three days without coughing up masses of the same kind, but none so large: she was tolerably easy when sitting still, or in motion in the open air; and though her pulse never beat less than a hundred and twenty strokes in a minute, she had a good appetite, gained some degree of strength and flesh, and entirely lost her night-sweats. She was now suddenly attacked at night with another paroxysm of distressful breathing and a sense of suffocation, and, in the morning, threw up a larger membranous concretion than at any time antecedently, and in the course of the four ensuing days, a quantity quite as large as in the six preceding weeks. From this time the oppression on the lungs returned irregularly after intervals of five, eight, ten, or twenty days, always followed and always relieved by an exspuition of the same concrete material; till at the close of a twelvemonth from the first attack, the patient complained of a pain in the right heel: an abscess formed there, and the os calcis was found carious. From this time the bronchial affection ceased, the breathing was perfectly free, and no more concretion was thrown up.

Dr. Warren conceived this concrete substance to have been secreted by the mucous glands of the bronchial vessels. But the existence of fibrin, as a constituent part of the blood, was unknown at the period in which he wrote; and his plates and description of the membranous matter expectorated, show evidently that, like that discharged in croup, and often from the intestinal canal, it was composed of this formative element, intermixed with gluten, secreted in layers, and affecting a tubular structure.

In connexion with the plan of treatment already pointed out, it is highly probable that much benefit might, in this chronic form of bronchlemmatitis, be derived from the use of mercury and foxglove, and a seton or issue.

Since the publication of the second edition of this work, M. Bretonneau,* in his treatise on the specific inflammations of the mucous membrane to which we have just referred, has noticed another form of this disease, in which the inflammation either spreads from the trachea to the tonsils and pharynx, or, as is more commonly the case, begins in the latter with the ordinary symptoms of paristhmitis maligna, or malignant sore-throat. In the cases to which he refers, this last disease was epidemic and contagious: and when the affection took this complicated course, the ulcerative process ceased, and the concrete membrane was produced in its stead. There seems to have been something peculiar in the season or the locality that could thus deflect the inflammation of quinsy from its ordinary course, though we meet with instances

* Dr. Bard, of New-York, in a Treatise on Croup, published fifty years before the date of Bretonneau's work, is said, by a French writer, to have pronounced croup and gangrenous angina to be identical.—See *Dict. de Med. et de Chir. Pratiques*, tom. ii., p. 544.—ED.

of modification at times in other inflammations. A speedy cure was sometimes obtained by a rapid and momentary application of concentrated muriatic acid on a piece of sponge, where the inflammation could easily be reached; but, in other cases, it best yielded to a free course of calomel and mercurial friction.—(*Des Inflammations Spéciales du Tissu Muqueux, &c.*, 8vo., Paris, 1826.)

[Dr. Cullen, as we have mentioned, noticed the occasional redness of the fauces in croup; and, as the subject was also considered by Dr. Cheyne, some of the observations of M. Bretonneau may not appear altogether new. Dr. Cheyne objected to the plan of regarding the disease as croup, when variously complicated; but, as an able critic has remarked, if the cough, voice, and mode of breathing be those of croup, and if a membrane be actually found on dissection after death, although sloughs may have been observed on the uvula and tonsils, and although the paroxysm may have supervened to, or been complicated with scarlatina, with measles, or with smallpox, still it is croup; not, indeed, pure and idiopathic, but, though complicated, still croup, still inflammation of the larynx and trachea, exudation, and formation of membrane, giving rise to the same series of symptoms which distinguish idiopathic croup.* The cases and dissections recorded by M. Louis (Op. cit., p. 204, &c.), materially corroborate the doctrine defended by the anonymous critical writer.†]

* Edin. Med. Journ., vol. v., p. 457. According to M. Bretonneau, diphtheritis does not yield to bleeding; and, notwithstanding the train of inflammatory effects attending it, its progress is arrested by stimulants, as the hydrochloric acid, alum, and the chloruret of lime. Hence Andral infers, that though congestion exists, it does not constitute the whole of the disease.—Anat. Pathol., tom. ii., p. 233.—Ed.

† American practitioners have added not a little to our knowledge of croup. In 1781, Dr. Bayley, of New-York, in a communication addressed to Dr. Hunter, of London, ably discriminated between croup and the sore-throat distemper: he maintained the inflammatory character of croup, and strongly recommended repeated bleedings ad deliquium, the free use of tartar emetic, blisters, &c.—(See an Historical Review of some early American writers on croup, by Dr. J. B. Beck, in the New-York Med. and Phys. Journ., vol. i., p. 257.) According to Dr. Hosack (Med. Essays, vol. ii.), the disease sometimes attends other affections, as scarlatina, smallpox, measles, &c.; hence he divides it into two species, viz., idiopathic and symptomatic: “idiopathic, where the disease is primarily and exclusively situated in the trachea, bronchia, and surface of the lungs; symptomatic, where it is the consequence of other previous diseases.” Dr. Hosack adopts the remedial measures for the cure of croup according to the three stages into which he divides the complaint: in the first, or forming stage of this disease, we must employ the most active means for restoring the suppressed secretions of the trachea and surface of the lungs. For this purpose, he directs an active emetic of tartarized antimony and ipecacuanha. Blood-root (sang. Can.), is highly recommended in this stage by Dr. Nathan Smith; and of this remedy Prof. W. Tully remarks, “that if given early, it may be considered as almost a specific.”—“In the

SPECIES VII.

EMPRESMA PNEUMONITIS.

PERIPNEUMONY.*

INFLAMMATION OF THE LUNGS; OBTUSE PAIN IN THE CHEST; CONSTANT DIFFICULTY OF RESPIRATION, ALLEVIATED BY AN ERECT POSITION; TUMID, PURPLE FACE, OR LIPS; COUGH, GENERALLY MOIST, OFTEN BLOODY; PULSE USUALLY SOFT.†

INFLAMMATION of the lungs has been described under many names. The most common, perhaps, is peripneumonia; for which pneumonitis, employed first, I believe, by Bourgaud, in his Dissertation, published in 1754, is here substituted, merely on account of the regularity of its termination. [The disease is one of the most severe and frequent, and in cold and tem-

second stage,” says Dr. Hosack, “such is the determination of the circulating fluids to the part affected, that the most efficient means of diminishing the plethora of the bloodvessels, and of diverting the irritation from the part affected, become necessary:” with this view he employs blood-letting, the warm bath, blisters, and calomel. If these remedies do not subdue the symptoms, and divert the irritation from the lungs and trachea, the third stage of the disease will ensue, termed the membranous or purulent stage. In this stage, Dr. Hosack relies on calomel in small and repeated doses; on the seneka snake-root, introduced as a remedy in croup by Dr. Archer, of Maryland; and on those medicines which excite the secretion from the lungs without impairing the general powers of the system. In this stage, Dr. Francis has succeeded in saving life when nearly extinct, by administering emetics of the sulphate of zinc, or of the sulphate of copper. This practice, which was introduced to the notice of the profession by Dr. Francis some eighteen years since, has been pursued with success by many eminent practitioners on both sides of the Atlantic, and particularly in Germany. For details of some cases treated with this remedy by Dr. Francis, see the New-York Med. and Phys. Journ., vol. iii., p. 54.—D.

* This word “is more properly applied to inflammation either of the air-cells or the cellular membrane around them, whichever it may be. I have no doubt, however, that the inflammation is inflammation of the air-cells themselves.”—(Professor Elliotson, in Lectures at Lond. Univ. as published in Med. Gaz. for 1833, p. 130; also Andral, Clinique Méd., tom. ii., p. 312.) An inflammation of the parenchyma of the lungs, occasionally, but not necessarily, extending to the pleura investing them.—(Dr. C. Williams, in Cyclop. of Pract. Med., art. PNEUMONIA.) When the pleuritic covering is involved, Andral terms the case pleuro-pneumonia.—Ed.

† The common well-known symptoms of this disease, those which are discernible without the aid of the ear, are pyrexia; general feverishness; rapidity and shortness of respiration; cough and expectoration.—(See Elliotson’s Lect., op. cit.) The following is the character which Dr. C. Williams considers as most generally applicable to pneumonia; fever, with more or less pain in some part of the chest; accelerated, and sometimes oppressed, breathing; cough, with viscid and rusty-coloured expectoration; at first the crepitant rchus, afterward bronchial respiration, and bronchophony, with dulness of sound on percussion in some part of the thorax.—Ed.

perate climates, is calculated by Laennec to be productive of more deaths than any other acute disease.]

The disease, as above characterized, is traced under the three following varieties:—

- α Vera. Fever a cauma; pain severe, little expectoration in the beginning.
- β Maligna. Fever a synochus or typhus; the debility extreme from an early period. Often epidemic.
- γ Notha. Great secretion and expectoration, with a mild cauma. Occurring in weakly habits, and often connected with a catarrh.
- Spurious Peripneumony.

The FIRST of these varieties, or TRUE PERIPNEUMONY, is perhaps the most common, and has been more generally treated of than the rest.

Dr. Cullen has united inflammation of the parenchyma of the lungs, which is here alone contemplated, with inflammation of their membranes; believing that we have no means of ascertaining a difference from the course or concomitancy of the symptoms, and, in this view of the disease, he has been followed by Professor Frank (Op cit., tom. ii., sect. 185), who, however, retains the term *pleuritis*, but limits it to what has occasionally been called *bastard pleurisy*. In pleurisy, however, the face is comparatively but little flushed, and far less tumid; the pulse is harder; the cough less violent, and, from the beginning to the end, without expectoration; the seat of pain also is fixed: while in peripneumony it shifts not only to different parts of the same side, but often from the one side to the other. However, some degree of pleurisy frequently accompanies pneumonitis from continuous sympathy (*Morgagni, De Sed. et Caus. Morb. Ep.*, art. 13, 14, 37); but then it is not idiopathic pleurisy, nor strictly possessed of its symptoms. ["Nothing is more common," says Professor Laennec (Op. cit., p. 125), "than to find pneumonitis altogether simple, or complicated only with so slight a degree of pleurisy as in no respect to increase its danger, or modify its progress."] Percussion, if skillfully managed, will often ascertain the particular part in which the inflammation is seated, but the stethoscope will prove a still better diagnostic.

Inflammation of the substance of the lungs bears nearly the same relation to pleurisy, or inflammation of the membrane that lines the chest and covers the lungs, as profound or parenchymatous cephalitis bears to meningic. The two former, however, are somewhat more distinct, and less liable to run into each other than the two latter; because one half the pleura, from its duplicature, is more remotely situated from the lungs, and less connected with them. And I have hence followed the ordinary division, and treated of pneumonitis and pleuritis as distinct species, rather than varieties of one common

species, which is the view taken of meningic and profound cephalitis. In both sets of disease, however, the membranous is the more acute affection, evinces more violent and painful symptoms, and runs through its course more rapidly. And hence, in pneumonitis, as in deep-seated phrensy, the pulse is sometimes soft (*De Cabanis, Phanom. Med.*), the fever small (*Cleg-horn*, p. 262), and the disorder occasionally protracted to twenty days or more.—(*Stoll, Rat. Med.*, part ii., p. 376; *Act. Nat. Cur.*, vol. v., obs. 124.)

[According to Professor Laennec, the lower parts of the lungs are those most commonly occupied by pneumonitis; and he says, that when the disease involves the whole organ, it is almost always in the inferior part that it commences. These circumstances he views as affording a strong argument against the opinion of Broussais, that tubercles are the product of inflammation. "If this were true," he says, "the inferior and not the upper lobes ought to be the principal site of tubercles, but the reverse is well known to be the fact."—(Op. cit., p. 199.) From a note, however, inserted in Dr. Forbes's translation of Laennec's invaluable treatise, some doubt appears to exist respecting the correctness of this author's statement. It is, indeed, corroborated by Andral, although, as Dr. Forbes remarks, hardly in the degree we might have expected from Laennec's observations. Out of eighty-eight cases of pneumonitis examined by Andral, the lower lobe was affected in forty-seven; the upper lobe in thirty; and the whole lung in eleven.—(*Clin. Médicale*, tom. ii., p. 317.) Since the publication of Laennec's work, the pupils of Broussais have very often shown the latter physician cases of hepatization of the upper lobe; Frank even declares (Op. cit., tom. ii., p. 139) his own experience to be the reverse of Andral's. "Frequentius forte superiores pulmonum lobos inflammatos deteximus."—(*De Cur. Hom. Morb.*, tom. ii., p. 132.) In fifty-nine cases, examined by M. Chomel, there were thirteen examples of the upper lobes being affected; eleven of the lower; thirty-one of the whole lung; two of the posterior part; and one of the middle. The right lung is said to be more frequently attacked than the left, not only in cases of pneumonia, but in almost every other disease to which the lungs are subject. This fact, which is noticed by Morgagni, is confirmed by M. Andral, who has calculated, that out of two hundred and ten cases of pneumonia, recorded either at La Charité, or by Morgagni, Stoll, De Haen, Pinel, or Broussais, the right lung was affected in one hundred and twenty-one; the left in fifty-eight; and both lungs in twenty-five; the particulars of the other six being unknown.—(*Andral, Clin. Médicale*, tom. ii., p. 317.) In fifty-nine dissections, performed by M. Chomel (*Diet. de Médecine*, tom. xvii., p. 508), the right lung was affected in twenty-eight of the patients, the left in fifteen, and both in sixteen.]

The causes of true peripneumony are those of inflammation in general; particularly excessive exertion of the lungs, or cold applied to

the skin, mouth, and stomach.* It attacks the robust and plethoric more frequently than the spare and delicate. [While Laennec admits, that in such persons the inflammation is more acute, the fever higher, and the disease more easily recognised and cured, he asserts, that the disorder is much more common and fatal in old persons, in whom it is apt to run rapidly into suppuration. Children are likewise very subject to it, and the more so the younger they are.† “In them,” says Laennec, “the disease is frequently mistaken, because they swallow the expectoration, and death mostly takes place before any hepatization has occurred, or only very partially.” The facility with which they fall victims to the disorder at its very commencement, is ascribed by Laennec to the greater necessity of free respiration in early infancy.] The disease prevails most in cold weather, or sudden changes from hot to cold. [It is remarked by Laennec (Op. cit., p. 220), that cold operates as a cause much less powerfully when it immediately follows excessive heat, and is not prolonged. The Russian, who rolls himself in the snow after coming out of the hot bath, or the bakers, who go from their heated ovens into an atmosphere of a temperature below zero, escape the disease; while porters, whose occupation leads them to stand for a length of time at the corners of the streets, are frequently affected by it. In general, it is a disease of winter and cold climates, and is comparatively rare in the equatorial regions.] Noxious exhalations have sometimes proved a cause. To these we may refer the frequency of this disease in the outskirts of Mount Vesuvius, as remarked by Vivenzi (*Epist. ad Haller.*, iv.); and, on this account, it is described by Baronius (*Pleurpneumoniâ ann. 1633, Flaminium infestante*, Fidi., 1536) and Bovillet (*Mémoires sur les Pleurpneumonies Epid.*, p. 556) as endemic. [The poison of serpents, and especially that of the rattlesnake, frequently brings on pneumonitis, and the injection of various medicinal substances into the veins has the same effect.‡

* This influence of cold is proved by the greater prevalence of the disease in cold seasons and cold climates. Of the cases described by Andral, the number occurring in March and April amounted to a third of the whole; the fewest took place in May, October, and November; and the remaining months had an equal share. Dr. C. Williams has observed the greater prevalence of the disease in London from the beginning of December to the end of April.—(Cyclop. of Pract. Med., art. PNEUMONIA.) Frequently undetermined epidemic influences are likewise concerned in exciting the disease.—Ed.

† According to M. Guersent, three fifths of the children who die in the Hospital for Sick Children at Paris, before the completion of dentition, are cut off by pneumonia (Dict. de Méd., tom. viii., p. 96); and Dr. C. Williams says, that of fifty-five cases of pneumonia, attended by himself and Mr. Byam, at a Dispensary in St. Marylebone, in the course of the year, thirty were in subjects only six years old, or under this age.—Cyclop. of Pract. Med., art. PNEUMONIA.—Ed.

‡ A previous attack of pneumonitis leaves a considerable tendency to another. Rush refers to a

In an anatomical point of view, pneumonitis presents three degrees or stages, to which Laennec assigns the terms *obstruction*, or *engorgement*, *hepatization*, and *purulent infiltration*.

In the first stage, the lung is externally of a livid or violet hue, heavier, and much more solid than natural. It is, however, still crepitous, but much less so than in the sound state, and, on pressing it, we find that it is injected with fluid. It retains the impression of the fingers nearly like an œdematous limb. When cut into, it presents a livid or blood-coloured appearance, and a frothy, serous, more or less bloody fluid, issues from it in abundance. The natural areolar and spongy texture of the viscus, however, may yet be distinguished, except at some points where the part is more solid, indicating the transition from the first to the second stage.

In the second stage, or that of hepatization, the crepitous feel is entirely lost, and the lung has acquired the consistence and weight of liver. It is also frequently less livid externally than in the first stage, but internally its redness is more or less deep, the colour varying at different points from that of violet-gray to blood-red. With these different colours, as is pointed out by Laennec, a striking contrast is formed by the bronchial tubes, the bloodvessels, the specks of black pulmonary matter, and the thin cellular partitions dividing the pulmonary substance into portions or lobules of unequal size. These partitions, which, in a sound state of the organ, are not easily perceived, are now rendered quite distinct by their whiteness. If a portion of lung in this state be cut in pieces, hardly any fluid escapes from it; but if the incised surface be scraped, a little bloody serum may be collected, which is turbid and thick, and not unfrequently blebbed with another fluid which is thicker, opaque, whitish, and puriform. When the incised surfaces are exposed to the light, the pulmonary substance will be found to have entirely lost its cellular appearance, and presents a granular aspect, as if composed of small red grains, oblong and somewhat flattened. This granular texture is considered by Laennec to be the criterion of inflammation of the lungs, by which it may be best discriminated from the tubercular obstruction. The granular appearance is rendered still more conspicuous when a portion of hepatized lung is torn. The pulmonary substance now seems to consist of an infinity of small grains, round or oval, very equal in size, and of the several colours already men-

native of Germany, resident in Philadelphia, who had the disease twenty-eight times; and Andral mentions one case, in which the disease occurred not less than sixteen times in eleven years.—(Clin. Méd., tom. ii., p. 129.) Dezoteux had under his care a patient seven times with pneumonitis, who had suffered fifteen attacks of it.—(Dict. des Sc. Méd., tom. xliii., p. 396.) Chomel alludes to its occurrence a tenth time in the same individual (Dict. de Méd., art. PNEUMONIE); also Dr. C. Williams (in Cyclop. of Pract. Med.), who observes, that, perhaps, the only other circumstance that can be fairly viewed as a predisposing cause, is the presence of tubercles in the lungs.—Ed.

tioned. They are plainly the air-cells changed into solid grains by the thickening of their parietes, and the obliteration of their cavities by a concrete fluid. Andral even regards pneumonitis as consisting essentially in inflammation of the air-cells, the inner surface of which, he says, secretes at first a muco-sanguineous, and then a purulent fluid.—(*Clinique Médicale*, tom. ii., p. 312.) The hepatized lung seems at first sight larger than natural, but this is not the fact, and the appearance is referred by Laennec to the lung not contracting, as a sound lung does when the chest is laid open. He has measured the chest, but never found it to be dilated, which is one great difference of peripneumony from pleurisy.

In the third stage, or that of purulent infiltration, the lung has the same degree of hardness, and the granular appearance; but it is of a pale yellowish colour.—(See *Dr. Hope's Illustrations of Morbid Anatomy*, No. 1.) The pus, as it begins to form, appears in small detached yellow points, increasing the mottled colouring already noticed. By degrees, these points unite, and the whole lung assumes a uniform straw or lemon colour; and, when incised, pours out more or less of a yellow, opaque, viscid matter, evidently purulent, but much less fetid than the pus of a wound. The substance of the lung is also more humid and soft than the red hepatization. As the purulent softening increases, the granulated texture gradually disappears, and at length the parenchyma of the lungs breaks beneath the fingers. According to Laennec, when the lung contains much black pulmonary matter, as is commonly the case in adults and old persons, the pus and substance of the lung assume an ash-gray colour. At other times, particularly in children, the pus is of a whitish yellow colour. The collection of the pus in one cavity, so as to form a true abscess, Laennec represents as an uncommon result of pneumonia; a point, however, on which Professor Himley and Sir A. Crichton do not agree with him. The foregoing three stages are frequently combined. Sometimes the hepatized portions are exactly circumscribed by a lobule; and, in children more especially, we sometimes find in the centre of the lungs a certain number of lobules arrived at the stage of hepatization, while those immediately around them are perfectly sound. The lining of the bronchiæ is generally very red in the inflamed portions of lung; it is also occasionally swelled; and sometimes the redness pervades the whole bronchiæ, but this is uncommon. In the purulent stage, the membrane is sometimes pale, sometimes red or purple, and in both cases softened.

Laennec maintains, that the species of supuration above described is the only one of common occurrence in cases of pneumonia; for the vomica of Hippocrates and modern practitioners, he says, is the result of the softening of a large mass of tubercular matter. Among several hundred dissections of peripneumonic subjects, he has not met with a collection of pus in an inflamed lung more than five or six times. They were not of large extent, nor

numerous in the same lung. They were dispersed in different situations, and the lungs were in the third stage of inflammation. The walls of these abscesses were formed by the pulmonary tissue filled with pus, and in a state of soft disorganization, which gradually decreased as it receded from the centre of the collection. When we drag from the chest an inflamed lung, adherent to the pleura costalis, the parts most infiltrated with pus frequently give way, or, without breaking outwardly, yield internally under the pressure, so as to form a soft sanious mass (see also *Andral, Clinique Médicale*, tom. ii., p. 310): if cases of this kind were received as examples of pulmonary abscess, nothing would be more common. In the course of twenty years, Laennec had never seen in the lungs a true abscess of considerable extent except once, and in this case, as in all the rest where abscess was found, the inflammation occupied only a part of the lung.

As Dr. Forbes has observed, the testimony of Broussais on the foregoing point is also very strong; for he declares, he has never met with a case of ulceration, without tubercles, but once; and then the inflammation arose from the lodgment of a musket-ball six years in the lungs.—(*Hist. des Phlegm. Chron.*, tom. ii., p. 111.) Dr. Bright's work contains but a single example unaccompanied by tubercles.—(*Bright's Reports of Medical Cases*, p. 134.) The frequency of pulmonary abscess, as described by Dr. Baillie, and believed by the generality of English practitioners, is therefore considered by Dr. Forbes to be an error.

Laennec has seen the disorder continue in its first stage seven or eight days, and affect the whole of one lung and part of the other, and prove fatal before the occurrence of any distinct hepatization.—(*Andral, Clinique Médicale*, tom. ii., obs. 8 and 9.) On the contrary, in other cases, particularly when the disorder has attacked debilitated or very old subjects, or come on in the course of another severe malady, the inflammation reaches the stage of purulent infiltration in thirty-six or even twenty-four hours. With these exceptions, Laennec fixes the ordinary duration of the different stages of pneumonitis as follows: the first stage usually lasts from twelve hours to three days, before hepatization is completed; this, or the second stage, lasts from one to three days before spots of purulent infiltration appear; and the suppurative stage continues from two to six days.

With respect to what Laennec terms the physical signs of the disease, the crepitous rattle, as ascertained by the stethoscope, is the pathognomonic sign of the first stage. The sound of respiration is still heard distinctly, and percussion affords the natural resonance. The extent over which the stethoscope detects the rattle, denotes the extent of the inflammation. When hepatization has taken place, neither the crepitous rattle nor the respiratory sound can be distinguished in the part affected; but, if the inflammation be near the surface, or at the roots, or in the upper lobes of the lungs, bronchophony, or a resonance of the voice within

the bronchiæ of the inflamed part may be perceived. The bronchial respiration and cough always accompany bronchophonism. In the third, or suppurative stage, as soon as the pus begins to soften, the mucous rattle of Laennec becomes more or less perceptible.]

The first symptoms are those of inflammation in general; but there is usually more shivering, or cold fit, and the hot stage is proportionally violent; the head aches considerably, and the urine is high-coloured, [or, to use Laennec's expression, it is of as deep a red as if it held blood in solution; and this character is as strongly marked as in any inflammatory disease whatever. The disorder is attended by active fever from its very beginning, the exceptions being rare, and only happening when the disease is of small extent. There is a great determination of blood to the head, and the face is much flushed.] The pain in the chest is rarely felt in any oppressive degree till these symptoms have continued for a day or two: though sometimes it is coetaneous. It is chiefly felt in a recumbent position, and more on one side than on the other. [It is obtuse and deeply seated. It is generally slight and extensively diffused; but sometimes confined to a point, even when there is no accompanying pleurisy. However, when it becomes very acute, it is commonly on account of the inflammation having extended to some part of the pleura.]* The cough is usually short, peculiarly distressing, and obstinate; [though, according to Laennec, sometimes so slight as not to be acknowledged by the patient or attendants. The expectoration has, in many cases, an appearance quite characteristic. The sputa, when received into a flat and open vessel, unite into so viscid and tenacious a mass, that we may turn it upside down, even when full, without the sputa being detached. Their colour is often a shade of red, particularly that of rust; or it may be sea-green, tawny, orange, saffron, yellowish, or dull green. These various colours are often intermixed in stripes in the same spot. The mass of expectorated matter has a semitransparency like that of horn. It is further remarked by Laennec, that if such sputa constantly existed in pneumonitis, no other sign of the presence of the disorder would be requisite. They commonly appear in the stage of obstruction, and retain their character until hepatization is advanced; but frequently they are less viscid, little coloured, and nearly destitute of air-bubbles; and, at other times, we perceive only a few glutinous and slightly tawny sputa, amid a great mass of mucous expectoration. Frequently the characteristic sputa are

observed only at the very beginning of the disease, and sometimes not at this period, or only in such small quantity as hardly to admit of being collected. This is stated by Laennec to be particularly the case in old subjects, and in very rapid attacks. During the period of hepatization, the expectoration is slight and variable, but it usually consists of a small quantity of pituitous sputa, more or less viscid and vitriform, or of a whitish, or yellowish, and half opaque mucus. After the purulent infiltration occurs, the expectoration is more decidedly mucous, and like that in the latter stage of catarrh. It rarely becomes entirely purulent. Lermier and Andral consider an expectoration of a mixture of blackish blood and diffuent pituita as characteristic of the period of supuration.] The pulse is variable: in some cases hard and strong; in some, soft or oppressed; but, with the advance of the disease, it becomes feeble, sometimes fluttering. [When the determination of blood to the head is very great, and marked by coma in the beginning of the disease, as is often the case in old plethoric persons, the symptom is extremely unfavourable, as the patient then usually dies before hepatization is complete, or the inflammation reaches the stage of purulent infiltration in a few hours.] —(Op. cit., p. 217.) Delirium is an occasional accompaniment, and a highly dangerous symptom, except where it alternates with the pneumonic symptoms, in which case it augurs well. In favourable terminations, the violence of the disease diminishes on or before the seventh day: if it increase beyond this, it commonly proves fatal.

Peripneumony, like other inflammations, terminates in effusion, suppuration, or gangrene; and it has also a termination peculiar to itself, which is that of hemorrhage. The most salutary mode is effusion; for the vessels hereby become relieved, and the secretions immediately add to the relief by commencing an increased action, and consequently an increased discharge of mucus. In consequence of effusion, however, we occasionally find adhesions take place between the lungs and the pleura; and sometimes a collection of water in different parts of the chest; and not unfrequently a flow of blood, apparently from the mouths of the exhalants, without any rupture of vessels, giving a bloody tinge to the sputum. This last has been often regarded as an alarming symptom, but the alarm is altogether unfounded, for it generally affords considerable relief. Indeed, a hemorrhage itself from the lungs has not always been attended with fatal consequences: it has occasionally proved critical, and carried off the disease in a few days: though a hemorrhage from the nose, no unusual attendant, is far preferable, as producing a like benefit with less risk. If the inflammation run into suppuration, the change is generally indicated by shiverings, with a remission of pain, and sometimes by perspiration where there has been none before. If gangrene ensue, the pulse sinks, the debility rapidly increases, and the eyes are fixed with a ghastly stare.

* Laennec, op. cit., p. 214. In several cases noticed by Andral, various degrees of pain had been experienced, though no mention is made by him of any inflammatory appearances on the pleura after death.—(Clinique Méd., tom. ii., obs. 29, 38, 43, 46.) This merits particular attention, because this eminent pathologist happens to observe in another place (p. 327), that pain is never experienced unless the inflammation extend to the pleura. This incongruity has been adverted to by Dr. C. Williams.—Ed.

[With respect to gangrene of the lungs, it is rather uncommon; so rare in pneumonitis, that Dr. Elliotson has never seen it. The severest inflammation of the lungs, he thinks, seldom, if ever, brings on mortification.* Laennec (Op. cit., p. 221) is of opinion, that it can scarcely be reckoned one of the terminations of pulmonary inflammation, and still less the consequence of its intensity; since, in cases of this kind, the inflammatory character is very slightly marked, as well in regard to the symptoms as the appearances on dissection. He conceives, that there is some resemblance between gangrene of the lungs and that of anthrax and malignant pustule, in which the surrounding inflammation seems to be rather the effect than the cause of the sphacelus. Gangrenous excavations in the lungs constitute the ulcerous phthisis of Bayle.—(*Recherches sur la Phthisie Pulmonaire*, Paris, 1810.) The examples of this affection recorded by Dr. Bright, merit particular attention.—(See *Bright's Reports of Medical Cases*, p. 136, et seq., 4to., Lond., 1827.)

From the time of Hippocrates to the present day, pneumonitis has been considered as one of the disorders in which the abstraction of blood is productive of the most unequivocal good effects. The same agreement, however, has not prevailed with respect to the quantity of blood to be drawn at one time, the period of the disease when bloodletting ceases to be useful, and the part of the body from which the blood ought to be taken. The greater number of the ancient physicians, as Laennec has remarked, bled only at the onset of the disease, and allowed the blood to flow until syncope took place. The same practice is common in England, where physicians frequently direct twenty-four, thirty, or thirty-six ounces of blood to be taken away in the beginning of pneumonitis. In subjects not debilitated by age, or previous habits and disease, Dr. Good, in the former editions of this work, recommended the "bleeding to be prompt and copious, at least to eighteen or twenty ounces, and, if necessary, to be repeated in twelve hours." M. Andral states, that the first bleeding should be from sixteen to eighteen ounces, and that the operation may be repeated twice, or even thrice, within the first twenty-four hours.—(*Clin. Mtd.*, tom. ii., p. 379.) The advantage of a very copious bleeding at the onset of pneumonia has been placed in a strong light by Dr. Robertson (*Edin. Med. and Surg. Journ.*, vol. x.), whose practical observations on the subject merit attentive consideration, and whose precept is sup-

ported by Dr. Gregory's celebrated aphorism, that "the danger of a large bleeding is less than the danger of the disease." However, notwithstanding the propriety of copious bleeding in the early stage of pneumonia, the extent to which the evacuation should be carried, ought certainly to be modified according to the age and strength of the patient. Hence, in the preceding editions, Dr. Good delivered the following caution:—The chief evil is, that the fever is apt, at times, to run into a typhus form, and assume the second of the varieties before us. And hence, where there is any doubt upon the subject, local bleeding is to be preferred, whether by leeches or cupping-glasses, and repeated according as the evacuation appears to be demanded.

[This doctrine, that the fever of pneumonia is particularly apt to become typhoid, has always appeared to the editor one of doubtful validity. Having seen many cases of this disease in the public service, the experience which he has had makes him conclude, that the symptomatic fever of inflamed lungs is not more disposed to assume the character of typhus, than the fever resulting from the inflammation of other important viscera. The case of which he speaks, however, is not to be confounded with other examples, in which the pneumonitis is only an incidental attendant on typhus, which is the primary affection. As Laennec justly observes, a copious bleeding, in the beginning of the disease, reduces the inflammatory orgasm much more speedily than repeated smaller venesections, and leaves less chance of a relapse. And, with respect to the fear of bleeding, derived from the consideration of debility and dreams of typhus, although the patient's state of health and strength should always be allowed to modify the practice, and even sometimes to prescribe local instead of general bleeding, the editor believes that Diemerbroek's maxim, quoted by Dr. Forbes (*Laennec on Diseases of the Chest*, &c., 241, note 2d ed.), ought never to be forgotten, "præstat ægrum debilem sanari, quam fortem mori." And, as the latter physician inculcates, the vastly inferior power of bleeding in the second and third stages of pneumonitis ought to make us principally depend upon what we can effect in the first stage. Indeed, after the stage of hepatization, Lorinser (*Lorinser, Lehre von den Lungenkrankheiten*, p. 259) considers bleeding as useless, if not injurious. In the beginning of the case, however, when the patient is young, strong, or plethoric, venesection, and local bleeding, by means of leeches or cupping, may be simultaneously practised.*

On this particular subject, one valuable caution is offered by Laennec, namely, that, in pneumonitis, a weak pulse is not always a token of weakness: the feebleness, he says, is some-

* Dr. Elliotson has seen two examples, in which there was gangrene of the lungs under other circumstances: one was in a man, who had long suffered from a loud hollow cough; the other in a woman, who laboured under an encysted tumour of the pancreas. In her case a slight cough came on, which attracted no attention, and at last symptoms of gangrene appeared; cadaverous look; sudden prostration of strength; great feebleness of pulse; intolerable fetor of the breath and sputa.—Ed.

* Our author has not mentioned mercury as one of the means for subduing inflammation of the lungs. Dr. Elliotson regards mercury as quite as useful in this disorder as in bronchitis.—(Lect., see *Med. Gaz.* for 1833, p. 133.) It must of course be preceded by bleeding.—Ed.

times only apparent, and the pulse will become stronger and fuller after bleeding. For the removal of any doubt about the propriety of bleeding, when the pulse is weak, the stethoscope is mentioned as a most valuable instrument. According to Laennec, whenever the pulsations of the heart are proportionally much stronger than those of the arteries, we may bleed without fear; but, if the heart and pulse are both weak, the practice generally causes complete prostration of strength.

Blisters are employed in pneumonitis by the generality of practitioners, but with very little discrimination. The common error consists in applying them too early, in which circumstance they increase the fever, and do more harm than good. The best physicians seem now to agree, that blisters should not immediately follow the first bleeding, but be kept back till the acute stage has somewhat subsided.

With respect to purgatives in cases of pneumonitis, clysters and gentle laxatives are generally preferable to stronger medicines. The editor has seen two cases very lately, in which the expectoration seemed to be stopped by the operation of active purgatives, and the patients, though already benefited by bleeding, suddenly became worse, and died. As Dr. Forbes has observed, when pneumonia is complicated with gastric inflammation, strong purgatives are highly improper.

Refrigerants are frequently prescribed in this disease: one of the most common and useful is nitre;] which may be combined with the citrate of potash, or made to produce a more certain determination to the skin, by the addition of camphire or of antimonial wine, or by a combination with the citrate or acetate of ammonia.

In other countries, emetics have seldom been given except in an early stage of the disease, and then only as a gentle puke; yet, from my own practice, I can recommend them when the disease has made a considerable advance; but they must be used boldly, or so as to produce full vomiting, and the action of vomiting must be maintained for an hour, or even two; and in this way they will often produce a transfer of action of as beneficial a nature as the same process is found to do in purulent ophthalmia; and will, at the same time, peculiarly stimulate the exhalants of the lungs to an increased secretion of mucus. [On the continent, the free exhibition of tartarized antimony in pneumonitis has always had some partisans. To Laennec's knowledge, the practice was constantly followed by M. Dumangin, physician to La Charité, who scarcely ever joined bloodletting with it, and yet his practice was quite as successful as that of Corvisart, who bled much in this disease. Rasori, a modern Italian physician, first revived this method of treatment.—(*Storia della Febbre Petechiale*, &c., Milano, 1813.) After venesection, Laennec gives a solution of one grain of tartarized antimony every two hours, repeating the dose six times. After this, if the symptoms be not urgent, and the patient disposed to sleep, he leaves him quiet for six or

eight hours. But, if the oppression be great, or the head affected, the medicine is continued, the dose being then sometimes increased to a grain and a half, or two grains, or even two grains and a half. Many patients bear the medicine without being either purged or affected with vomiting. Most of them, however, vomit two or three times, and have five or six stools the first day. On the following days they have very slight evacuations, and sometimes none at all. As soon as some amendment is produced, we may be sure, says Laennec, that the continuation of the remedy will effect a cure, without any fresh relapse; a point in which this practice is represented to differ especially from that of bleeding. Of forty-seven cases, treated by Dr. Hellis, of Rouen (*Clinique Méd. de l'Hôtel Dieu de Rouen*, 1826), by repeated emetics, only five were lost, being a proportion somewhat less than one in nine. Laennec experienced even greater success with large doses of the medicine. The average number of deaths, under the treatment with bleeding and derivatives, is computed to be one in six or eight cases. When the medicine operates too freely, Laennec joins a small proportion of opium with it.—(Op. cit., p. 250.)] M. Peschier, of Geneva, also prefers the treatment with tartarized antimony; and depends upon it alone, or nearly so, even discarding the lancet; for he gives it in large doses, so as to purge as well as vomit. His usual quantity at first is, according to the age, from six or eight to fifteen grains, dissolved in six ounces of water, which is taken in divided doses, in any diluting drink, in the course of twenty-four hours. And, under this plan, he tells us that he cured all his patients, old or young, without exception. He admits, however, the conjoint use of blisters, which ought unquestionably to form a concomitant in the general plan; and the obstinacy of the cough may be alleviated by demulcents, or inhaling the steam of warm water. [The plan of making tartarized antimony the chief means of treatment has not yet gained many advocates in England. With Dr. John Forbes, the belief of pneumonia being frequently complicated with gastric affections, influences him much against the practice, the merit of which, however, must be determined by experience.] Opiates have been tried in every form, but have never been found of decisive benefit; if opium be used at all, it should be in conjunction with gum-ammoniac or squills: but, upon the whole, either of these expectorants seem to answer best without opium. [The best, the easiest, and even the natural cure of peripneumony, is expectoration, which ought to be encouraged by all the means in our power. It forms the *optima crisis* of Stoll, though, as he adds, a crisis too rarely obtained.] Dr. Saunders recommended the extract of the white poppy; and that of the garden lettuce has since been tried, upon the recommendation of Dr. Duncan; others may have been more fortunate than myself, but, in my hands, both have proved altogether insignificant.

If the disease proceed favourably, the pulse

becomes slower and softer; the yellow, tenacious, and perhaps bloody sputum, is mixed with points of a whiter matter, which increases with the amendment of every other symptom; for the cough is less violent and straining, the breathing freer, the skin moister, and the tongue cleaner at the edges. If the progress be less favourable, the expectoration becomes darker and more viscid; the pulse lower, indistinct, and often intermitting; a low, wandering delirium supervenes, with subsultus; and the patient dies, apparently suffocated, from the oppressed vessels no longer permitting an expansion of the lungs.*

When a salutary expectoration has commenced, it sometimes ceases suddenly, from some unknown cause, or some irregularity in the mode of treatment. This symptom is alarming; and every means should be instantly taken to bring the discharge back; such, particularly, as increased doses of the expectorants already noticed, to which may be added the steam of vinegar, alone, or impregnated with the essential oil of aromatic plants, as rosemary. And if a diarrhoea, which sometimes proves a very distressing concomitant, should supervene, it will be best relieved by the pulvis cretæ comp. cum opio.

Inflammation of the lungs is also occasionally found as a symptom or sequel in rheumatism, lyssa, or canine madness; various exanthems, as smallpox, measles, miliaria, and commonly in phthisis; in which last it has a very frequent tendency to suppurate, as we shall have to notice when treating of this distressing complaint. [Peripneumony, thus forming a combination with other disorders, is termed by Laennec *latent* and *symptomatic*, being then particularly liable to be overlooked. Besides the cases just now specified, on which it is frequently an attendant, some others merit recollection: as, for instance, hæmoptysis; different kinds of catarrh; gout; severe erysipelas; violent continued fevers; and bad local injuries and important surgical operations.]

* The progress of pneumonia to a fatal result is marked by a continued aggravation of the dyspnoea, with increasing failure of the strength. The cough becomes less capable of expectorating the sputa, which sometimes retain their viscosity and sanguinolent hue, as long as any are avoided. In the greater number of instances, there is a total suppression of the expectoration for some hours before death; but, in others, it is still excreted, though of a different character. The whole sputa, however, in the latter stages of the disease, are generally scanty. Andral describes sputa as sometimes taking place, which consist of a slightly glutinous liquid, and of a reddish-brown colour, resembling liquorice-water, or thin sirup of prunes. Towards the concluding scene, the pulse becomes thready and intermittent; the countenance pallid, cadaverous, and bedewed with a cold sweat; the lips livid, the breathing gasping and convulsive, with a rattle in the throat; the sensorial functions, if entire before, now give way; and the patient dies asphyxiated. Whoever has seen the fatal end of pneumonia, must recognise the fidelity of this description, as given by Dr. C. Williams in the Cyclop. of Pract. Med., art. PNEUMONIA.—ED.

THE MALIGNANT PERIPNEUMONY, contrary to the true or common inflammatory affection, is generally an epidemic, and may be easiest explained by describing it as an epidemic synochus, or typhus, occurring in such situations, at such seasons of the year, or in such a temperament of the atmosphere, as have a tendency to excite inflammation of the lungs. The debility is often so extreme from an early stage of the disease, that the pulse ceases on the pressure of the finger; and the vascular action is too weak to accomplish expectoration. It is supposed by many writers, and especially by Sarcocoe and Ludwig, to be a pulmonic erysipelas, by which they mean an erysipelatous erythema. The symptoms are those already described, with a great addition of sensorial debility, and consequently with increased laboriousness of respiration. The disease is usually fatal on the fourth or fifth day; and if the system be incautiously lowered by venesection or a laxative of too much power, it often takes place earlier; and has sometimes occurred within twenty-four hours after bleeding.

Our attention must here, therefore, be turned rather to the constitutional disease, than to the local affection; and the plan recommended in typhus is to be pursued on the present occasion: for it will be in vain to attempt expectoration under circumstances in which the system will probably sink before the usual time arrives for effecting it. Camphire is here a medicine of considerable service, and may be used in conjunction with the aromatic confection, and wine in large quantities. It should be taken freely in the form of pills, rather than in that of julap; though both may be employed conjointly. Even the bark has a powerful claim to be tried, particularly the sulphate of quinine, as in putrid fever; nor has it been found to produce difficulty of breathing. Bark may be advantageously combined with the aromatic spirit of ammonia, which of itself often proves a useful stimulus. If evacuations be necessary, they should be obtained by injections alone. A light breathing perspiration, a free excretion, and a more animated appearance of the countenance, are among the most favourable diagnostics.*

* Perhaps there is no part of the "Study of Medicine" more appropriate than the present, to notice a form of disease which at times has prevailed in different and distant sections of the United States with extraordinary fatality. This disorder has been termed the *petechial*, or *spotted fever*, the *malignant nervous fever*, *peripneumonia typhoides*, the *malignant pleurisy*, *pleurisy of the head*, *typhus petechialis*, *epidemic pneumonia*, &c. Though it was first particularly noticed some twenty years since, some authorities state that it was described by Sauvages, Huxham, and others. Dr. Gallup, indeed, thinks that a similar disorder has raged at different times in Europe for the last three hundred years. In the Am. Med. and Phil. Register, vol. i., Dr. Bard has described it as it prevailed on Long Island in 1749; and in the New-York Med. Repos., vol. ii., Dr. H. Williamson has noticed its occurrence in North Carolina in 1792. In 1806, the spotted fever appeared at Medfield, and for many years it proved a severe scourge to the inhabitants of Maine, Massachusetts, Rhode Island,

The SPURIOUS or BASTARD PERIPNEUMONY is usually allowed to offer another variety of this disease; and is described under the name of *peripneumonia notha* by Boerhaave, Coze, and Sydenham. It is, in many instances, little more than a severe catarrhal affection of the lungs, accompanied with great obstruction, occurring in habits of a peculiar kind; and is hence denominated by many authors *catarrhus suffocatus*, and by Professor Frank, *catarrhus bronchiorum*.—(*De Cur. Hom. Morb.*, tom. ii., p. 138.) It is characterized by great secretion and expectoration, with a mild cauma; and is chiefly found in those of advanced life, or who have weakened their constitution by excesses.

Sydenham, however, has properly distinguished this malady from catarrh, notwithstanding the close resemblance it bears to it on particular occasions. The following is his description

Connecticut, Vermont, New-Hampshire, and some districts of New-York. It has also existed in some of the middle, southern, and western states, but our information as to its nature in these states is extremely limited. We would refer those who desire more knowledge of this malady than can be embraced in a brief note, to the treatises of Drs. North, Hale, and Job Wilson on the Spotted Fever, and to Dr. Yates' essay on the Bilious Epid. Fever. The American medical periodicals contain many excellent papers on the same subject, by Stuart, Hosack, Low, Fuller, Stearnes, Hudson, Dunbar, Hunt, &c. Dr. Gallup in his "Sketches of Epidemics," Dr. Mann in his "Medical Sketches," and Dr. Thacher in his "American Modern Practice," devote some pages to it. The best article, however, on this disease, is the Report made by order of the Mass. Med. Society, in 1810, drawn up by Drs. Warren, Jackson, and Welsh. The invasion of the disease was generally sudden and violent, presenting many of the symptoms mentioned in the text, although they varied excessively, and were so different in individual cases as not to admit of enumeration; at times, it was marked with greater depression, and assumed more of a typhoid type; the patient often laboured under extreme congestion and coma; macule, vibices, &c., occasionally appeared. As to the treatment, the most opposite modes of practice prevailed; in many cases the lancet was fatal, and the same was true of the administration of diffusible stimuli: emetics, cathartics, sudorifics, blisters, &c., were among the most effectual remedies. Bloodletting, although sometimes abused, was often indispensable; in short, the spotted fever frequently presented two entirely different forms, demanding different modes of treatment; a local inflammation, and a typhoid state of the system.

On dissection, the brain was almost constantly diseased, and in most instances there was an effusion of serous fluid, and of coagulated lymph within the ventricles. The heart and pericardium generally exhibited some appearance of morbid affection, and the same remark applies to the pleura and lungs.

By many, the causes of this disease were thought to be the vicissitudes of pestilential seasons; and, inasmuch as the disease proved extremely fatal to the American soldiers, in the war of 1812-14, its exciting cause was considered by others to be the unwholesome grain used by the soldiers, and the exposure incident to military life. Both these causes doubtless operated, but the extreme changes in the temperature probably had more effect.—D.

VOL. I.—Ii

of the disease:—"The patient is hot and cold alternately, feels giddy, and complains of an acute pain in the head, especially when there is a teasing cough. He rejects all fluids, sometimes from paroxysms of coughing, and sometimes without; the urine is turbid, and of a deep red; the blood appears as in pleurisy. The patient breathes quick and with difficulty; complains of a general pain throughout the entire breast, and, as he coughs, discovers a wheezing to the attendants. The cheeks and eyes appear slightly inflamed; the pulse is small, often intermitting; and lying low, or on one side, is peculiarly distressing."

As the fever is here of no great moment, we may, with considerable advantage, carry our local stimulants to a greater extent, and thus excite the lungs more actively to throw off the burden of mucus with which they are overpowered. Squills, gum-ammoniac, balsam of Peru, and even some of the turpentine, may be tried, and will mostly be found serviceable. The tetradynamia, as charlock, wild rocket, and mustards of various sorts, and the alliaceous plants, will form useful auxiliaries in the plan of diet. Blistering is highly serviceable; after which, as soon as the chest is a little unloaded, a regimen directly tonic should be commenced, by means of bitters, chalybeate waters, a moderate portion of wine, gentle exercise, pure air, and the irritation of an issue or seton; for a common result of this disease is hydrothorax. Perhaps more persons fall a sacrifice to some sequel of the disease than to the disease itself.

SPECIES VIII.

EMPRESMA PLEURITIS.

PLEURISY.

ACUTE PAIN IN THE CHEST, INCREASED DURING INSPIRATION; DIFFICULTY OF LYING ON ONE SIDE; PULSE HARD; SHORT, DRY, DISTRESSING COUGH.

As the proper seat of the preceding species is in the substance of the lungs, or the pleuritic membrane that immediately covers their surface, or in both, the proper seat of the present is in the surrounding membranes of the pleura; and as these differ, the difference has laid some foundation for several varieties; of which the three following may be noticed as matter of curiosity, though the subdivisions lead to nothing of practical importance, as the causes are nearly alike, and the same mode of treatment is applicable to the whole.

- a Vera. Fever a cauma; pain felt chiefly on one side; the inflammation commencing in that part of the pleura which lines the ribs.
- β Mediastina. Heavy pain in the middle of the sternum, descending towards its ensiform cartilage; with great anxiety; the inflammation, from its symptoms, being obviously seated in the mediastinum.

γ Diaphragmatica. Painful constriction around Pleurisy of the præcordia; small, diaphragm. quick, laborious breathing: manifesting that the inflammation is seated chiefly in the diaphragm.*

We have already pointed out the distinction between true pleurisy and peripneumony; and observed that, in the former, the cough is dry and commonly without expectoration from the beginning to the end, contrary to what occurs in the latter; that the seat of pain is fixed, instead of shifting from side to side; and that the face is far less flushed and tumid. It must be conceded, however, to Dr. Cullen, who has treated of these affections under one common definition, that the general features of the two have a considerable resemblance; and, with the exception of expectorants, which in pleurisy are of little avail, the mode of treatment already proposed for the former disease, is the same that will be found necessary in the latter: the causes of both are alike, and as peripneumony rarely, though we have reason to believe sometimes, occurs without any degree of pleurisy, so it is commonly affirmed that pleurisy rarely occurs without some degree of peripneumony; in both which cases it has been called a pleuro-peripneumonia.

[With all the best informed practitioners of the present day, *pleurisy* always signifies inflammation of the pleura, whether attended with stitch, or pain in the side, or not; *peripneumony*, *pneumonia*, or *pneumonitis*, will always stand for inflammation of the lungs, even when accompanied, as it sometimes is, with acute pain in the side; while *pleuropneumonia* will mean the co-existence of inflammation in both organs. The observations of Laennec fully confirm the facts, that pleurisy and peripneumony are very frequently combined; that, in cases where the pleura alone is inflamed, the stitch of the side may be scarcely perceptible, quite transient, or entirely wanting; and, on the other hand, that a violent peripneumony, complicated with a slight pleurisy, may be attended with a most severe pain in the side.† The latter symptom is, therefore, not pathognomonic of pleuritis. Sometimes, though seldom, the pleura is inflamed on both sides of the chest, so as to constitute what has been termed *double pleurisy*.‡ It is indeed, as Laennec states, not uncommon to meet with slight degrees of pleurisy on both sides of the chest, produced a few hours before death in several

acute and chronic diseases; or with a similar affection that has occurred on one side in the last hours of life, while the other side is violently inflamed. But it is extremely rare to see the pleura of both sides simultaneously attacked with violent inflammation and abundant effusion; and, when such a case does occur, it is almost always speedily fatal.]

Like peripneumony, we also find pleurisy an occasional symptom or result of typhus, catarrh, rheumatism, various exanthems, and hypertrophy or enlargement of the heart.—(*Original Cases, &c.*, by John Forbes, M.D., p. 222, 8vo., 1824.) The pleurisy, however, that is supposed to accompany rheumatism, is often an inflammatory affection of the intercostal or other thoracic muscles alone, since the pain is confined to the origin and insertion of the muscles. Where this has been accurately attended to, it has been distinguished by the name of *bastard pleurisy*; and simply by that of *pleuritis* by Dr. Frank (Op. cit., tom. ii., p. 126), and those who have regarded genuine pleurisy as a mere modification of pneumonitis, or peripneumonia.

Like the preceding species, true pleurisy commences with the usual signs of a febrile attack, as chilliness or shivering, succeeded by heat and restlessness. The pain, or stitch in the side, is usually just above the short ribs, and the dyspnoea is characterized by the expirations being less painful than the inspirations.* The pulse is hard, strong, and frequent; and though the cough is mostly dry and suppressed, there is sometimes a bloody or puriform mucus spit up from the lungs. The patient generally lies most easily on the affected side, or the back, and cannot turn on the opposite side without a great increase of the difficulty of breathing.† [As soon as effusion takes place, the natural sound of the chest on percussion is lost over the whole space occupied by the fluid; and, with the stethoscope, a total absence or great diminution of the respiratory sound, and the appearance, disappearance, and return of ægophony will be detected. When the effusion is considerable, the respiration usually becomes *puerile* on the sound side, and the diseased side is larger than the other.]

* The pain, which is acute and severe, is usually restricted to a circumscribed space; and is considerably increased by any attempt to make a full inspiration. In truth, the respiration is quickened in pleurisy to compensate for the small quantity of air that can be inhaled on each imperfect expansion of the chest. The pain is not augmented by slight pressure, though it is so by strong. At all events, as Dr. Elliotson remarks, the pleurisy must be very severe, if the pain be increased by slight pressure. On the other hand, in rheumatism of the muscles of the chest, the least touch causes pain and soreness. It is also remarked by Dr. Elliotson, that, for the most part, there is profuse sweating in acute rheumatism, such as does not occur in pleuritis. In the latter, the constitution is more disturbed, but the pain is less excruciating than in acute rheumatism.—Ed.

† The best medical writers contradict one another in their statements about the position in which a patient, labouring under pleurisy, finds himself most easy. The truth is, that some differ

* Instead of this division, the editor would have preferred that into acute and chronic pleuritis.

† Laennec, Op. cit., p. 420. Pneumonia is alleged more frequently to produce pleurisy, than pleurisy pneumonia.—Dr. Law, in Cyclop. of Pract. Med., art. PLEURISY.

‡ Pleurisy of one side, as Dr. Law observes (Cyclop. of Pract. Med., art. PLEURISY), is not unfrequently complicated with some disease of the opposite lung, which may either become emphysematous, or the subject of bronchitis, or pneumonia. Another frequent complication of pleurisy is tubercles of the lungs.—Ed.

Like the preceding species, also, pleurisy terminates in resolution, suppuration, and gangrene. The former is the ordinary and most favourable issue. The last occurs rarely, and Laennec has seen only one instance of it from acute inflammation; but suppuration is by no means uncommon; in which case, if the abscess do not point outwardly, an empyema will necessarily follow; and the formation of pus is indicated by a remission of the pain, one or more shivering fits, and, in some instances, a sense of fluctuation. This, however, is a termination far more common to pleurisy from external injuries, than from internal causes.

[The pleura, when acutely inflamed, exhibits a punctuated redness, or an infinity of small bloody spots of very irregular figure. They occupy the whole thickness of the membrane, and leave small intermediate portions retaining the natural white colour. It cannot be doubted (says Laennec), that, during life, the redness was uniform; and that the punctuated appearance and partial whiteness are owing to changes which occur after death. Besides this particular redness, the superficial blood vessels of the pleura are always redder and more distended than in the natural state. Many consider a thickening of the pleura a very common result of its inflammation; but Laennec thinks that, in most cases, where such thickening has been supposed to exist, the appearance was produced by an extensive congeries of milary tubercles on the outer or inner surface of the pleura, a cartilaginous incrustation on the parts covered by it, or a layer of coagulating lymph on its internal surface. Inflammation of the pleura, he says, is always accompanied by an extravasation on its internal surface; the matter effused being either coagulating lymph, termed a *false membrane*, or else scrocity, or a sero-purulent fluid. The serous effusion is commonly of a light yellow colour and transparent, or with its transparency only slightly interrupted by the intermixture of small fragments of pus or lymph, so as to give it the appearance of unstrained whey. In acute pleurisy, it is mostly free from smell. Generally speaking, the more violent the inflammation, the more extensive and thick is the membranous exudation, or layer of coagulating lymph. On the contrary, in weak leucophlegmatic subjects, we find a great quantity of limpid serum, with a small portion of thin membrane often floating in it. In such cases the pleurisy seems to pass insensibly into hy-

ence prevails in different cases. Dr. Law gives it as the result of his observations, that, generally, as long as the acute lancinating pain of the side continues, the aggravation of it, caused by the pressure, makes the patient put himself either on the opposite side or upon his back. When the pain has ceased, and extensive effusion takes place, the position before avoided is now adopted; because, the effusion having interrupted the function of one lung, a necessity for greatly augmented action devolves upon the other; and in order to favour this, and to let the muscles have the freest action on the unaffected side of the chest, the patient lies on the diseased side.—See Cyclop. of Pract. Med., art. PLEURISY.

drothorax. In some rare instances we find a pseudo-membranous exudation, uniting the contiguous surfaces of the pleura, without any serous effusion. This, as Laennec observes, would be a very common case, if we took into our account those pleurisies which had made some progress towards a cure, the absorption of the fluid being the first step in the sanative process. But the less common examples to which he alludes above are noticed in persons dying of some other disease, and who were at the same time affected with a slight and partial pleurisy. In these cases we find a white, almost colourless, semi-transparent exudation, which, while recent, readily allows the parts to be separated, and remains on the surface of each, exactly like a thick and moist paste, which had united two leaves of paper.

The pleura pulmonalis near the inflamed part is also sometimes covered to a small extent with a layer of lymph of various consistence and thickness. In some cases, we find no serous effusion after death; and Laennec has met with similar examples of partial pleurisy, in which no extravasated fluid could be perceived with the stethoscope.

Many physicians imagine that the effusion does not occur till after some time, and even some days. This opinion is pronounced by Laennec to be incorrect. He has several times observed all the physical signs of effusion, viz., ægophonism, and absence of the respiration and sound on percussion, in one hour from the first invasion of the disease, and he has seen the side manifestly dilated at the end of three hours.

The false membrane, or exudation of lymph, is gradually changed into cellular substance, or rather into a true serous tissue, like that of the pleura. The serous effusion is absorbed, the compressed lung expands, and the false membrane investing it and the costal pleura becomes united into one substance, which afterward becomes vascular and organized, and constitutes permanent adhesions. A severe pleurisy, that has terminated by numerous adhesions, renders the part so affected much less liable to subsequent attacks of the same disease; and when it occurs, the inflammation and effusion do not extend to the adherent parts.

When pleurisy is simple, the pulmonary tissue is free from inflammation, even in the vicinity of the inflamed portions of the pleura; but it is rendered more dense and less crepitous from the compression of the effused fluid. If the extravasation has been very great, the lung becomes flattened and completely flaccid; it no longer contains air, or crepitates; its vessels are compressed, and contain little blood; and the bronchiæ are rendered smaller. Yet there is no trace of obstruction, as in pneumonitis; and if air is blown into the bronchiæ, the lungs expand.—(Laennec, op. cit., p. 421, et seq.) When the effused fluid is tinged with blood, or, what is rare, contains coagula (see *Case recorded by Andral, Clinique, Med.*, tom. ii., obs. 15), Laennec terms the disorder *acute hemorrhagic pleurisy*.

Among the occasional causes of pleurisy enumerated by Laennec are, inclemency of the winter; long exposure to cold after violent exercise; metastasis of gout, rheumatism, and cutaneous diseases; blows on the chest; and fracture of the ribs. One of the chief dangers of penetrating wounds of the chest, is inflammation of the pleura or lungs. Dr. Law has seen a fatal case of pleurisy produced by perforation of the pleura, in passing the needle round the subclavian artery for the cure of an axillary aneurism.—(*Cyclop. of Pract. Med.*, art. PLEURISY.) Among predisposing causes are, a slender frame, narrowness of the chest, the immoderate use of spirits, and tubercles in the lungs. In youth and middle life, plethora, violent exercise, intemperance, and cold, frequently bring on pleurisy; but in old persons, and subjects of delicate constitution, who take great care of themselves, it is still more frequent. The worst cases, as Laennec truly remarks, occur in the weakest subjects, and in cachectic habits.—(*Op. cit.*, p. 445, 2d edit.)]

Perhaps there is no disease in which profuse bleeding from a large orifice may be so fully depended upon, or has been so generally acceded to by practitioners of all ages and all nations; the only question which has ever arisen upon the subject being, whether the blood should be taken from the side affected, or from the opposite. The earlier Greeks recommended the former, the Galenists and Arabians the latter; and the dispute at one time rose so high, that the medical colleges themselves not being able to determine the point, the authority of the emperor Charles IX. was whimsically appealed to; who, with much confusion to the controversy, died himself of a pleurisy before he had delivered his judgment. He, too, had been bled, and his death was immediately ascribed to the blood having been drawn from the wrong side. At present, from a knowledge of the circulation of the blood, we can smile at these nugatory solemnities. It is possible, however, that there are some controversies of our own times that have as little groundwork, and at which future ages may smile with as much reason. The blood drawn in this disease has a peculiarly thick, yellowish, tenacious corium, and is hence specifically distinguished by the name of the pleuritic corium or coagulum.

[Should the pain and fever not yield to the first or second venesection, Laennec very properly recommends it to be followed up by local bleeding, preferring, however, cupping to leeches. As Dr. J. Forbes judiciously observes, one of the many practical advantages of accurate diagnosis in pleurisy and peripneumony is, the much greater benefit derived from local bleeding in the former than in the latter disease. He believes we are accustomed to trust too much to general, and too little to local bleeding in this disease, and that both, combined in moderation, are greatly preferable to either in excess.—(See note in *Laennec*, p. 479, 2d edit.)]

Purgatives should be used freely; blistering the side is very generally beneficial after bleeding has been tried and repeated, and should be

accompanied with diluents and diaphoretics. [Blisters should not be applied in too early a stage, as they are then apt to increase the fever and pleuritic affection. In this disease, as well as in pneumonitis, Laennec prescribes tartarized antimony freely, and states that it speedily subdues the inflammatory action, and obviates the necessity of abstracting profuse quantities of blood.] Opium may also be employed with less caution than in peripneumony, and is a most valuable medicine, joined with calomel, as recommended by Dr. R. Hamilton.* For promoting the absorption of the effused fluid, the latter medicines, acetate of potass, digitalis, with mercurial inunction, and blisters, are the best means. When the accumulation increases so as to form dropsy, paracentesis of the chest may become necessary.†

The heart and pericardium are sometimes apt to associate in the morbid action, as well as the lungs themselves. This is particularly the case in the SECOND VARIETY. Dr. Perceval, in his manuscript commentary on the Nosology, has given me a striking example of this, in a

* Dr. Elliotson enumerates bleeding, mercury, starvation, and purging, among the remedies indicated for the relief of this as well as other inflammations. Mercury is now, indeed, universally acknowledged to be one of the most powerful means of subduing inflammation of the serous membranes in general.—ED.

† Sometimes the affected side of the chest seems more expanded than the other; and if the effusion be in the left pleura, the heart may be so displaced, that it pulsates to the left of the sternum. An accumulation of fluid in the right pleura may push down the liver in an extraordinary manner, so as to cause an appearance in the abdomen, as if that viscus were enormously enlarged, whereas there may not be the slightest disease of it; a mistake which often took place before auscultation began to be employed, but which, with the valuable aid of the stethoscope and percussion, will hardly happen again. The want of a hollow sound on percussion, even without ægophony, which prevails only while the quantity of fluid is moderate (see Elliotson's Lectures), will, with attention to the history of the case, render the diagnosis of fluid in the chest sufficiently clear. When effusion takes place, there is a dead sound on percussion, and no respiratory murmur is heard. Dr. Elliotson observes, that the part of the chest where we should first listen for ægophony, is from about one to three fingers' breadth from the lower angle of the scapula to the nipple, because it is *below* this point that the fluid generally accumulates; and, if the whole lung be covered with effusion, still the thickness of the body of the fluid is always less at the posterior part of the chest. If the lung has been so compressed that it will not expand, and the fluid has been absorbed or let out, and no more has formed, the ribs on that side fall, and lie closer together than natural; the shoulder on that side becomes lower than the other; and the muscles, especially the pectoral, waste. Even the spinal column at length inclines, in some cases, to the affected side. These circumstances were first well described by the celebrated Laennec. Dr. Elliotson, in his Lectures, gives an excellent account of them, with the particulars of a case, in which a chronic pleuritis, terminating in such changes, had been mistaken for phthisis cured by means of muriate of lime.—ED.

patient who complained of excruciating pain in the region of the heart, with dyspnoea, not at all relieved by copious and repeated bleedings. After death, a slight effusion was discovered in the pericardium: but the mediastinum was more inflamed than the membrane of the heart. The treatment of this variety ought not to differ from that of the preceding.

The cerebrum is, however, still more disposed to associate in the morbid chain of action than the heart. And hence, when any of the varieties of pleuritis, and particularly the last, are combined with an affection of this organ, and produce delirium, the disorder was formerly distinguished by the terms *paraphrenesis* and *paraphrenitis*; terms derived apparently from the peripatetic philosophy, which supposed the seat of the *φῆνῃ*, or soul, to be the *præcordia*; whence this region was denominated *φῆνῃς*; while, as Hippocrates supposed its seat to be in the brain, phrenitis, with a lamentable confusion of terms, was, as we have already remarked, applied to an inflammation of this last organ, and continues to be very generally so applied in the present day.

It is in the LAST VARIETY that the head is most commonly affected: probably from the general sympathy which the diaphragm holds with the lungs and the stomach, and the close community of action between both these organs and the brain. The breathing is here peculiarly distressing and anxious, the diaphragm being the muscle chiefly concerned in respiration, which now takes place without its aid. The hypochondria are drawn inwards, and kept at rest as much as possible: the patient is tormented with hiccough and sickness; and there is a peculiar tendency to spasmodic action; whence the angles of the mouth are often involuntarily retracted: there is a sardonic laugh on the countenance, a sense of tightness like the stricture of a cord at the *præcordia*, and convulsions wander from one part of the system to another. Professor Frank mentions a case in which all these symptoms were present, and which was consequently supposed to be, and was treated as, a diaphragmatic pleurisy, but which on dissection (for it proved fatal) was ascertained to be a case of intestinal worms, the diaphragm showing no manifest affection. It is highly probable, however, that the diaphragm was here influenced by sympathy, and that the distinctive symptoms were the result of such irritation. The treatment should be as in the preceding varieties.

SPECIES IX.

EMPRESMA CARDITIS.

INFLAMMATION OF THE HEART.

PAIN IN THE REGION OF THE HEART, OFTEN PUNGENT ANXIETY; PALPITATION; IRREGULAR PULSE.

THE symptoms in the definition sufficiently distinguish this species from the preceding. At the same time, it must be acknowledged,

that carditis, like pleuritis, has many signs in common with pneumonitis; which may readily be conceived from the vicinity and close connexion of the thoracic viscera with each other, and particularly from the very strong sympathy with which they co-operate. Dr. Cullen affirms, indeed, that he has often met with cases of carditis evincing no other symptoms than those of pneumonitis, and Dr. Frank concurs in the same testimony. Vogel's definition is founded altogether upon this view, "*Cordis inflammatio ferè ut in peripneumonia.*" I have hence been at some pains to draw a line of distinction; and I think it may be found in the symptoms now delivered as the specific character of the disease. We may add to these symptoms, that there is sometimes, though not always, great difficulty of breathing, generally some degree of cough, but without expectoration, and a perpetual tendency to fainting; and that if deliquium take place, and the patient do not soon recover from it, it proves fatal.* Portal asserts, that the organic pain is accompanied with an increase of heat, which often spreads to the surrounding regions. This is Portal's *acute* modification of the disease: but he also notices an *obscure* or latent modification, in which its symptoms are but little conspicuous, and whatever exists of them are ascribed to some other disease. The spirit, he tells us, is here suddenly subdued and broken; the pulse is slow, soft, and feeble: there is little pain in the heart, and little or no palpitation. Fainting, nevertheless, is a frequent appendage, and is peculiarly apt to lead astray. This, however, can hardly be called an idiopathic disease. Portal has drawn his description entirely from post-mortem appearances in those who have died of severe atonic typhus, or of plague; and observing, as Chicoyneau had before him, occasional proofs of suppuraton and gangrene of the heart, he has inferred the previous existence of carditis, and has ascribed the almost instantaneous sinking of the patient to a rapid march of inflammation in this organ, notwithstanding it was not manifestly accompanied with its ordinary indications.†

* Abercrombie, Contributions to the Pathology of the Heart.—Trans. of the Medico-Chir. Soc. of Edin., vol. i., 1824.

† Mémoires sur la Nature et le Traitement de plusieurs Maladies, par A. Portal, tom. 4me., 8vo., Paris, 1819. One case, the fatal result of which had been preceded by several of the symptoms frequently noticed in pericarditis, was opened by Andral. The following is a sketch of the disorder:—In the midst of a good state of health, sudden dyspnoea; pain not very acute about the heart; tumultuous beatings of this organ; very frequent, irregular pulse; increasing suffocation, and death. Nothing wrong was detected about the pericardium and substance of the heart, its auriculo-ventricular openings, the mouths of the great arteries, or its vessels; but the internal surface of its left cavities were of a bright red colour. No other morbid changes. In another example, where the patient was seized with pleurisy, and died, after having suffered for three weeks pain about the heart, dyspnoea, and palpitations, and where each contraction of the ventricles was fol-

[The obscurity in the diagnosis of pericarditis is still generally acknowledged. Dr. Ribes continues to assert, that it has no group of distinguishing symptoms. Sometimes, their assemblage would lead one to suspect an extravasation in the pericardium, and dissection afterward reveals only a partial pleurisy, with matter effused exclusively in the pleura.—(Andral, *Clinique Médicale*, tom. ii., p. 483.) Sometimes great dyspnœa, augmenting until death, with a regular pulse, and without pain, shall be the only sign of an affection of the pericardium, with fluid effused in its cavity.—(Id., tom. iii., p. 438.) In another instance, where a tuberculated state of the lungs is ascertained, and yet the respiration is little oppressed, a severe dyspnœa suddenly comes on, and proves rapidly fatal; dissection disclosing a purulent collection in the pericardium.—(Ibid., Case following that last cited; see Andral, tom. iii., obs. 9.) There has been no pain; but aneurismal symptoms have occurred, which the post-obituary examination has not explained the cause of. Such is the influence of disease of the pericardium over the organ which it encloses, that it has occasioned appearances of complaints which had no existence; and the symptoms of chronic inflammation of the membrane may assume a form resembling that of organic disease of the heart. On other occasions, palpitations are the main effects, and the other local symptoms afford no information. In Andral's twelfth case, there was pain at the bottom of the sternum, and in the region of the heart; obscurity in the pulsations of this organ; but strength and regularity in the pulse: dissection showed a stratum of coagulating lymph in the pericardium. Several times in the course of the disease, the dyspnœa and general anxiety subsided with the pain.*

No modern pathologist has investigated the characteristic symptoms of pericarditis with greater discrimination than M. Louis. The cases which he witnessed and verified by dissection show, that the symptoms most to be depended upon are, *a more or less acute pain in the præcordia, taking place suddenly; accompanied with oppression and palpitations in a greater or less degree; irregularity, or intermissions of the pulse, sooner or later followed by an obscure, dull sound in the region of the heart on percussion, while the rest of the chest*

lowed by a dull, grating sound, Andral found no lesion, but a *vivid red colour of the valves of the aorta*, the texture of which was thickened. In certain cases of organic disease of the heart, where great redness of the whole of this organ, or parts of it, is found after death, not ascribable to putrefaction, and where the patients are suddenly seized with alarming symptoms, connected with exasperation of the disease of the heart, and die in the midst of these aggravated symptoms, Andral suspects that the catastrophe is referrible to the organic disease becoming complicated with acute inflammation.—See *Clinique Médicale*; and *Anat. Pathol.*, tom. ii., p. 279.—Ed.

* F. Ribes, de l'Anatomie Pathologique, considérée dans ses vrais Rapports avec la Science des Maladies, tom. i., p. 88, Paris, 1828.

yields a clear resonance. When all these symptoms are combined in a person previously well, the existence of pericarditis may be inferred. If the pain were absent, and the other symptoms occurred, the diagnosis, according to M. Louis, would be hardly less clear; for the only doubt would be between pericarditis and hydrops pericardii, and this last disease is formed less quickly, and without all the series of symptoms above detailed. In a chronic case, more difficulty would be experienced.*

The anasarca and coldness of the lower extremities, in cases recorded by M. Louis, approximate them to other affections of the heart, and make an additional line of division between this disease and those of other organs.†]

In carditis, adhesions have been occasionally found to a very considerable extent between the heart and pericardium, even where little inconvenience had been felt during life; from which we may, at least, collect, that the extent of motion of these two parts on each other is not very great. A purulent kind of fluid has at times also been detected on the outer surface of the heart, without the slightest appearance of ulceration either of the heart or pericardium; and, as the same sort of secretion has often been traced, without ulceration, in other cavi-

* Dr. Latham mentions two cases, which were supposed to be marked inflammation of the brain; yet this organ was found, after death, perfectly sound in each example, and the heart affected with intense pericarditis.—(Med. Gaz., vol. iii., p. 209.) Andral relates a similar case.—(Clinique Méd., tom. iii., p. 444.) Cases so anomalous as these Dr. Hope considers rare. The principal symptoms of pericarditis, enumerated by the latter physician, are, acute inflammatory fever; a pungent, burning, lancinating pain in the region of the heart, shooting to the left scapula, shoulder, and upper arm, but rarely descending below the elbow, or even quite to it. The pain is increased by full inspiration, and especially by pressure between the præcordial ribs, and by forcing the epigastrium upwards, underneath the left hypochondrium; inability of lying on the left side; dry cough; hurried respiration; palpitation of the heart, the impulse of which is sometimes violent, bounding, and regular, though its beats may be unequal in strength; at other times its action is feeble, fluttering, and irregular; pulse always frequent, and generally at first full, hard, jerking, and often with a thrill; dyspnœa; a constrained position, any deviation from which brings on a feeling of suffocation; extreme anxiety; constant jactitation, &c. As many of these symptoms attend other complaints, it must be confessed that they would leave the diagnosis obscure.—Ed.

† P. C. Louis, Mém. Anat. Pathologique, p. 274, Paris, 1826. The observations on pericarditis in this work are highly important. Dr. Elliottson, in describing a case of dilatation and attenuation of the ventricles, and disease of the aortic valves, as proved by dissection, mentions that the symptoms were, universal dropsy; difficulty of breathing; loud action of the ventricles, and a bellows sound at the apex of the heart. These things, he says, frequently occur in persons under thirty, and they also generally occur in consequence of pericarditis, and pericarditis as the result or attendant of rheumatism.—See Clin. Lect., Lancet, 1830-31, p. 488.—Ed.

ties, Mr. Hewson, as we have already seen, first suspected, and Mr. Hunter afterward endeavoured to establish, that this fluid is nothing more than coagulable lymph thrown forth from the vasa vasorum, but changed in its nature in consequence of passing through vessels in a state of inflammatory action. And it was this discovery, and the hint thus founded upon it, that gave rise to the doctrine now so generally admitted, and apparently so well sustained, of a distinct secretion of pus, in many cases, without ulceration.*

The causes of carditis are often obscure: where we can trace them, they are for the most part those of pneumonitis; and the mode of treatment needs not essentially vary. Dr. Frank gives an interesting case of violent carditis, brought on by terror in a prisoner condemned capitally. The inflammation proved fatal; but, on dissection, was found not to be confined to the heart.

[Inflammation of the heart appears to be a rare affection,† and, as Laennec remarks, it is

* In the bodies of persons who died of pericarditis, Laennec frequently found the heart softened, and of a very pale colour, which he compared to that of a dead leaf. According to Andral, there is, in such cases, rather a flaccidity of the heart than a true softening of it.—(Anat. Pathol., tom. ii., p. 300.) Dr. Elliotson has given some interesting particulars of an instance of pericarditis, joined with hypertrophy of the left ventricle. The symptoms were, dyspnoea; violent and extensive palpitation; beatings of the heart, 160 in a minute; violent pain about this organ, darting to the clavicle and shoulder, and back to the scapula; extreme tenderness on pressure over the heart. The impulse and sound of the heart's action were perceived very extensively over the chest. The sound, which was that of the bellows kind, occurred with the pulse at the wrist, when the heart struck the side. The pulse was often irregular, very small, and at times hardly distinguishable; a symptom alleged by Dr. Elliotson to be common in pericarditis. There was a great and extensive dullness of sound on percussion over the cardiac region, which did not arise in this case from effusion in the pericardium. There was also great cough without expectoration; the legs were anasarcaous, and the belly dropsical. The patient was bled in the arm, cupped freely, and put under the influence of mercury. Some relief followed; yet the heart yielded the same sound, and the signs of hypertrophy, and dilatation, and obstruction, as before. As the patient was getting up to take some food, he suddenly expired. On dissection, hypertrophy and dilatation of the left ventricle, and universal adhesions of the pericardium to the heart were noticed, some of which were ancient, others recent. The neighbouring pleura had suffered, and bands were seen between the lungs and pericardium, and lungs and costal pleura.—See Clinical Lectures, in *Lancet* for 1830-31, p. 427.—Ed.

† The redness of the substance or lining of the heart, frequently observed in the dissection of bodies more than twenty-four or thirty hours after death, in warm or damp weather, is not an indication of carditis, but merely a change that has followed dissolution.—(See Andral, *Anat. Pathol.*, tom. ii., p. 276.) In animals poisoned by the oxy-muriate of mercury, the lining of the heart is studded with red spots.—Ed.

consequently very imperfectly known, both in a practical and pathological view. Our author enumerates merely some of the symptoms of pneumonitis, or pleurisy, joined with palpitation, irregularity of pulse, and tendency to fainting. Yet these characters can hardly be received as pathognomonic; because, as Senac observes, (*Traité du Cœur*, tom. ii., ch. vii.), they are extremely uncertain; and, with respect to palpitation, although its presence may lead us to suspect that the heart is affected, yet it is probably only a hypothetical opinion, since, in that inflammation which arises from wounds of the heart, palpitation does not occur. What Corvisart describes as inflammation of the heart, seems to Laennec to have been in reality pericarditis, conjoined with a paleness, and sometimes also with softness of the substance of the heart.—(Laennec, *Op. cit.*, p. 621.) Indeed, as Dr. J. Forbes remarks, carditis, properly so called, has been almost universally confounded with pericarditis. He has never seen an unequivocal case of inflammation of the muscular substance of the heart. Yet he has no doubt of its occasional existence, from the statements of Dr. Baillie, and from ulcers and abscesses having been met with in that substance.*

There seems sometimes to be an increase in the action of the vessels of the heart, which, though short of inflammation, is sufficient to give thickness to its walls, and considerable magnitude to its general substance: and hence, a frequent origin of enlargement of the heart. M. Bayle has published an interesting case, which appears to belong to this kind of morbid structure. The patient was a young man of delicate constitution and limited intellect. He was attacked in 1819 with mental derangement; and, in a few months afterward, seemed to labour under a general oppression in every organ, under which he died in a few days. The membranes of the brain were infiltrated and thickened; the heart was twice and a half its natural size; the aorta and pulmonary artery, as well as various other vessels, gave evident proof of a direct inflammatory action.—(*Obs. d'Arterite*, *Bibliothèque Médicale*, Sept., 1821.)

There is often a slow or chronic inflammation subsisting in a portion of the heart, which does not betray itself by any peculiar symptom; for abscesses in the substance of the ventricles, and ulcers on the external surface, are occasionally found after death, without any symp-

* Of universal carditis, with effusion of pus generally throughout the muscular tissue, Dr. Hope believes (*Cyclop. of Pract. Med.*, art. PERICARDITIS), that there is not more than a single instance on record, and that occurred to Dr. Latham. "The whole heart," says Dr. L., "was deeply tinged with dark-coloured blood, and its substance softened; and here and there, upon the section of both ventricles, innumerable small points of pus oozed from among the muscular fibres. This was the result of a most rapid and acute inflammation, in which death took place after an illness of only two days."—*Med. Gaz.*, vol. iii., p. 118. Portal and Chicoyneau are alleged, however, in the text (see p. 501), to have seen proofs of suppuration and gangrene of the heart.—Ed.

toms of previous inflammation.—(*Morgagni*, epist. xxv., art. xvii.; *Bonet*, tom. i., p. 849.)

SPECIES X.

EMPRESMA PERITONITIS.

INFLAMMATION OF THE PERITONEUM.

PAIN AND TENDERNESS OF THE ABDOMEN, ESPECIALLY ON PRESSURE, OR IN AN ERECT POSTURE; WITH LITTLE AFFECTION OF THE SUBJACENT VISCERA, OR ABDOMINAL WALLS.*

THE inflammation may be seated in the peritoneal membrane lining the cavity of the abdomen, or in its extension to the mesentery or omentum. And hence Dr. Cullen has noticed the three first following varieties, [to which modern experience has added a fourth]:—

- | | |
|----------------------|---|
| a Propria. | The inflammation taking the general range of the peritoneum; pain extreme, often pungent, with little or no relief from stools. |
| β Omentalis. | With a more sensible swelling in the region of the omentum. |
| γ Mesenterica. | Pain more deeply seated, and more immediately in the mesenteric region: external tenderness less than in the preceding varieties. |
| Chronica. | Progress slow and insidious; pulse accelerated; little or no tension of the abdomen; sense of pricking, or slight tenderness in the belly; bowels generally costive, sometimes loose. |
| Chronic peritonitis. | |

* "Pain, tumefaction, and tenderness of the abdomen on pressure, are the most prominent symptoms which characterize this affection during life; and increased vascularity, thickening, effusions of coagulable lymph, of serum, of pus, or blood, are the principal local effects produced by it. These elementary features, accompanied in general with more or less of pyrexia, will exist in different degrees and combinations, in every variety of age, sex, or constitution; modified, however, by circumstances, derived partly from the nature of the cause, and partly from the condition of the patient at the time of the attack. Peritonitis may assume either the acute or chronic form. It may exist as a sporadic disease, or prevail as an epidemic. It either presents itself openly, with a numerous group of well-marked symptoms, or creeps on in a latent state, with scarcely one of its characteristic features. It may be limited in its extent to a small portion of membrane, or spread over a large surface. It may run its course uncombined with any other affection, or be complicated with various diseases. There is no period of life exempt from its attacks, &c.: pursuing the same course, and exhibiting similar effects in all, it yet presents a vast variety of symptoms in individual cases, principally according to the organ whose peritoneal covering is the chief seat of the inflammation."—Dr. MacAdain, in *Cyclop. of Pract. Med.*, art. PERITONITIS.—ED.

It is singular that Dr. Cullen, after distinctly characterizing this species in his *Nosology*, and following it up into three subdivisions, each of which, with him, forms a separate species, as the general disease does a genus, should take no other notice of the entire complaint in any form, except what is expressed in the following laconic remark:—"Among the inflammations of the abdominal region, I have given a place in our *Nosology* to the peritonitis; comprehending under that title, not only the inflammations affecting the peritoneum lining the cavity of the abdomen, but also those affecting the extensions of this membrane in the omentum and mesentery. It is not, however, proposed to treat of them here, because it is very difficult to say by what symptoms they are always to be known; and further, because when known, they do not require any remedies besides those of inflammation in general."

This remark is by far too sweeping. If the diseases referred to have no specific symptoms by which they can be known, they have no more claim to be admitted into a system of symptomatic nosology, than into a treatise of practice. Dr. Cullen is right in assigning them a place in the former; and he is, therefore, necessarily wrong, in banishing them from the latter; and the more so, as the treatment ought, in some degree, to vary from that of enteritis, to which his general observation seems chiefly to refer.

THE TRUE PERITONITIS occurs, as we have already observed, as a symptom in PUERPERAL FEVER;* and, as we have treated of it at some length under that disease, it is the less necessary to be minute in our account at present. Puerperal fever, indeed, is sometimes, though not quite correctly, made a variety of PERITONITIS; for it is a disease of a peculiar kind, produced by peculiar causes, and is only connected with peritonitis as the latter enters as a symptom into its general character, and may hence take the name of *puerperal peritonitis*, to distinguish it from *idiopathic*.

[Acute peritonitis generally begins with chills and shiverings, though these are occasionally slight, and sometimes not at all observable. The pulse becomes quick and frequent; the urine is scanty and high-coloured; there is considerable thirst; and the general affection, called fever, ensues. These symptoms are attended from the very beginning with a sense of heat and pain in the abdomen; at first, generally confined to one part, though sometimes more diffused. This pain is much increased by pressure;† or, in other words, there is a great tenderness or soreness of the belly; but it is not

* From what is stated in the notes upon puerperal fever, the reader will see that peritonitis is not a constant or an essential part of the disorder.—ED.

† In order to judge whether the tenderness depends upon a real increase of sensibility, the hand should be laid flat on the centre of the abdomen, and then pressed successively on every part of it. Care should be taken not to make pressure with the ends of the fingers; for thus pain may be excited where there is no disease.—*Marquet's Pathology*, by Quain, 3d ed., p. 68.

accompanied by any inclination to go to stool. The pulse is at least 100 in a minute, and small; yet the tongue is not much altered at first from its natural appearance.

In the course of twenty-four hours, however, the pain and tenderness on pressure increase, so that sometimes even the weight of the bed-clothes becomes intolerable, and the pulse rises to 120 or 130 in a minute. At this time, the tongue begins to be covered with a cream-coloured mucus, and, though it is moist, there is great thirst. A considerable degree of tension and swelling now takes place over the whole abdomen, and the patient finds most relief from pain by remaining motionless upon the back, with the knees in a small degree elevated. Along with these symptoms, you will frequently notice singultus, nausea, and vomiting; at first, of the ordinary contents of the stomach, and afterward of bile; though such gastric disturbance is still more characteristic of enteritis, and may not always accompany simple peritoneal inflammation. The tension of the belly continues to increase to the sixth, seventh, or eighth day; on one of which days, unless proper measures have been taken to remove the disease, the patient most commonly expires. Previously to death, the pain often suddenly ceases, and the change may be mistaken for amendment; but, if the symptoms be minutely examined, the pulse will be found to be sinking and increasing in rapidity; the patient's strength is also sensibly diminished, the countenance collapses, cold clammy sweats break out, the extremities lose their warmth, and, at length, a laborious respiration manifests the concluding struggle of life.

A favourable prognosis, however, is to be deduced from a gradual cessation of the pain, especially when it is accompanied by a diminution of tension and soreness, and when, at the same time, the pulse becomes fuller and less frequent, the skin less parched, soft, and moist, the respiration less laborious, and the countenance more open and expressive of ease.

Inflammation of the peritoneum may be distinguished from colic by the permanency of the pain and the frequency of the pulse, as well as by the tenderness on pressure, even before any tension of the abdomen has taken place; and by the absence of any inclination to go to stool, when the pain is severe.* It is not so easily distinguished from inflammation of the bowels, or enteritis. In this latter disease, however, there is obstinate constipation, and frequently vomiting; while the pain is more acute, and not so much aggravated by external pressure.—(See *Bateman's art. PERITONITIS in Rees's Cyclopadia.*)

In the specific definition it is stated, that peritonitis occurs "with little affection of the subjacent viscera or abdominal walls." In effect, it often happens that these are not at all influenced, and, whenever they are, it is only secondarily; and hereby peritonitis is suffi-

ciently distinguished from puerperal fever. "If the peritoneum," says Mr. Hunter (*On Blood, &c.*, p. 244), "which lines the cavity of the abdomen, inflames, its inflammation does not affect the parietes of the abdomen; or if the peritoneum covering any of the viscera is inflamed, it does not affect the viscera. Thus, the peritoneum shall be universally inflamed, as in the puerperal fever, yet the parietes of the abdomen, and the proper coats of the intestines, shall not be affected: on the other hand, if the parietes of the abdomen, or the proper coats of the intestines are inflamed, the peritoneum shall not be affected."

[The researches of Bichat into the tissues of which the various organs consist, confirm Mr. Hunter's opinion, that inflammation of the peritoneum may exist alone, and independent of the subjacent parts. In fact, the organs are composed of several tissues of different natures and structure, and their affections also differ according as this or that tissue happens to be primarily attacked; and the disorder never fixes on all the three coats of the stomach and bowels at once, but first begins in one of them. When the affection is acute, only a single tissue is generally found altered, the others continuing unchanged. Frequently, when the peritoneal covering of an intestine is acutely inflamed, the mucous membrane is remarkably pale.—(*MacAdam in Cyclop. of Pract. Med.*, art. PERITONITIS.)

Not only may the peritoneum be inflamed without the subjacent organs being similarly circumstanced, but such inflammation actually has no essential dependance upon or connexion with those organs. Hence the view sometimes adopted, of gastritis, enteritis, cystitis, &c., being an inflammation seated exclusively in different portions of the serous membrane connected with the stomach, bowels, and bladder, is erroneous, inasmuch as it is supposed that the cases depend upon the corresponding organs. Inflammation of the serous abdominal membrane is never exactly restricted to a single viscus, the surrounding portion of the membrane continuing healthy, but is propagated over a greater or less extent of the peritoneum.—(See *Bichat, Anat. Générale; Leçons d'Anat. Pathol. et Diet. des Sciences Méd.*, art. PERITONITE.)

Numerous dissections of persons destroyed by peritonitis prove, that the whole or only a part of the peritoneum may be inflamed, without the subjacent organs being concerned. In many instances, the muscular and mucous tissues of the stomach and intestines were found unaffected, even when gangrene had begun to show itself in the peritoneum. In general, the marks of inflammation are stronger, in proportion as the disorder is more advanced and violent. Sometimes the membrane seems as if it were very minutely injected; while in other cases, as Bichat remarks, the redness is hardly discernible, the blood having escaped by the collateral vessels.

Bayle, Broussais, and others, have seen as consequences of acute peritonitis:—1. Redness, thickening of the serous membrane, and here and there sloughs penetrating into the mucous coat.

* "Colic may be distinguished from peritonitis by the absence of fever; the pain being relieved by pressure; the state of the pulse; and the suddenness of the attack."—Dr. MacAdam, op. cit.—Ed.

2. A solid exudation of unorganized coagulating lymph, in the form of false membranes, uniting the surfaces of the peritoneum. 3. A fluid effusion, sometimes turbid, sometimes limpid or reddish. More or less of a sero-purulent fluid was almost always remarked on the surface of the intestines in various places. Broussais also noticed red coagula on the reddened and thickened peritoneum, unaccompanied with any fluid blood; masses of fibrin, destitute of the colouring particles of the blood; and, lastly, pure blood itself, when the effusion was considerable. Gangrene is a much rarer termination, and, according to Dr. Abercrombie, slight and partial, and always accompanied by a deposition of false membrane. It more frequently occurs, when enteritis coexists with inflammation of the peritoneum.

Most examples of peritonitis terminating favourably, leave after them organized adhesions. In general, little gas is found in the bowels; and it is not to it, therefore, that the great distension of the abdomen, remarked before death, can be ascribed.* One remarkable effect of inflammation of the peritoneum is, to lessen its transparency, and render it even quite opaque.]

From what has been said, it appears that the membranous tunics of the different viscera do not, therefore, always hold an equal intimacy of action. And it would be interesting to follow up the discrepancy, and draw a scale of their readiness, or inaptitude, to sympathize with the viscera which they cover. The membranes of the brain, as we have already seen, are so peculiarly disposed to partake of the inflammatory action of the parenchyma, as to render solitary inflammation of the one or of the other a rare occurrence. In the lungs and in the heart, the play of relationship is far less conspicuous, and in the viscera of the abdomen it rarely takes place. And it is owing to this circumstance, that we are able so generally to draw the line between inflammation of the peritoneum and of the intestines, from the pain being much more superficial in the former than in the latter case, and, in many instances, not accompanied with sickness, or any other disturbance of the alvine canal. Portal is too little disposed to admit this distinction, and seems to think that idiopathic inflammation of the peritoneum is by no means a common disease, and that, when it does exist, its manifestation is far from being clear.† But this is to render a general rule universal, and to

sweep away from it the exceptions that chiefly establish its proof.

The causes are those of inflammation in general, as cold, residence in damp situations, the abuse of intoxicating liquors, external injuries, ulceration and rupture of some portion of the alimentary canal, and consequent extravasation of the contents of the stomach or bowels,* and a morbid transfer of action; and, in a few cases, sympathy with the adjoining organs, as in puerperal fever. [Peritonitis is alleged to be more common in adults than children; in women than in men; and in sanguine and plethoric individuals than in others.†]

The treatment is, in like manner, that of inflammation in general, particularly that of *E. ENTERITIS*. Bleeding, both general and local, should be carried into effect copiously and with all possible speed; [nor should the practitioner be deterred from the use of the lancet by the seeming prostration of strength and feebleness of the pulse, which are not uncommon symptoms at the very onset of the disease, especially when the peritoneum of the stomach and bowels participates in the inflammation. Under such circumstances, bleeding will be followed by a rise in the pulse, diminution of the general weakness, and subsidence of pain.—(See *Pemberton on Diseases of the Abdominal Viscera*, chap. i.)] But purging, though at all times of service in inflammatory affections, is less imperiously demanded than in inflammation of the intestines, except where the peritonitis is puerperal, and the system affected generally; in which case we have already observed, that calomel should be given liberally at the commencement of the complaint. [It should be understood, however, that the bowels should always be kept open, and that this should be effected with as little irritation as possible. In ordinary cases, castor-oil, small doses of sulphate of magnesia, and emollient clysters, are

produce little or no inconvenience in enteritis. The action of the diaphragm in full inspiration, or coughing, does not produce so much suffering in enteritis; neither does motion of the body or abdominal muscles.—Dr. MacAdam, *op. cit.*—Ed.]

* See Abercrombie on Pathology of the Stomach, &c., *Edin. Med. Journ.*, No. lxxviii.; Dr. Crampton and B. Travers in *Med.-Chir. Trans.*, vol. viii.; Lewis in *Archives Gén. de Méd.*, Jan., 1823; also, Dr. Stokes in *Cyclop. of Pract. Med.*, art. PERITONITIS, from Perforation of the Serous Membrane.

† Dr. MacAdam in *Cyclop. of Pract. Med.* This intelligent physician: arranges the causes into the mechanical, the chymical, and the vital. The mechanical causes include all injuries inflicted on the abdomen, by falls, blows, wounds, pressure of the gravid uterus, enlarged ovaries, or other morbid growths, extra-uterine conceptions, &c. The chymical causes include all extravasations into the peritoneal cavity, not quickly absorbed, whether of blood, urine, bile, chyle, or feces. The vital causes comprehend all aberrations of healthy actions, transmission of morbid action from a part previously affected to the peritoneum, or extension of inflammation from a contiguous organ or tissue to this membrane. This arrangement seems judicious and well founded.—Ed.]

* Tension and tumefaction of the abdomen are constant and characteristic symptoms of peritonitis. According to Dr. MacAdam, they do arise in the early stages from a tympanic distention of the intestines, though at a later period of the affection, they may be caused by effusion in the peritoneal cavity. In individuals with strong abdominal muscles, the swelling is not very manifest in the early period of the disorder, though the hardness is considerable.—*Cyclop. of Pract. Med.*, art. PERITONITIS; Chomel, *Dict. de Méd.*—Ed.]

* † *Mém. sur la Nature et le Traitement de plusieurs Maladies*, tom. iv., 8vo., Paris, 1819. The most important diagnostic symptom between peritonitis and enteritis is, the sensibility of the abdomen to pressure. In peritonitis, pain is excited by a very slight degree of pressure, which would

the most proper means for this purpose.*] Warm stimulant fomentations may be advantageously applied to the abdomen, and blisters in succession. [The application of a blister should be deferred till the constitutional effects, produced by the inflammation, are partly removed by bleeding.] After a very free use of leeches, I have found more benefit in applying a large folded flannel wrung out in simple hot water, or water impregnated with aromatic herbs, over the whole of the abdomen, and letting it remain there for many hours or till dry, wrapped over with a broad calico or flannel swathe that surrounds the entire body. All we can possibly aim at, in applications of this kind, is a continuation of moist warmth, as in a common poultice; and this is obtained more easily, and with infinitely less fatigue to the patient or danger of giving him cold, than in the ordinary way of applying fomentations. When the bowels have been well opened, opiates may be given with freedom, and especially in union with ipecacuanha, or antimonials, to determine to the surface.

When the INFLAMMATION commences or is seated in THE OMENTUM or EPIPLOON, the pain is more limited, and points rather towards the superior and middle region of the abdomen, a little above and below the navel; though it sometimes inclines to the right or left hypochondrium. The peritoneum itself does not readily pass into a secretion of genuine pus; and still less so the omentum, which, where ulceration takes place, generally evinces a foul and sanious secretion. Sauvages gives a striking example of this in a woman, who was at first attacked with an acute lancinating pain in the umbilical region; and had a tumour formed towards the right hypochondrium about the size of a man's fist, which by degrees occupied the whole abdomen. By an application of emollient cataplasms, the pain and general swelling were diminished in the course of three days; but a fluctuation in the abdomen was next detected, like that of an ascites; in consequence of which, a trocar was introduced into both sides of the abdomen, and a putrid ichorous fluid was discharged, which induced the operator to enlarge the opening; when sloughs of the omentum, already separated, came away with an intolerable stench, and with about two pounds of what Sauvages calls ichorous water. But the skill of the surgeon was overpowered by the disease, and the patient fell a victim to it.—(*Nosol. Med.*, Class III., Ord. III., XVI.)

The mesentery has but a small degree of sen-

* Many judicious practitioners are not afraid, however, of prescribing calomel very freely in peritonitis. Thus, Dr. Mac Adam recommends giving from five to ten grains of calomel, joined with one or two of opium, directly after the local bleeding; and this dose to be followed up by smaller ones every three or four hours. After the second or third dose of calomel, the bowels are to be opened with castor-oil and clysters. If vomiting be urgent, Rochelle salts, with the supercarbonate of soda, in a state of effervescence with lemon juice, may be given in repeated doses so as to produce a moderately laxative effect.—Dr. Mac Adam in *Cyclop. of Pract. Med.*, art. PERITONITIS.—Ed.

sibility, and hence, as well as from the greater depth of the seat of the disease, MESENTERIC INFLAMMATION is only discoverable by pressure. If the affection be strictly mesenteric, the symptoms are mild and gentle; but this is a rare case, and chiefly occurs when the glands are obstructed, and any accidental irritation is applied to them. Most commonly it is catenated with inflammation of the spleen, liver, or intestines. The chief point of tenderness or pressure is the navel; though, in the commencement of the disease, the pain seems to shoot upward from the back; the bowels are often obstinately confined.—(*J. P. Frank*, op. cit., tom. ii., p. 188.)

The medical treatment will be the same as in HEPATITIS or SPLENITIS: though bleeding, in general, effects but little benefit.

[It is to Dr. Pemberton, M. Broussais, and Dr. Gregory, that the profession is indebted for the best descriptions of chronic peritonitis. The disease advances very slowly and insidiously, manifesting itself only by occasional superficial pricking pains over the abdomen, without the patient feeling any inclination to go to stool; or, as Broussais says, by a sort of constant sensibility in the abdomen, often not distinguishable but by the touch. The pulse is somewhat accelerated, with considerable thirst, white tongue in the morning, and a pallid, doughy countenance. There is no tension of the abdomen, as in the acute species; on the contrary, the skin and abdominal muscles seem to sit loosely upon the peritoneum, which feels like a tight bandage underneath them; or, as Broussais states, the abdomen is slightly swelled and elastic, which symptom increases towards the evening. The appetite and digestion often remain undisturbed; but, in other instances, there are vomitings, which Broussais suspected to happen chiefly when the peritoneal coat of the stomach was affected. The same writer also speaks of the feeling of a ball moving about in the belly, and tending towards the throat; referred by him to the mass formed by the agglutination of the bowels and thickened mesentery, moveable in the effused fluid.]

In time, the bowels become agglutinated together, or fluid is effused, so as to produce dropsy. The symptoms are all equivocal, and not one of them pathognomonic. The disease is sometimes the result of protracted acute peritonitis. Old age; a delicate, feeble constitution; occupations confining the abdomen in an habitual state of compression; unhealthy, damp, cold stations, and the rigour of intermittent fever, according to Broussais, are among the chief causes of chronic peritonitis.

By Broussais, chronic inflammation of the peritoneum is regarded as inevitably fatal. The treatment, therefore, in his view, can only be palliative. When any degree of active peritonitis is suspected to prevail, he recommends antiphlogistic remedies, and moderate stimulation of the skin. But when there is no pain, and the symptoms are less marked, he recommends blisters, sudorifics, and the tincture of squills and cantharides, with a nourishing diet,

Emetics and purgatives he considers useful only when some incidental complication calls for them.

On the other hand, Dr. Pemberton's treatment consists in the prohibition of animal food and fermented liquors, and keeping the patient strictly on milk and vegetable diet, with small bleedings once or twice a week, generally by leeches or cupping. The bowels are to be kept open with small doses of sulphate of magnesia or castor-oil. Dr. Pemberton differs from Broussais in not regarding chronic peritonitis as totally incapable of cure.*]

SPECIES XI.

EMPRESMA GASTRITIS.

INFLAMMATION OF THE STOMACH.†

BURNING PAIN AT THE PIT OF THE STOMACH, INCREASED ON SWALLOWING; REJECTION OF EVERY THING; HICCOUGH; EMACIATION; OP-
PRESSION AND DEJECTION OF MIND; FEVER A SYNOCHUS.

If to this species we add the ensuing, or EMPRESMA ENTERITIS, we shall have a general type of fever, according to the doctrine of M.

* Children of a scrofulous habit are subject to one variety of chronic peritonitis, characterized during life by great tenderness of the abdomen on pressure, with occasional paroxysms of acute pain, at first coming on only once or twice a day, but afterward becoming more frequent, after which the child appears quite lively, and free from indisposition. At first the pain is limited, but afterward extends over the whole abdomen, which, in the early stages, becomes swollen and tense, but afterward subsides. The pulse is generally about 100, with some strength and fullness; the tongue clean; appetite irregular, but generally good, and frequently voracious; some thirst; the bowels free, the evacuations unusually large in quantity, and peculiar in appearance, consisting generally of a whitish-brown matter. This state may continue for six weeks or two months, with progressive emaciation, until diarrhoea, attended with petechia, puts a period to the child's life. Dissection exhibits the mesentery, bowels, and peritoneum, united together into one mass; the peritoneum thickened, and containing large masses of scrofulous matter; the intestinal mucous membrane perforated by ulcerations, which form numerous communications between the convolutions of the bowels; and the intestines and abdominal cavity containing matter resembling that which was passed during life by stool. The disease is generally fatal. The treatment recommended by Dr. Gregory consists of leeches and fomentations in the early stage, followed by purgatives, mercurial alteratives, tonics, chalybeates, and absorbents. Laudanum is the only means of relieving the pain.—See Gregory on Scrofulous Inflammation of the Peritoneum, in *Med. Chir. Trans.*, vol. xi., p. 262; and Dr. MacAdam in *Cyclop. of Pract. Med.*, art. PERITONITIS.—Ed.

† Gastritis, a term commonly used to express an inflammation of all the tunics of the stomach, with the exception of its serous covering; but, says Dr. Stokes, as it is now generally believed that this diseased action commences in the mucous membrane and glands, the term is employed to designate an inflammation of the internal tunic, which may or may not affect the remaining tissues.—See *Cyclop. of Pract. Med.*, art., GASTRITIS.—Ed.

Broussais, and that which is commonly received in the present day throughout France: for we have already observed, that this celebrated teacher regards fevers of all kinds as an inflammatory affection of some part or other of the alimentary canal; or, to give a close copy of his own words, "all the ESSENTIAL fevers of authors," says he, "may be referred to *gastro-enteritis*, simple or complicated; and all the acute examples of this inflammation, in its aggravated form, proceed to stupor, typhomania (*fuligo*), lividity, fetidity, and prostration; and represent what have been called typhus, putrid or adynamic fever, or those in which the irritation of the brain is considerable, whether it amount to inflammation or not, whether it produce delirium, convulsions, &c., or take the name of malignant, nervous, or ataxic fevers."—(*Examen des Doc. Méd.*, &c., *Par. J. F. V. Broussais, Prof. de Méd.*, cxxxviii., cxxxix., translated by Hays and Griffith, Phila., 1833.)

Having already entered into the question, whether fever be essentially dependant upon inflammation of any particular organ, as the head, the alimentary canal, the liver, or the pancreas, for all have had their respective advocates, and having pointed out the pathognomonic distinctions between idiopathic fever and organic inflammations, it is not necessary to return to any detailed consideration of this subject. But we ought to add, that there seems more foundation for M. Broussais' opinion in France, than perhaps in any other country; since inflammatory affections of the alimentary canal, in some part or other of its length, or under some modification or other, often indeed accompanied with ulceration, appear to be more common in Paris than in any other town or region in Europe, or perhaps in the world. To what cause this is owing has not been very clearly pointed out; the diet is perhaps chiefly concerned; the water has also been denounced; but there are various auxiliaries which are not so easily detected.

The fact, however, admits of no question: for the observations of MM. Prost, Petit, Serres, and others, concur in proving that by far the greater number of febrile attacks in France, whether sporadic or epidemic, are combined with some modification of gastritis or enteritis, and very generally show symptoms of diarrhoea and dysentery. But that, even in Paris itself, idiopathic fever and inflammation of the alimentary canal are distinct diseases, has been sufficiently established of late by the valuable post-obit examinations of M. Andral; which have been conducted upon a very extensive scale for the express purpose of settling this disputed question. This excellent and indefatigable investigator was selected by M. Lermier, physician to the hospital of La Charité, for the purpose of providing cases and dissections for a valuable system of Clinical Medicine, that has now been in part published. In pursuit of this branch of study, he has been particularly attentive to the state of the alimentary canal through its whole course in patients who have died of fevers of almost every

type and modification; and he has found, that although, as already observed, this organ, in some part or other, has often given proof of inflammatory action, yet that, occasionally, there has been no such effect whatever, and very frequently none sufficiently violent or extensive to become the cause of dissolution, or even of any serious evil to the living frame. In thirty-eight individuals, eleven only presented traces of gastric inflammation sufficiently distinct to warrant the opinion, that they had influenced the symptoms observed during life. In thirty persons, red patches, eruptions, or ulcers were found in the small intestine; but in fourteen only did these lesions appear to bear any proportion to the severity of the symptoms. In the great intestine the alterations were more rare, and less vehement, than in any other portion of the canal.

On comparing the lesions observed in the three great divisions of the canal, the following results were obtained:—In five patients, the entire tube was exempt from every lesion of consequence. In seven others, they appeared too inconsiderable to exercise any influence on the state of the disease. And where the affection was more strictly and manifestly inflammatory, the effects were extremely diversified. In some cases were found eruptions of varied form and character, occasionally running into ulceration. In other cases, the mucous membrane was studded with large patches of inflammation, and the subjacent cellular tissue was advancing to a gangrenous state. In several instances, the ulcers were detached, and assumed a carbuncular appearance.—(*Andral, Clinique Médicale*, tom. i., Paris, 8vo., 1823.)

In most of these examples, there can be no question of the existence of idiopathic gastritis or enteritis: but the simple fact of the existence of numerous instances of fever, and fever too so violent as to prove fatal, without any such accompaniments, together with the certainty that inflammation and even gangrene of particular parts of the alimentary canal are, in numerous instances, effects instead of causes of fever, are a sufficient ground for regarding fever and inflammation either of this or any other kind as distinct diseases, and prove a complete subversion of Broussais' hypothesis.

Inflammation of the stomach may be either of the adhesive or the erythematic character; the latter is the more common (*J. P. Frank, De Cur. Hom. Morb. Epi.*, tom. ii., p. 250); and the species hence offers us two varieties, with considerably different symptoms; which are chiefly, indeed, the result of the peculiar nature of the fever that accompanies this inflammation, already stated to be a synchus, or fever commencing with caumatic, but terminating in typhous symptoms. For this kind of fever it is not difficult to account. We have often had occasion to state, that the stomach is the common centre of sympathy; it is also an organ of acute sensibility; and it is hence impossible for it to suffer from inflammatory action without suffering severely, and without extending its effects very widely.

- α* Adhæsiva. The pain very acute; the Adhesive inflammation of the stomach. fever violent.
- β* Erythematica. With an erythematous blush, Erythematic inflammation of the stomach. extending to and visible in the fauces; pain more moderate; fever less violent; pulse low and quick.

Dr. Cullen seems to have been the first writer that distinctly pointed out the nature of these two varieties, which he has unnecessarily advanced to the rank of species, and later writers have justified the expediency of a distinction. This distinction, as already remarked, is produced by the nature of the accompanying fever; and, consequently, in a considerable degree, by the nature of the constitution in which the disease occurs. The fever is perhaps in every instance a synchus, the cause of which we have just stated; but, while in a firm and robust habit the febrile course has, comparatively, but little tendency to pass from the entonic action with which it commences into a dangerous languor and atony, in relaxed and irritable habits it is apt to run into this stage almost from the first, and the synchus degenerates rapidly into a typhoid character.

In both varieties the causes are alike; as external or internal cold suddenly applied in a heated state of the stomach, acrid substances, or excess in eating. The acrid substances chiefly recorded are jalap, and other drastic purgatives taken in excess; sulphuric acid; corrosive sublimate; and very large doses of nitre, or quantities swallowed by mistake, as an ounce, or an ounce and a half, of both which we have an example in the *Journal de Médecine*.—(*Laflize*, tom. lxxi.; *Souville*, tom. lxxiii.) It is also said to have sometimes been produced by a severe paroxysm of chololithus (*Calt-schmied, Pr. de Ægro inflamm. ventr. demortuo calc.*, &c., Jcn., 1757); and occasionally to have followed *trichosis Plica*, the matted hair of Poland.—(*De la Fontaine, Chirurg. Méd.*) A sudden chill, from swallowing cold water or some other fluid when the body is heated, is a frequent cause: as is also repelled gout, indigestible food, and especially ardent spirits drunk profusely.

The symptoms are sufficiently detailed in the specific definition. Several of them are those of cardialgia; but, in the latter, there is neither fever nor vomiting. The most decisive signs are a permanent local pain, and general emaciation; and these, as M. Chardel has justly observed (*Monog. des Dégén. schirr. de l'Estomac*, 8vo., Paris, 1808), increase with the prolongation of the disease, till both become extreme, and even opium will scarcely relieve the former, in whatever quantity administered.* In a few cases, the food is not rejected for several days; and as the bowels are constipated, and the digestion is imperfect, it remains in the stomach,

* General emaciation can only be expected in cases which are chronic, and of longer duration than the acute form of gastritis.—Ed

and forms a tumour sensible to the pressure of the hand, which, upon rejection, disappears. The presence of this tumour is peculiarly characteristic of an inflamed state of the pylorus, as its absence is of the same state of the cardia; for, in this last case, the contraction of the cardia renders deglutition extremely difficult, and the food is for the most part rejected without reaching the stomach.* From the close sympathy of the stomach with other organs, the disease has sometimes been accompanied with delirium, and in a few instances with hydrophobia. Where the inflammation is violent, it destroys in a few days. If no fatal symptom occur within the first week, it terminates for the most part favourably. Shiverings and a remission of pain are, as usual, marks of suppuration.†

Of the ADHESIVE VARIETY Mr. Cruickshank has given a good illustration in the case of a young lady who died after two or three days' illness, before which she had been in perfect health. "I was called in," says he, "but she was dead before I got to the house. From her history I was at a loss to account for her death; but on opening the abdomen a day or two after, I found the contents of the stomach in that cavity; that they had produced peritoneal inflammation, and killed. On examining the stomach, I found a hole in it large enough to admit the end of my finger. This hole had been formed by absorption of part of the substance of the stomach from scrofulous ulceration: its edges had adhered by inflammation to the under surface

* Dr. Good does not seem to have been aware, that inflamed muscular fibres are not so much disposed to contract as when they are healthy. This fact, which was distinctly mentioned by Desault, is confirmed by later observations. However, the disease called gastritis is seated chiefly in the mucous membrane, and is extremely rare in the acute and idiopathic form.—(See Abercrombie's *Pathol. and Pract. Obs. on Diseases of the Stomach*, &c., i., p. 13, edit. 2.) This physician confesses that he has never seen a case of this nature (p. 15). Dr. Stokes also says, inflammation of the stomach in its highest degree is rarely met with, except in cases of corrosive poisoning. From such examples he infers, that the symptoms would be "intolerable thirst, constant nausea and vomiting, præcordial distress, sunk countenance, extraordinary prostration, fever."—(*Cyclop. of Pract. Med.*) It is conceivable, however, that the action of a corrosive poison on the stomach might lead to other consequences than those of simple inflammation: the local effects would be more rapid, more certainly fatal, and the immediate effects on the system different.—Ed.

† It seems as if the general symptoms, as well as the effects of the inflammation on the stomach itself, were liable to variety. In a case recorded by Mr. Annesley, in his work on the Diseases of India, the early symptoms were acute pain in the stomach, increased by pressure, with slight fever, and no vomiting. On the fourth day vomiting began, and the patient died on the seventh. The coats of the stomach were found thickened, and its internal surface minutely injected. And, in another instance related by the same gentleman, and which was fatal in seven days, the symptoms were, incessant vomiting and hiccough, with fever of a tertian type, but no complaint of pain. The mucous coat was covered with small ulcers.—Ed.

of the small lobe of the liver. This inflammation was evidently raised by the powers of the body to prevent the accident which happened. and if no violent vomiting had taken place, and torn this adhesion at this particular time, she might have lived for years, notwithstanding the ulcer."—(*Anat. of the Absorbent Vessels*, p. 122.)

In many cases of this kind the inflammation is chronic, and indeed of long standing; for the diseased parts of the stomach exhibit great thickening and induration. Where the inflammatory action proceeds very slowly, it is often astonishing to find how little the general health, or even the local state of the stomach, is disturbed. For, as in the case before us, it proceeds without being suspected till the ulcer is complete, the external tunic gives way, and the contents of the stomach are evacuated; which irritate, as a foreign body, in whatever situation they are lodged, excite a new and active inflammation, and destroy in a few days. This indeed is the usual termination, whatever be the progress. Yet the march of the disease is not always thus quiet or deceitful; for it is often preceded by many or all the ordinary concomitants of dyspepsy, as acidity, eructations, flatulence, and oppression of the stomach after eating; often, indeed, accompanied with emaciation and debility, and not unfrequently with hæmatemesis; by which last signs it is chiefly to be distinguished from idiopathic indigestion. The death, however, is commonly sudden, within a day or two, or even a few hours, from the cause just stated. M. Chardel (*Op. cit.*) has given various examples of this form: M. Gerard (*Perf. spon. de l'Estomac*) and Dr. Abercrombie, others.—(*Edin. Med. and Surg. Journ.*, vol. xxi., p. 1.)

[It is observed by the latter writer, that acute inflammation of the stomach is not a common disease in this country,* and when it does occur, the symptoms are so severe and well-defined as immediately to indicate the nature of the affection.† But the stomach is liable to inflammatory action in a chronic form, which often advances so slowly and insidiously, that the dangerous nature of it may be overlooked, until it reaches that stage in which it assumes the characters of organic and hopeless disease. In the early stage, the prominent symptoms, in

* The same remark will equally apply to this country; though it deserves to be noted, that dissections have demonstrated the stomach to be more frequently than any other organ the seat of the immediate ravages of yellow fever, as it has prevailed in the United States.—D.

† Acute idiopathic inflammation of the mucous coat is a rare disease in this country. As Dr. Abercrombie observes, it is from the action of poisons that we chiefly meet with inflammation of that coat of the stomach; but such cases cannot be regarded as necessarily exhibiting the same symptoms which would accompany the idiopathic form of the disorder.—(On Dis. of the Stomach, &c., p. 13.) In fact, we know that each poison is productive of symptoms peculiar to itself, and hence, in this point of view, our author's definition cannot but be imperfect. According to my own judgment, it would have been more consistent with the plan of this system to have treated here only of idiopathic gastritis.—Ed.

fact, merely indicate derangement of the functions of the stomach, and are consequently very apt to be included under the general term dyspepsy.]

Gastritis in its ACUTE form has often been represented in a more dangerous light than it deserves to be; for, in neither variety, under this modification, is it frequently attended with fatal effects under judicious treatment. In the true adhesive form, copious and repeated venesections have been very generally recommended, and have often been found of the highest advantage, particularly in robust and vigorous habits.* To be, however, of any decided avail, this plan of treatment should be commenced early; for the fever is so apt to pass into a typhoid form, that, after the first two or three days, too much inroad will generally have been made upon the constitutional strength to allow the use of the lancet. If acid poisons or excess of eating be the cause, an emetic should be administered; but otherwise this, as well as all other stimulants, should be avoided. Gentle cooling laxatives,† a blister applied after bleeding to the pit of the stomach, mild nutritive drinks (Dr. Stokes particularly recommends cold ones, such as iced water, iced lemonade, &c.), nutritious injections, and, if the pain or sickness be extreme, doses of a drachm of the sirup of white poppies, and perhaps about five grains of nitre in an emulsion of gum arabic or spermaceti, will generally be found the most successful plan. It is, however, extremely difficult to get any medicine to remain on the stomach; and hence the best preparation is that of pills. [In idiopathic inflammation of the internal surface of the stomach, or when that surface becomes inflamed in the progress of dysentery, gout, or other diseases, Dr. Cheyne has often directed entire abstinence from medicine of every description, and from fluids even of the blandest nature, until the inflammation has been removed by bleeding, blistering, fomentations, &c. The inflamed stomach, he observes, is often incapable of retaining even a spoonful of water, and at first, every description of medicine produces an aggravation of sickness, vomiting, and general distress. After one or two days, calomel, in doses of one grain, may be repeated every hour, or four or five grains, and half a grain of opium, given every third or fourth hour, alternating these medicines with a solution of Rochelle salts and soda, to which lemon-juice may be added. But before these remedies be employed, he particularly enjoins a previous reduction of the inflammation.—(*Dublin Hospital Reports*, vol. iv., p. 266.)] If gangrene take

place, all further exertion will be in vain; and we may determine its presence by a sudden cessation of pain, coldness about the præcordia, and languid or intermitting pulse, which are its sure attendants. Under the chronic form we have just noticed, Dr. Abercrombie has found sulphate of iron, in the proportion of two or three grains three times a day, a valuable and decisive remedy, and it is well entitled to attention. [The utility of leeches and counter-irritation on the epigastrium, with a strict regimen, is universally acknowledged, and the superior success of this practice in the cure of many cases of dyspepsy from chronic gastritis, is a fact attested by all the most judicious practitioners.]*

Upon the ERYTHEMATIC VARIETY, the following remarks of Mr. Hunter are too valuable to be omitted; and they are the more valuable, as they apply to disorders of other internal cavities besides the stomach. "There is," says he, "an inflammation which attacks internal

* A peculiar species of gastritis occurs in some parts of America, particularly in Ohio, Tennessee, Illinois, Missouri, North and South Carolina, and Georgia, that merits a passing notice. By some practitioners it is called *sick stomach*, but it is more generally known by the term *milk sickness*. Although some physicians, with Dr. Wnght (see *Western Med. and Phys. Journ.*, 1827), consider this disease as the common autumnal fever of the country, yet the majority of them believe that it presents an additional instance of the influence of animal disease on the human constitution; and that it arises in the human subject from eating food prepared in some manner from animals which are affected with a disorder of the same character: and experiments have been made, and facts are numerous, proving in the most direct manner the conveyance of the disease from one animal to another by milk.

Among the symptoms of this disorder, as detailed by Dr. Yarkin (*Transylvania Journal of Medicine*, vol. i., p. 318) the following are the most remarkable:—"After the use of milk, butter, or recently slaughtered meat, the individual is attacked with a distressing sense of burning in the epigastrium, followed by vomiting, with insatiable thirst. These symptoms are uniformly pathognomonic, and continue throughout the complaint. The bowels are constipated; the pulse, at first natural, becomes in the sequel small, tense, vibratory, and often irregular. Epigastrium tender to the touch; body hot, extremities cold; the patient's breath has a peculiar odour, sui generis, which is indescribable. The symptoms of the chronic form of the complaint are, a slight burning in the stomach, continued, and distressing; occasional vomiting; general debility; costive bowels; sullen countenance; intellectual dulness."

In the treatment of this disease, Dr. Y. observes, that cathartics are the sheet-anchor; and he prefers calomel, the operation of which is to be assisted by stimulating enemata, until free catharsis is induced, and then the patient may be considered as convalescent. Venesection, blisters, and cold affusions to the extremities, are also useful. The chronic form of the complaint is to be treated with calomel in minute doses, given to salivation, epispastics, castor-oil, sulphur, and the alkalis.—(See *McCall in the Med. Recorder*, vol. vi., p. 254; and *L. Beck, in the New-York Med. and Phys. Journ.*, vol. ii.)—D.

* In a weak subject, or where an acute attack supervenes on a chronic gastritis, Dr. Stokes deems general bleeding almost inadmissible. "The great remedy," says he, "is the application of leeches to the epigastrium, which should be done freely and repeatedly, until decided relief be obtained."

—*Cyclop. of Pract. Med.*, art. GASTRITIS.—ED.

† "The bowels, which are commonly confined," says Dr. Stokes, "are to be relieved by enemata; but on no account is purgative medicine to be given by the mouth."

canals, which is classed with the erysipelatous; but how far it is the same I do not know. It is certainly not the suppurative. Whatever it is, it may be considered in some of its effects to be in direct opposition to the adhesive and suppurative inflammations; for where the adhesive most readily produces adhesions, there the erysipelatous does not, as in the common cellular membrane; and where the adhesive seldom takes place, excepting from extreme violence, there this inflammation (if erysipelatous) has a tendency to produce adhesions, as in canals or outlets. It also opposes in some degree the suppurative, in being backward in producing suppuration, even in those places where suppuration most readily takes place, such as canals and outlets; for there, as above observed, it more readily throws out the coagulating lymph. Whatever the inflammation may be, it is certainly attended with nearly the same kind of constitutional affection. The fever in both appears to be the same, viz., accompanied with debility, languor, &c.—(*On Blood*, &c., p. 270.)

The erythematic inflammation of the stomach comes on more insidiously than the adhesive; and is best characterized by the inflammatory colour of the fauces, for it usually spreads to these, and the lowness and rapidity of the pulse. The inflammation often extends through a great part of the alvine canal, as well as the œsophagus; and, after a subsidence of the sickness, produces diarrhœa, and mucous discharges from the bowels. It is sometimes so gradual and tardy in its progress as to produce little fever, or even local disturbance, for many days or even weeks.

If this variety of gastritis be excited by acrid or poisonous substances, the stomach-pump should be used, or a brisk emetic be exhibited with as much speed as possible; and afterward such antidote as the character of the poison may point out: opposing acids to alkalines, and alkalines to acid erosives, and the most active stimulants to narcotics. When the cause is internal, mild, diluent, and cooling drinks are to be employed freely. The infusion of roses will often prove one of the most serviceable medicines we can make use of; blisters should be applied and repeated, and the bowels kept open with laxative clysters.

Inflammation of the stomach is also found in the one or the other of its varieties, as an occasional symptom in aphtha, measles, smallpox, and other exanthems, tetanus, and hydrophobia.

We may here observe, that the PANCREAS is also sometimes, though rarely, affected with inflammatory action; and that, in this case, the symptoms are a combination of *empresma gastritis* and *e. hepatitis*. There is pain and distention in the epigastrium, with frequent vomiting. There is also a defined tumour seated higher than the liver, and generally more polarized, but always accompanied with some degree of jaundice, from its pressure on the bile-ducts. The affection often yields to depletion by cupping, brisk purgatives, and blistering.*

* Perceval, in *Trans. King's and Queen's Col-*

SPECIES XII.

EMPRESMA ENTERITIS.

INFLAMMATION OF THE BOWELS.

GRIPING PAIN IN THE BELLY; TENDERNESS, AND VOMITING; FEVER A SYNCHUS.

In inflammation of the stomach, the pain is seated higher, and is rather burning than griping; this last, also, has usually some degree of hiccough, and great dejection of mind: neither of which belongs to inflammation of the intestines; and it is by these characters that the two are to be distinguished from each other. Stoll adds, that intestinal inflammation is also accompanied with a suppression of urine; but we cannot rely upon this as a specific symptom.

Our opening remarks upon gastritis, in respect to the nature of that disease in France, apply to the present as well. Enteritis also exhibits two varieties:—

- | | |
|---|--|
| <i>a</i> Adhæsiva. | Pain very acute; fever violent; vomiting frequent; and costiveness obstinate. |
| Adhesive inflammation of the bowels. | |
| <i>β</i> Erythematica. | Pain more moderate; fever less violent; little vomiting; and diarrhœa, instead of costiveness. |
| Erythematic inflammation of the bowels. | |

Of these varieties the former is more frequent in this species, as the latter is in the preceding.—(*Frank*, ut *suprà*, tom. ii., § cccxxviii., p. 250.)

The causes of both, as also of the accompanying fever being a synchus, may be understood from the remarks already offered upon gastritis; the intestines partaking in a very considerable degree of the character of the stomach.

[Medical writers do not always agree respecting the meaning of the term *enteritis*. Some imply by it an inflammation of the several tunics which form the intestinal canal; while others signify an inflammation of the mucous membrane that invests the bowels from the pylorus to the anus. The inflammation, however, sometimes extends from the mucous coat to the others, so as to affect the whole thickness of the intestines. The inflammation may also be either acute or chronic.—(*See Diet. des Sciences Méd.*, tom. xii., p. 359.)]

To the causes enumerated under gastritis, may be added some natural or accidental organic mischief in some part or other of the intestinal canal, as ventral, inguinal, or other hernias, or intussusceptions of various kinds; or infarctions from coprostasis, scybala, or enterolithus. The *plica polonica*, or matted hair, is said by De la Fontaine, to be a cause of this species, as other writers affirm it to be of gastritis.

The progress of the FIRST VARIETY usually commences with a sense of coldness or shiver-

lege, Dublin, vol. ii., p. 128, 1824. To all who desire a correct knowledge of affections of the mucous membrane of the stomach, the editor strongly recommends the *Memoir* by M. Louis, entitled "*Du Ramollissement, &c. de la Membrane muqueuse de l'Estomac.*"—*Mém. Anat. Pathol.*, Paris, 1826.

ing, and an uneasiness in some part of the belly, at first remitting or intermitting, but gradually acquiring permanency, and rising into an acute pain. The pain now spreads over the whole abdomen, which is tense and tender to the touch, though less so than in peritonitis; there is great flatulence, accompanied with occasional spasms that shoot backward to the loins, usually obstinate costiveness, and unconquerable vomiting, though sometimes diarrhoea and tenesmus. The pulse is small, hard, and frequent, but has sometimes been soft; the tongue dry; thirst extreme; urine high-coloured, small in quantity, and discharged with difficulty; the breathing is laborious; and from the contraction of the abdominal muscles, the patient is perpetually bending forward.—(*Περὶ Νοσῶν*, iii., p. 491.) If no beneficial change take place, all these symptoms become aggravated; instead of feculent stools, there is an ineffectual straining, with a small mucous discharge; and with the increase of the retching, the feces burst through the valve of the colon, and are occasionally thrown up from the stomach. At length the torture suddenly diminishes, and the patient appears to have obtained relief; but his pulse intermits, his face grows pale, his extremities cold, convulsions succeed, and he sinks in death.*

The general termination, therefore, when unfortunate, is that of gangrene; for it is rarely that the inflammation runs into a suppurative state. If, in the course of the first two, three,

or even four days, a free feculent discharge can be procured from the bowels, the vomiting and pains will gradually diminish, the pulse abate in quickness, and the patient be in the way of recovery.

In treating this complaint, it is hence of the utmost importance to procure free evacuations, for the cure depends almost entirely upon our success in this respect. Yet the difficulty is often very great, and increased from the tendency of the stomach to reject whatever medicines are introduced into it. Most practitioners commence with bleeding, which they urge very copiously, and repeat every six or eight hours, according as the pulse will bear the lancet. The remarks we have made upon this practice, under GASTRITIS, will apply to the present species. If the disease occur in a patient of a hardy and vigorous habit, and particularly if we have an opportunity of employing venesection within the first day or two, we shall commonly find it of essential service: but if we do not succeed, we shall assuredly hasten the stage of gangrene, and abbreviate the term of remedial operations. And hence, unless free bleeding can be employed early, and the constitution evinces a tolerable portion of vigour, there is no inflammation in which the lancet is less likely to be serviceable, or may become more mischievous. To local bleeding, even under the conditions we are now supposing, there is less objection; but we have less chance of benefit from it than in peritonitis.*

* Inflammation seems to destroy the action of the muscular fibre. Thus, intestine which has been highly inflamed, is generally found in a state of great distention, showing the complete loss of its healthy muscular action; and if the disease has gone on until the intestine has either become ruptured, or has given way by ulceration, it is found to have fallen together like an empty bag; whereas, healthy intestine, when it is empty, contracts uniformly into a round cord. When we find gangrene, we have reason, in general, to conclude, that inflammation has existed in the muscular coat; but each of the coats may be inflamed separately, and give rise to important differences in the symptoms.—(See J. Abercrombie's *Pathol. and Prac. Researches on Dis. of the Stomach*, &c. p. 7, ed. 2, Edin., 1830.) The following are the general symptoms of inflammatory affections of the digestive tube, as described by Dr. Stokes:—Indigestion; anorexia; vomiting; thirst; jaundice; tympanitis; constipation; alteration of the fecal discharges in quality or quantity; pain; tenderness on pressure; contraction of the features; morbid state of the tongue; dryness of the skin and conjunctiva; suppression of the urine; stupor; delirium; headache; prostration; accelerated and thoracic respiration; fever. "We shall find," says he, "that the greatest variety in the combinations of these symptoms may occur, principally arising from the following circumstances: the intensity and extent of the inflammation; the situation of the disease, both as to the different parts and tissues of the tube; the complications with other diseases; the different degree of excitability of the nervous system in different individuals. Thus, when the inflammation is extensive and severe, occupying both the stomach and intestines, we may have the worst forms of bilious and gastric fevers; when it occupies the duodenum, jaundice is a common symptom; and the disease may occur

with or without fever; in the small intestine, a slight inflammation is often nearly latent, or only pointed out by a little swelling or pain; while in the cæcum or colon, the disease produces all the varieties of diarrhoea and dysentery. When the upper portion of the tube is engaged, constipation is a common symptom; when the lower, the reverse takes place. If the mucous membrane alone is engaged, pain and costiveness are often absent; but, when all the coats are in a state of acute irritation, we may find the most violent symptoms of peritonitis and ileus, with contractions, intussusceptions, &c. The complication of the disease with other affections also produces great varieties. Thus, when it occurs in the advanced stages of phthisis, diarrhoea is often the only symptom; or, when complicated with erysipelas, or pneumonia, its most prominent indication is an extraordinary prostration. The different degrees of excitability of the nervous system cause the greatest irregularity of symptoms: in the child, acute enteritis is commonly mistaken for inflammation of the brain; in the adult, a circumscribed irritation will in one case be accompanied by violent delirium, while, in another more severe, this symptom shall be completely absent."—Ed.

* Modern practitioners speak more decidedly in praise of bleeding than our author has done. Thus, Dr. Stokes gives it as his advice, that the lancet should never be neglected; and that, if the violence of the disease continue unsubdued, venesection should be frequently repeated. After the first bleeding, Dr. Abercrombie recommends smaller quantities of blood to be taken away. The great efficacy of general bleeding alone in reducing inflammation of the mucous membrane is considered, however, by Dr. Stokes, to be a well-established fact; but when the disease has been in the small intestine, he has always found the greatest advantage from local bleeding. If the symptoms

From the first, therefore, we must attempt cathartics. If the stomach will retain the milder, as castor-oil, neutral salts, or senna, these are by far the most advisable; as our object should be to diminish, instead of increasing the irritation of the intestines. But, in the first species, this is rarely the case; and we must hence, without loss of time, apply to those that are more active; as calomel in combination with the colocynth pill; assisting their operation by injections frequently repeated, and in as large quantity as the bowels will retain.

It does not necessarily follow that the irritation of these more active purgatives will add to the inflammatory irritation; nor do we always, or even commonly, find any such effect. For, firstly, the operation of the two irritations is very different; and, by exciting the former, we may even diminish or take off the latter by a transfer of action, in the same manner as we take off inflammation from any other organ by the application of a blister to some neighbouring part. Secondly, the direct effect of the cathartic is to restore a natural action, the peristaltic action of the intestines, which it is the direct effect of the inflammatory action to oppose. And, thirdly, we find, in fact, the beneficial influence of such a practice, not only generally, but almost uniformly, and are incapable of accounting for it upon any other principle.

Opiates would be desirable through the whole course of this disease, but that, in their general intention, they add to the costiveness if given alone, and retard the effect of purgatives if given in conjunction with them. Nevertheless, if after copious bleeding the costiveness should be intractable, and the flatulence and spasmodic pains very distressing, it will be better to trust for a few hours to two or three grains of opium alone, and withhold the purgative plan for the present. [Opium is frequently useful in quieting the sickness, and in enabling the stomach to retain laxative medicines.] Dr. Baillie recommends as a general rule, "the inflammation to be subdued, or at least much lessened, before any active purgative be administered."—(*Lectures and Obs. on Medicine*, 1825.) But we have already stated the principle on which purging and bleeding may be combined from the first in ordinary cases.

[The editor's experience leads him to place more reliance on early and free bleeding, and less on premature purging, than the author. The excessive constipation of the bowels is in general merely an effect of the inflammation, and is often attacked with active purgative medicines, as if it were the primary object, and the source of all mischief. The inflammation is to be subdued by bloodletting from a large orifice to an extent which must be various, and repeated or not, according to the constitution of the patient, and the violence of the symptoms.

do not yield at once to this treatment, the leeches are to be repeated, and a large poultice applied over the belly. The bowels are to be gently opened by the mildest laxatives, and emollient injections should be frequently given.—Cyclop. of Pract. Med., art. ENTERITIS.—ED.

Purgatives given by the mouth are not generally successful, when the inflammation has not been previously checked by local and general bleeding and blistering. Dr. Gregory used to remark, in his lectures, that a purgative had often been known to operate as soon as a blister applied to the belly began to rise; and this observation is still more commonly verified after free venesection.*]

Fomentations and blisters to the abdomen form a regular course of the therapeutic plan, and have, no doubt, been occasionally serviceable; but, like local bleeding, they are less so in the present disease than in peritonitis. And, where fomentations are advisable, I prefer the epithem of a folded flannel wrung out in hot water, and confined with a swathe, as already recommended in peritoneal inflammation, to all other fomentations whatever.

Injections of warm water alone forcibly thrown up the rectum in as large a quantity as the bowels can be made to contain, are moreover often found of essential benefit, and are generally to be preferred to the warm bath, which, by adding to the debility, has accelerated the approach of gangrene.

After the bowels have been freely emptied, diaphoretics, and especially combined with opiates, will be the best plan we can pursue; and if the stomach become quiescent, the patient should drink freely of diluents.†

There is a singular fact noticed by Rhodius (Cent. ii., obs. 69), which sometimes occurs in this disease, and is peculiarly worthy of notice, as sustaining our hopes to the last: and it is this; that occasionally, in the extreme moment of a seeming mortification, a sudden revolution takes place, and stools are evacuated; and this, too, after the extremities have begun to grow cold, and an apparently deadly languor has

* Bateman on Enteritis, in Rees's Cyclopædia. Also, Edin. Med. Surg. Journ., vol. i., p. 64. When enteritis is joined with diarrhœa, the warm bath, leeches, a blister, anodyne injections, and small doses of pulv. ipecac. comp., with or without rhubarb, are some of the remedies commonly resorted to. In the early stage, astringents are pernicious.—ED.

† For allaying the vomiting, the common practice has been to give effervescing draughts of the carbonate of soda or ammonia, with or without a few drops of the tinct. hyosciami to each draught; the region of the stomach being sometimes fomented with the decoction of poppy-heads. Dr. Stokes has found nothing so efficacious as the application of a dozen leeches to the epigastrium, and the liberal use of iced water, or even ice, which may be given *ad libitum*. In the more advanced stages of the disease he has constantly applied leeches to the epigastrium, though in smaller number, and has seen what has been called the typhoid state disappear after their use. He has also applied a small blister to the epigastrium, and afterward sprinkled the surface with a little of the acetate of morphia, according to the plan suggested by M. Lambert in tetanus, hydrophobia, and some other cases, where the patient may not be able to swallow medicine at all.—See *Leçons Orales de Clinique Chir.*, faites par M. le Baron Dupuytren, tom. ii., p. 608, 8vo., Paris, 1832.—ED.

overpowered the frame. In such case, we must snatch the patient from impending death by a free use of wine, and warm generous cordials; closely attending, at the same time, to a copious discharge from the bowels, of which, with the liberal plan now recommended, we need not be afraid, and which we should be extremely cautious of checking by opiates.

From the less threatening character of the symptoms, as they show themselves in the ERYTHEMATIC VARIETY, this affection often exhibits a fallacious appearance, and is misunderstood. "Sapè," says Professor Frank, "nec febris in pulsibus umbra; ardor, dolor, ad intestina aut nullus, aut certè non vehemens; nec ferè ulla tam diri morbi phænomena observantur."—(Op. cit., tom. ii., p. 254.) Its real nature, however, is as we have explained it above: and, from the debility superinduced, ascites has occasionally followed rapidly. It has been well ascertained, that the seat of this variety is sometimes in the external coat of the intestines, and it is said, by some writers, that this is the most common seat. It is not easy to determine upon this point: nor always, at its commencement, whether the inflammation be of the one variety or the other; the modifying causes being, in some constitutions, and some seasons of the year and temperaments of the atmosphere, so nicely balanced as to leave the course doubtful.

In distinct and simple examples of erythematic inflammation, bleeding ought unquestionably to be abstained from; and acids, and the milder tonics, and bitters, as infusion of roses, cascarilla bark, and cinchona, supply its place.

We have said, that in enteritis there is less pain and tension to the touch than in peritonitis. It is singular, that at times there should be little or none whatever on pressing the abdomen. "Gastro-enteritis," observes M. Broussais, "exists without any painful point, when the inflammation is not vehement in the stomach and duodenum; and pressure of the belly does not produce uneasiness."—(*Examen*, &c., prop. cxxxvi., *Par. F. J. V. Broussais*.) M. Petit speaks nearly to the same effect, though he modifies the opinion; affirming, "that if the belly be pressed a little deeply at its lower part, especially towards the right, between the spine of the ilium and the navel, the patient is sensible of pain, and at times makes complaint of the pressure, and exhibits the same by his countenance."—(*Traité de la Fièvre Entéro-Mésentérique*, &c., p. 131.) Yet, even in ulcerations of the mucous membrane, there is not always much uneasiness. "Nothing," says M. Andral, "is more common than an absence of every kind of pain in cases in which numerous ulcerated spots cover the inner surface either of the ileum, or of the cæcum, or of the colon; while we frequently see patients complaining of sharp abdominal pains, where the gastro-enteric mucous membrane is not inflamed."—(*Andral, Clinique Médicale*, tom. i., 8vo., Paris, 1823.)

The last of these writers has lately favoured the world with a valuable and extensive range of examinations into the state of the alimentary

canal in patients who have died of gastritis and enteritis; and we are hence enabled to arrive at some calculation of the comparative frequency of inflammatory action in different parts of the canal. Ulcerations, he observes, may take place in every part, from the cardiac orifice to the anus; but they are not in all places equally common. They are rare in the stomach, and still more rare in the duodenum and jejunum: they are very frequent in the lower third of the small intestine, and they are again less frequent in the different parts of the great intestine. These conclusions are drawn from the following observations, comprising seventy-one distinct cases of disease:—

In ten individuals ulcerations were found in the stomach; in one in the duodenum; in nine in the jejunum; in thirty-eight in the lower part of the ileum; in fifteen in the cæcum; in four in the ascending colon; in eleven in the transverse colon; in three in the descending colon; in one in the rectum.

I have said that enteritis is sometimes a result of hernias. It has also, occasionally, been produced by a forcible protrusion of a part of the intestinal canal through the anus; of which a singular instance is given in the *Medical Transactions*, vol. iv., in a paper communicated by Dr. Latham. The part of the prolapsed intestine was very considerable, and the injury was occasioned by the passage of the wheel of a cart over the loins; a portion of the mesentery was protuded with that of the gut; gangrene supervened to the inflammation, and the prolapsed mesentery and intestine were cut off above the line of gangrene; the latter to a length of not less than fifty-seven inches. The patient, who was a boy, recovered; had motions regularly from the truncated extremity of the remaining intestine; and was able afterward to walk twelve or fourteen miles a day. He had no power, however, of retaining his feces.*

* Enteritis, a formidable disease in its idiopathic form, is also found to supervene in the course of other affections. Thus, it is daily noticed as a complication of fever. From what has been stated in a previous part of this work, however, when it occurs in typhus, it is not the cause, but simply a consequence of that fever; though, as Dr. Stokes has justly said, it is not the less important with reference to the prognosis and treatment. Compared with other affections, both acute and chronic, the frequency of intestinal disease must strike every observer. Andral declares, that in the great majority of diseases of other parts, a derangement either in the functions or structure of the intestinal canal will occur; and that, in chronic diseases, whatever be their nature, it is extremely rare for the digestive tube to escape alteration.—(See *Cyclop. of Pract. Med.*, art. ENTERITIS.) In this country, where it is so usual to attribute many complaints to affections of the liver, it is, as Dr. Stokes observes, of great importance that the relation of cause and effect between irritations of the upper part of the intestinal tube, and derangements of the hepatic function, should be carefully studied. "It is true, that gastro-duodenitis may exist without jaundice, or that hepatic inflammation may arise independent of disease in the mucous membrane; but, it is equally true, that the symptoms of gastro-duodenitis, both acute and

EMPRESMA HEPATITIS.

INFLAMMATION OF THE LIVER.

TENSION, SORENESS, AND PAIN IN THE REGION OF THE LIVER; PAIN ABOUT THE RIGHT SHOULDER; FELT ESPECIALLY WHEN LYING ON THE LEFT SIDE; SHORT, DRY COUGH.

INFLAMMATION of the liver, which may in general be sufficiently known by the above characters, has also two varieties, dependant upon its rapid and violent, or more tardy and obscure march.

a Acuta. In which the above symptoms are clearly marked, and the character of the disease is decisive.

β Chronica. In which the specific character is obscure; and the existence of the disease suspected from a previous exposure to its causes, in connexion with an occasional recurrence of the pathognomonic symptoms, accompanied by a slight degree of fever.

Next to the lungs and the brain, no organ more frequently has an hereditary predisposition to disease than the liver; and Frank has witnessed families suffering in consequence of it, as well in the acute as in the chronic form of inflammation.—(Op. cit., tom. ii., p. 268.)

The ACUTE VARIETY commences with the ordinary symptoms of visceral inflammation; chilliness, succeeded by heat, frequent pulse, and a furred tongue: the bowels are irregular, mostly costive; the evacuations little tinged with bile, the urine often saffron-coloured; the skin is dry, the thirst extreme, with occasional sickness.

No physiologist has yet been able to explain the cause of the pain so generally felt in the right shoulder. It is, however, sympathetic of other affections of the liver, as jaundice, or chololithus, as well as hepatitis; and hence it should seem to be produced by almost any morbid excitement of this organ, whether from inflammation, or the obstruction of gall-stones. [In several cases of hepatitis, reported by M. Louis, and the nature of which was verified by dissection, there was no pain in the right shoulder. Hence, this distinguished pathologist is disposed to doubt whether it be a symptom truly

chronic, are those commonly received as indicative of hepatic disease; and that this last affection may commence by inflammation in the digestive tube.* If any doubt exists as to the diagnosis, Dr. Stokes considers it better to give the patient the advantage of that doubt, and to treat him for gastro-duodenitis, before we have recourse to the hazardous plans usually recommended for hepatic disease. The reader will find much valuable information on the subject of enteritis, in Dr. Stokes's Observations.—Ed.

appertaining to the complaint, and suspects that, perhaps, when it does occur, the hepatitis is complicated with disease of the right lung, or pleura.*] The cough, which is often very distressing, is easily accounted for from the vicinity of the diaphragm to the seat of disease, and its sympathy with the liver. The sickness of the stomach is from the same cause.

The disease is sometimes accompanied with a jaundiced colour of the skin, and Sauvages and Sagar have made such a colour a specific symptom; but it is not always that the bile regurgitates, and, hence, such an appearance ought not to be enumerated among the pathognomonic characters.

Even where it exists, it is not a distinct symptom of hepatitis; for, to say nothing of proper jaundice, the feces, as Dr. Latham has well observed, may be light-coloured, and the eyes, skin, and urine peculiarly yellow, from the pressure of an indurated pancreas upon the bile-ducts, and an obstruction of their course.† [Out of five cases of hepatitis, detailed by M. Louis, four were attended with yellowness of the skin and pain in the right hypochondrium, but tension of the same part was remarked only in two. The concurrence of all these three symptoms actually characterizes hepatitis; but one or two of them alone accompanying an acute disorder, M. Louis thinks, have little validity; for, with respect to the yellowness, it frequently takes place in such case without any hepatitis; and as for the pain, it may depend upon so many causes, that it is not a very conclusive symptom. When, however, pain in the right hypochondrium and jaundice arise from chronic diseases, M. Louis has never seen the latter effect without an accompanying inflammation of the liver.—(Louis, *Mém. Anat. Pathol.*, loc. cit.)]

The ordinary remote causes are, suddenly suppressed perspiration, especially from currents of cold and damp air, and excess of spir-

* *Mém. et Recherches Anat. Pathologiques*, p. 403, Paris, 1826. Dr. Stokes also represents pain in the right shoulder as an extremely rare symptom; a point on which he coincides with Andral and Dr. Mackintosh.—(*Clinique Méd. et Elem. of Pathol. and Pract. of Physic*, vol. i.) The editor has observed, however, that, in the chronic hepatitis, so frequent among the free living inmates of the great prisons which he attends, pain in the right shoulder is commonly complained of. In acute hepatitis, tenderness and swelling of the liver are also usual symptoms, the latter being easily detected when the bowels are empty; yet, as the observations of M. Louis prove, it is not a constant symptom.—Ed.

† From a table of cases of hepatitis, drawn up by Dr. Stokes, from the records of Andral, Louis, and the Meath Hospital, it appears that no explanation can be given of the reason for the presence or absence of jaundice, from any consideration of the state of the alimentary canal. We find, in the list referred to, cases of hepatitis with jaundice, in which that canal was free from disease; and the same symptom with gastro-intestinal inflammation; and with respect to the cases without jaundice, the stomach and bowels were healthy in some, and diseased in others.—See *Cyclop. of Pract. Med.*, art. LIVER.—Ed.

itious potation: though often the cause is too obscure for detection. [Hepatitis is most common in the male sex, and is rarely met with in persons under the adult age.]

Dr. Saunders, and with some plausibility, suspects the acute variety is owing to an inflammatory state of the hepatic artery, and the chronic to a like state of the vena portæ. Winslow ascribes both to an inflamed state of the ramifications of the vena portæ,* which, in his opinion, constitute the seat of the disease; while Cullen refers us to the hepatic artery alone, and limits the seat of inflammation to its extremities. Dr. Heberden is not inclined to believe that the liver is primarily affected, but only influenced by a phlogistic diathesis, or preceding inflammatory fever.

If the inflammation originate in the peritoneal covering, the pain, as in most other cases of membranous affection, is peculiarly pungent, like that of pleuritis; the fever is severe, the tension very considerable, the pulse frequent, strong, and hard, the urine generally high-coloured. When the substance of the liver is primarily affected, the pain and pyrexia are far less acute, and especially at first; but they increase with the progress of the disease, or, in other words, as it extends to the peritoneal investment, the pain not only darting to the right shoulder, but sometimes as far as the throat and clavicle.†

Where the symptoms are most severe, and we have reason to suspect that the disease is confined to the peritoneal covering, the duration is often short, and the termination is in most cases that of resolution. But when less active, and seated in the parenchyma, it generally tends to suppuration; and if the convex side of the liver be the part affected, a tumour is visible externally, the cough becomes aggravated, and there is a difficulty of breathing.‡

* The inflammation and abscess of the liver, so common in phlebitis, are referred by Cruveilhier to the passage of pus, along with the circulating blood, into the minute ramifications of the vena portæ, in which it produces obstruction and irritation.—*En.*

† The effects of hepatitis vary according to the intensity, duration, and situation of the disease. In general, the first visible effect is the production of increased vascularity of the parenchyma. In a more advanced stage, a softening of the substance of the liver is also observed, and there may be a deposition of pus or lymph on the serous surface. In this respect, according to Dr. Stokes, there is a great difference between the liver and the lung, as we seldom meet with pneumonia without serous inflammation, while the reverse often obtains in hepatitis; a consideration of vast importance in the surgical treatment of the disease.—(*Cyclop. of Pract. Med., art. LIVER*; also, *Annesley's Dis. of India*, vol. i., p. 406.) The rarity of adhesions in hepatitis, even after the formation of matter, is a fact which had been observed by Drs. Graves and Stokes, before Mr. Annesley's work made its appearance.—See *Dublin Hospital Reports*, vol. v.—*En.*

‡ Abscess of the liver, as an effect of acute hepatitis, is very frequent in India, but rather uncommon in temperate climates. In relation to

If adhesions have preceded the suppuration, the pus points to the skin, and the abscess opens on the surface; but, if it break internally, it generally proves fatal by inducing a hectic; though sometimes, in consequence of fortunate adhesions below, the abscess discharges itself into the hepatic duct, and the pus is carried off by this channel. It has, occasionally, by the same means, made its way into the stomach and intestines, where the abscess has been very large: in which case, however, immediately upon the bursting of the abscess, the patient throws off, by sickness or by purging, a large mass of most offensive matter, and often dies in a few hours. In like manner, the pus has occasionally formed an empyema in the thorax; and, in a few instances, has been discharged from the lungs.*

The progress to a state of gangrene is sometimes very rapid, and especially in the swamps of the East and West Indies. Dr. Chisholm gives a striking example of this in a gentleman who, being "heated and profusely perspiring after violent exercise, lay down and slept in this state in a current of cool air. He awoke soon after in the most excruciating torture in the right hypochondrium, and with great tumefaction of the whole abdomen. In two days he was dead." The liver was found greatly enlarged, and reduced in many parts to a state similar to that of rotten cork.†

suppuration of the liver, as it presents itself in our latitude, the reader will find the most interesting information in the writings of M. Louis (*Recherches Anat. Pathol.*, Paris, 1826), and those of Drs. Graves and Stokes.—(*Dublin Hospital Reports*, vol. v.) The matter may be either diffused or in the form of numerous minute abscesses, or in that of one or more large accumulations, sometimes encysted; on other occasions merely bounded by the softened and yellow hepatic substance.—*En.*

* Dr. Stokes has known abscess of the liver make its way, 1. Through the diaphragm into the lung; 2. Into the duodenum; 3. Into the cavity of the peritoneum. Dr. N. R. Smith, of the United States, relates a case, in which an abscess of the liver burst into the pericardium. With respect to the thorax, then, as Dr. Stokes has explained, the abscess may open into the lung, pleura, or pericardium; and, with reference to the abdomen, into some part of the alimentary canal, the peritoneal cavity, the gall-bladder, the vena cava, or kidney.—See *Cycl. of Pract. Med., art. LIVER*.

† Climate and Diseases of Tropical Countries, p. 64, 8vo., London, 1822. Mr. Annesley, who alleges that he has made as many post-mortem examinations of subjects destroyed by liver diseases as any writer on the diseases of warm climates, never met with an instance of gangrene of the liver; and he suspects, therefore, that the appearances which have been taken for gangrene, have been merely that black, congested, and softened state of the organ, which is sometimes observed in the more acute attacks of hepatitis.—(*On Diseases of India*, vol. i., p. 435.) Andral met with one clear case, however, of gangrene of the liver, the only example he ever saw; a sufficient proof of the rarity of such an occurrence. Here, as Dr. Stokes observes, is another circumstance, in which the pathological relations of the liver differ remarkably from those of the lungs,

The disease sometimes terminates in induration, which bears an extent in some measure proportioned to the range of the preceding inflammation, and may often be felt by applying the hand to the region of the organ. This, however, is a more frequent result of the second or chronic variety.

In order to induce acute hepatitis, it is necessary that the organ of the liver, at the time of attack, should be in a state of at least moderate health and vigour; for it is in this condition only that inflammation running through its regular stages can take place; and hence the acute variety is found far more frequently in temperate than in intertropical climates; and, in the latter, more frequently among new-comers than among those that have been long habituated to the climate, and whose livers have been weakened and relaxed by the greater heat of the sun: "Among the men of the eighteenth regiment," says Mr. Christie, who was stationed at Trincomalee, and had the care of the entire garrison in 1798, "I found, for the first six or eight months, the disease was much more frequent, much more violent in its symptoms, showed more tendency to suppuration, and was more sudden in its crisis, than with the Company's European troops, who had been long in India, although the latter were the most debauched. Among the natives, hepatitis does not often occur: out of a thousand native troops, I did not, in the course of three months, meet with more than two cases of liver complaints, which is comparatively a very small proportion."—(*Letter to the Editor of the Med. and Phys. Journ.*, May, 1798.) There is, however, a striking distinction between the state of the bowels, as affected by this disease in hot and in temperate climates. In the latter it is rarely we have any diarrhoea, and often an obstinate costiveness, the evacuations being mostly untinged with bile. In the former, from the higher degree of irritation that prevails, and the greater extent of its range, a bilious flux is so frequent as to be almost a pathognomonic symptom; and as the gorged vessels are apt to give way from debility, this is sometimes intermixed with blood.

In our own climate, bleeding at the commencement of the disease is generally found serviceable, and ought to be prescribed as speedily as possible; and be repeated, generally or locally, as the violence of the symptoms may require, and the strength of the constitution allow. Frank advises leeches to the hemorrhoidal vessels, or to the hypochondrium; but the lancet is alone to be depended upon.*

in which gangrene is not an unfrequent occurrence.—Ed.

* Dr. Stokes's experience would lead him to say, "that general bleeding has not the same marked influence over hepatitis that it has over peripneumony, but appears principally useful in preparing the patient for local depletion, which seems to have the most direct influence on the disease. We have seen a case where upwards of one hundred ounces of blood were drawn at different times, and in which no apparent effect was produced on the inflammation, until local bleeding

Free purging, with calomel and Epsom salts, should immediately follow; and mercury be at the same time introduced into the system by the stomach or by inunction, or by both. [Drs. Pemberton and Saunders gave the preference to saline purgatives; Dr. James Currie to mercurial ones, and especially to calomel. With respect to inunction, or an attempt to affect the constitution generally with mercury in the early and highly inflammatory stage of hepatitis, it was disapproved by the latter eminent physician, who used calomel at first only as an evacuant.*] From the costiveness that usually accompanies the disease, it is rarely necessary to unite the mercury with opium; though, where it irritates the bowels, the latter should unquestionably be given; as it should also to allay the cough, where this symptom is very distressing and prevents sleep. The mercurial course, as recommended by Sir James M'Grigor (*Med. Sketches*), should be steadily persevered in, not only in hot climates, but in temperate, till a salutary change has been effected, or salivation has been freely excited. It will often be found, however, that the patient will bear a long continuance of the mercurial plan without any affection of the mouth, and will gradually and insensibly improve under it; the soreness and tension subsiding, the cough diminishing, the pulse becoming slower, and the heat and dryness of the skin yielding to a pleasant moisture; all of which are prognostics of a favourable issue. In hot climates, however, little benefit is obtained from mercury till it has produced pytalism; while, such is the still greater degree of torpidity under which the absorbents, as well as the excretories of the liver labour, that it is often almost impossible to excite this effect by the boldest practice. "I have myself," says Dr. J. Johnson, "taken calomel in twenty-grain doses, three times a day, without experiencing the slightest inconvenience from the quantity; nay, I often found large doses sit easier on the stomach, and occasion less irritation in the bowels, than small ones. At this time, too, I was using every exertion, by

was performed. In a robust adult, not less than thirty leeches should be applied, after the general bleeding, to the most painful part of the side," &c.—Cyclop. of Pract. Med.

* Twenty or thirty years ago, it was frequently stated, that mercury ought not to be given in acute inflammation of the liver, because it stimulated the organ; but that it was proper in chronic hepatitis. This doctrine is no longer respected in practice: mercury, given so as to bring on pytalism, is generally conceived to be just as useful in acute hepatitis, as in any other form of active inflammation.—(See Elliotson's Lectures at London Univ., as published in Med. Gaz. for 1833, p. 462.) And Dr. Stokes observes, that, after the employment of general and local bleeding, the production of pytalism appears to be the most powerful means of subduing the disease. Headmits, however, that it is often difficult to excite pytalism; and that the more severe the hepatitis is, the greater is this difficulty. As the best mode of ensuring the favourable action of mercury, he recommends the inflammatory condition of the organ to be diminished, as far as possible, before its exubitation.—Ed.

inunction, to forward the pyalism, yet it was several days before I could produce any effect of this kind."—(*Influence of Tropical Climates*, &c., 3d edit., p. 174.)

The application of large blisters over the hypogastric region in succession is recommended by most practitioners, but I have not found them successful; and have evidently derived more benefit from fomentations, epithems, and the warm bath.

Diaphoretics should certainly form a part of the curative process; and they combine admirably with the mercurial treatment, particularly the antimonial preparations. Cooling, diluent, and even acidulated drinks, should be taken copiously; the diet consist chiefly of light farinaceous foods; and the chamber be well ventilated. If, from sudden shiverings, and remission of the quickened pulse, we have reason to believe suppuration has taken place, columbo, the mineral acids, and, above all, the bark, where it can be retained, should be given freely; the cinchona, at least in the proportion of from half a drachm to a drachm, five or six times a day; and this whether the abscess be likely to burst externally or internally; and, if the former, the direction should be encouraged by maturing cataplasms, and the abscess be opened as speedily as possible.* The discharge is sometimes very considerable in quantity, and amounts to several pints; the pus is occasionally found pure, but more generally intermixed with coagulable lymph, or some viscid, yellow fluid. It is at times lodged in different sacs, and hence subsequent tumours ensue, and subsequent openings are necessary.†

It is not always, however, even after suppu-

* The adhesion of the liver to the peritoneum, in cases of hepatic abscess, a circumstance so essential to the safety and success of the operation, is alleged to be rare. If such adhesion should not exist, the matter would pass into the cavity of the peritoneum, and cause an almost certainly fatal inflammation of it. To obviate this risk, Dr. Graves has proposed that an incision should be made over the most prominent part of the tumour down to the peritoneum, without dividing this membrane. The wound is to be kept open with plugs of lint, and poultices are to be applied. The desired adhesions will then form, and the matter soon make its way out through the incision.—(See Dublin Hospital Reports, vol. iv.) Dr. Graves gives one instance of the success of the practice, and Dr. Stokes has seen two others. The passage of the matter of an abscess of the liver into the cavity of the pleura or peritoneum, is, no doubt, generally fatal; yet, in the Report of the Meath Hospital, a case is recorded in which death from peritonitis was apparently prevented by the opiate and stimulating treatment, first proposed by Dr. Graves in certain cases of peritonitis. In a case also of double abscess of the liver, related by Dr. Stokes (Cyclop. of Pract. Med.), the patient lived eight days after the rupture of the second abscess into the peritoneum, and it was evident, on dissection, that the process of cure had commenced, the gelatinous effusion in many places having assumed an appearance of layers, and presenting large bloodvessels in its interior.—Ed.

† Recueil d'Observations de Médecine des Hôpitaux Militaires, &c., art. par M. Boucher, tom. ii., 4to., Paris.

ration has taken place, that the abscess must necessarily open in any direction; for, when we have full reason to believe that such a result has occurred, the fluid may be carried off by absorption, and the organ be restored to a sound state.

[A softening of the liver has been noticed by several observers, and among others by M. Lallemand (*Troisième Lettre sur l'Encéphale*, p. 351), in a case of very acute hepatitis attended with abscess. But M. Louis conceives, that, in the present state of our knowledge, a softening joined with increased intensity of the red colour of the liver, cannot be deemed a certain proof of inflammation, unless the organ contain at the same time pus, or the patient had, while living, icterus and pain in the right hypochondrium. In fact, as these two symptoms took place in four out of the five histories recorded by him, he believes they are rarely wanting.—(*P. Ch. Louis, Mém. Anat. Pathologiques*, p. 407.)]

Dr. Chisholm found this disease on one occasion contagious. It was at Grenada, in the winter of 1786, in districts peculiarly exposed to the influence of chilling northerly winds, and possessing large tracts of marsh. The disease was lamentably mortiferous, though the symptoms were insidious rather than violent. It usually destroyed in the course of six days; and the deaths were calculated at one in every six.*

In CHRONIC HEPATITIS, all the specific symptoms, as already observed, show themselves obscurely. The pulse is something quicker than usual, and there is an obtuse pain in the region of the liver; but such as would not perhaps be noticed, if it were not inquired into, and the organ pressed upon, and connected with a sudden quick expiration after an attempt to inspire deeply: and there is also an indistinct uneasiness generally, though not always, about the right shoulder; all the symptoms becoming exacerbated at a certain period of the day, commonly about four o'clock in the afternoon. But, in conjunction with the proper hepatic symptoms, the most obvious are those of dyspepsy and atrophy; the appetite fails, the stomach is capricious, the animal spirits flag, and the flesh wastes away. The bowels are generally costive, and the stools often clay-coloured, though not always; and there is usually a sallowness on the skin, or a dirty greenish hue, which Dr. Darwin, from its resemblance to the colour of a full-grown silk-worm, has denominated *bombycinous*. The disease slowly advances to suppuration, or terminates in a scirrhus induration; but, in many instances, and especially after a habit of hard eating or drinking, is the index of a broken-up constitution.

Excess in eating and drinking, or indeed in any other voluptuousness, is the common cause of this variety of Hepatitis in temperate regions,†

* Climate and Diseases of Tropical Countries, &c., p. 66, 8vo., Lond., 1822. The circumstances mentioned in the text make it very clear that the disorder was not truly contagious, but epidemic.—Ed.

† In this country, chronic hepatitis is more com-

though it sometimes follows obstinate quartans. It is, however, a more frequent affection in hot climates, where, as already observed, it is far more apt to occur than the preceding variety. And it is on this account that we see so many persons returning annually to our own country, from the East or West Indies, with enlarged livers, irregular fever, indigestion, costiveness, fulness in the right hypochondrium, white stools, yellow complexion, dry cough, disturbed sleep, and dejected spirits; occasionally some of these symptoms being wanting, and occasionally others. In all such cases, the organ is torpid, yet irritable, and the cure must depend upon our ability to give it fresh tone and vigour. The general congestion is most effectually removed by smaller doses of calomel than advised in the acute variety, so as to produce an alternating effect, and gently excite the sluggish secretions into a state of renewed activity. Though here also pyalism is aimed at in hot climates, yet in a milder degree than in the acute variety.* And, in conjunction with these, we are to employ warm aromatic bitters; and, where they agree with the stomach, the mineral acids. Dandelion, as recommended by Boerhaave and Bergius, has often been found serviceable. Dr. Pemberton paid much attention to its virtues, and had often seen it of decided advantage in incipient scirrhus of the liver and other abdominal organs; and strongly recommended it in doses of half a drachm of the extract twice a day.—(*Treatise on the Diseases of the Abdominal Viscera.*) We cannot, however, always depend upon this preparation, and hence, as a general rule, it will be more advisable to employ the decoction. Where there is an evident tumour on the right side, a seton should be introduced over it.

In slighter cases, which have nevertheless compelled a return from India after a residence of eight or nine years, I have found all the symptoms vanish before a steady use of Plummer's or the blue-pill, taken every night for a month; and the Cheltenham air and waters, for the same period of time afterward.

Where a chronic inflammation of the liver has terminated in a scirrhus of the whole organ, or of a great part of it, the blood is obstructed

more than acute.—Bateman, in art. LIVER, Rees's Cyclopædia.—Ed.

* Before employing mercury, Dr. Stokes applies twelve leeches to the region of the liver every third or fourth day, until the pain and tenderness are removed. Afterward he resorts to counter-irritation, with repeated blisters, or antimonial ointment. If these means do not succeed, he endeavours to affect the system gently with mercury, for which purpose he prescribes a small dose of calomel, or blue-pill, combined with Dover's powder, to be taken at night, or mercurial inunction over the region of the liver. When any thing in the state of the constitution forbids mercury, Dr. Stokes speaks favourably of the nitromuriatic bath, or of sponging the surface of the body with this fluid. Frictions with the ointment of the hydriodate of potash on the right hypochondrium, and the internal exhibition of iodine, are also sometimes employed with benefit.—Ed.

in its circulation, congestion takes place in other organs, and we often meet with very extensive hemorrhages from the lungs, nostrils, stomach, or anus. These discharges are rarely, perhaps never, of service in chronic cases, and only contribute to weaken the system. But, in acute cases, constituting the first variety, by diminishing the phlogotic action, they are often of very essential use.

[Disease of the liver not uncommonly brings on a cough, which is sometimes so prominent a symptom, as to lead the practitioner to suppose the seat of disease to be in the lungs.*]

SPECIES XIV.

EMPRESMA SPLENITIS.

INFLAMMATION OF THE SPLEEN.

HEAT, FULNESS, AND TENDERNES IN THE SPLENIC REGION; WITH PAIN UPON PRESSURE.

Of the use of the spleen, as observed in the Physiological Proem to the first class, we know little or nothing. It secretes no peculiar fluid, except what serves to produce a change in its own blood, which is of a dark livid colour, and coagulates with difficulty. It is commonly supposed to be an organ auxiliary to the liver; and it is unquestionably subject to all its ailments: voluptuous living, however, and even the heat of a torrid sun, affect it less; but obstinate tertians and quartans more, and render it sooner congestive and scirrhus.

Inflammation of the spleen, together with the symptoms given in the definition, is accompanied with the usual pyretic signs; and often with a pain extending over the whole of the abdomen, but particularly in the left side, and shooting from the diaphragm to the left shoulder. There is also not unfrequently a dry, short cough, and sense of constriction in the præcordia, sickness or nausea, and a discharge from the rectum of black or livid blood, from a rupture of some of the splenic vessels. It is, however, a rare complaint. "The spleen," observes Dr. Baillie, "is much less subject to inflammation than many other of the abdominal viscera. I do not recollect a strongly-marked case of it in my practice; and I have never met with an abscess in the spleen in all the dead bodies which I have examined."† The common causes of inflammation of the spleen are the same as those of the liver; and the treatment need not essentially vary, as the progress and terminations of the disease are not different. In India, where it is more common than in temperate climates,

* See Dr. Brooke's Case and Obs. on Liver Cough, in Trans. of the King's and Queen's College of Physicians, vols. iii. and iv.; and Sir Thomas Moriarty's Communication in the latter volume.

† Lectures and Observations on Medicine, 1815. Unpublished. Notwithstanding these remarks, abscesses of the spleen, and these of different kinds, have been met with by other anatomists, as may be learned by reference to the additions made to the subject of parabsysma splenicum.—Ed.

‡ This remark of the editor is confirmed by occasional dissections in this country.—D.

the native practitioners use acupunctures and scarifications.

The SPLENALGIA, or pain in the spleen, of many writers, is for the most part a slight attack of this disease, with some small degree of fever. For further observations on diseases of the spleen, see *Parabysma Splenicum*.

SPECIES XV.

EMPRESMA NEPHRITIS.

INFLAMMATION OF THE KIDNEYS.

PAIN IN THE LOINS;* FREQUENT MICTURITION;
VOMITING; NUMBNESS OF THE THIGH ON THE
AFFECTED SIDE; RETRACTION OF THE TESTI-
CLE.

THE general causes of this species are whatever obstructs the flow of the fluids in the vessels of the kidneys; as a wound, contusion, tumour, strain of the muscles of the back that press on the kidneys, excess of horse-exercise, various acrids conveyed to the kidneys by the course of the circulation. It is, however, most frequently met with as a secondary disease, resulting from calculous matter blocking up the tubuli uriniferi, or from calculi formed in the pelvis of the kidneys, and obstructing that cavity or the canal of the ureters, concerning which we shall have to treat under the genus LITHIA, embracing calculous concretions in the urinary passages.†

The symptoms enumerated in the specific definition are sufficient to indicate the presence of nephritis, though the numbness and retraction of the testicle are common to calculi in the ureters, or body of the kidney, even when there is little inflammation present. In the case before us, however, the skin is usually hot and dry,‡ the body costive, and motion, and even

an erect position, are accompanied with considerable uneasiness. By the last sign we may distinguish the disease from an inflammation of the psoas, or almost any other adjacent muscle; while the immediate seat of pain separates it from colic, even when it is attended, as it is occasionally, with ventral gripings.

When the disease is violent, the urine is discharged in small quantity, and of a pale hue. And hence, if the urine become higher coloured, be secreted in a larger proportion, and be at length thick and mixed with mucus, a gradual relief may be expected to follow, and the cure will be effected by a copious flow. The disease sometimes passes off also by a metastasis. But if the symptoms be protracted beyond the seventh day, and there be stupor or heaviness in the organ, instead of acute pain, with frequent returns of chilliness and shivering, we have reason to expect that an abscess will ensue: in which event the pus may be discharged into the pelvis of the kidney, the abdomen, or, in case of adhesions, externally through the integuments and the skin. The first is the most favourable issue, next to that of resolution; the last is often succeeded by a cure, but an evacuation of pus into the cavity of the abdomen rarely. In some instances the suppuration has been so considerable as to destroy the substance of the affected kidney entirely, and leave nothing but the external membrane.* Yet there are cases in which a patient has recovered even in this state, and the office of secretion has been performed by the sound kidney alone.

Gangrene occasionally ensues,† and it is indicated by a sudden remission or cessation of pain, after great violence of vascular action; accompanied with cold sweats, a sinking pulse, discharge of black urine, and other symptoms of approaching dissolution. Generally speaking, the cases of complete recovery are but few, though the patient often lingers, and even with an occasional prospect of recovery, for many months, or even years. "The formation of matter," observes Dr. Baillie, "will sometimes be suspended for several months, and patients will recover in a considerable degree their general health. The disease will return, either from imprudence in diet or exercise, or without any known cause, and the patient will become as ill as ever. It very rarely happens that a

* Usually experienced only on one side, and descending along the ureter to the bladder; frequently a good deal of uneasiness is also felt in the glans penis. The numbness is in the inner part of the thigh, in the course of the anterior crural nerve. The testicle is often swollen and tender, as well as retracted.—Ed.

† Nephritis may be produced by cold, like any other inflammation, but it is rarely an idiopathic disease; it is more frequently the result either of mechanical violence, or of the action of turpentine or cantharides on the kidneys; or of stones lodged in it; or of a disposition perhaps to gout.—See Elliotson's Lectures, delivered at Lond. Univ., as published in Med. Gaz., p. 722, 1833.—Ed.

‡ Dr. Cullen inserts pyrexia as a part of his definition of nephritis, and, according to the editor's judgment, very correctly; for, as Dr. Carter observes, all the other symptoms are common to both nephritis and nephralgia: indeed, the pain in the latter affection may be much more intense than in inflammation of the substance of the kidney, and quite as severe as when its capsule is inflamed; but the pulse is little, if at all affected, and the other signs of inflammatory fever are absent. But if, with the symptoms of the local affection, we find a frequent, hard pulse, a loaded tongue, great heat and dryness of skin, we may at once pronounce the disease to be nephritis.—(See art. NEPHRALGIA, &c., in Cyclop. of Prac. Med.) In a rheumatic affection of the loins, the pain is usually felt on both sides, extending to the hip, and, if down

the thigh, not in the course of the anterior crural nerve, but in that of the sciatic nerve.—(See Elliotson's Lectures at Lond. Univ., Med. Gaz., p. 721, 1833.) There is no frequent desire to make water, no pain in the course of the ureter, no enlargement, no tenderness, no retraction of the testicle.—Ed.

* The editor was once required to sound a patient in a case of this description, attended with symptoms very much resembling those of stone in the bladder. The patient was under the care of Dr. Smith and Mr. Baker of Staines. The former gentleman published some of the particulars of the disease in one of the volumes of the Lond. Med. Gaz. The quantity of matter was very considerable.—Ed.

† See a Case by Dr. Turner, in the 4th vol. of the Trans. of the College of Physicians.—Ed.

patient permanently recovers from this disease, and I do not at present recollect an instance of it."—(*Lectures and Obs. on Medicine*, 1825.)

In attempting a cure of nephritis, we should commence with copious bleeding, and we may most conveniently apply cupping-glasses to the region of the kidneys. Saline purgatives should follow; and then oleaginous or mucilaginous emulsions, with small doses of nitrate of potash, or tincture of digitalis. The last has often proved highly serviceable in taking off the arterial action that maintains the inflammation, and at the same time in augmenting the urinary secretion. The loins should at the same time be covered with a large folded flannel wrung out in hot water, and confined, as already described in the case of peritonitis; and copious emollient injections should be frequently thrown up the rectum, and suffered to remain there as long as the patient may be able to retain them. The rest of the treatment and regimen should be that of inflammation in general.*

SPECIES XVI.

EMPRESMA CYSTITIS.

INFLAMMATION OF THE BLADDER.

PAIN AND SWELLING IN THE HYPOGASTRIC REGION; PAINFUL OR OBSTRUCTED DISCHARGE OF URINE; TENESMUS.

THE bladder is often irritated and inflamed by the lodgment of a calculus in it, by viscid substances that pass into the circulation, and particularly by cantharides, ardent spirits, and terebinthine essences or balsams. Idiopathic inflammation is not a frequent disease; yet it occasionally occurs; for the bladder is subject to the common causes of inflammatory affection. Its exterior serous coat, its muscular coat, and its internal mucous membrane may all be affected; or the inflammation may affect the muscular or mucous coat separately.† [Cystitis is sometimes brought on by gonorrhœa, the inflammation of the lining of the urethra extending to the mucous membrane of the bladder.]

If the lower part of the bladder be chiefly affected, the pain will extend to, and take the course of the perinæum. If the seat be in the neck of the organ, there will be a retention of urine with a constant urgency to evacuate; if in the fundus, the urine will flow stillatiously, and without ceasing; the bladder will give a feeling of being constantly full; and the patient

will be perpetually and fruitlessly striving to empty it. In this affection there is usually great restlessness and anxiety, with cold extremities, vomiting, wildness of the eyes, delirium, and other marks of great general irritation. Much heat and smarting are generally experienced in the urethra; the patient is troubled with continual tenesmus, and pressure on the hypogastric region occasions violent suffering. The disease runs its course with rapidity, and subsides, or destroys the patient, in a few days.*

It terminates, like all other inflammations, most favourably by resolution. But if this do not take place, it passes on to suppuration or gangrene; the diagnostics of both which are those already noticed in the preceding species. If suppuration take place, the pus may be discharged by the urethra, which is its happiest outlet; or it may follow the course of the ulceration, and be emptied into the cavity of the abdomen; or, if adhesions have been formed with the subjacent cellular membrane, it may work its way in a sinuous direction, and find an opening in some part of the perinæum. Of the last two terminations, the first is almost always fatal; and the second is extremely troublesome and tedious, though a cure is usually affected at last.

Repeated bleedings, aperients, and relaxants, with copious emollient injections, suffered to remain in the rectum as long as possible, form the chief part of the plan of cure. Blood should be drawn both generally and locally, and a large bladder about half full of warm water be kept constantly over the pubes. The warm bath has also been frequently of essential service.†

* When the lining of the bladder is inflamed, the disease is very likely to be mistaken for stone. The following are the considerations specified by Mr. Coulson, as indicating the difference of one case from the other:—"The uneasiness in the bladder, frequent desire to make water, and the passage of blood with the urine, are symptoms of stone, as well as of this complaint. But in stone the pain is principally experienced after the bladder has been emptied; whereas, in acute inflammation of the mucous membrane of the bladder, the pain is most intense when the bladder is full, and subsides when it is empty: in stone, larger quantities of blood are passed than in this disease, and the urethra is seldom so irritable."—*Med. Gaz.* for 1833, p. 666.—E.D.

† To the remedies which are mentioned in the text for affections of the bladder, may be added the buchu. This plant (the *agusthosma crenatum* of Willdenow, the *diosma crenata* of Thunberg) has long been used by the Hottentots at the Cape of Good Hope for a variety of diseases, and was thus brought to the notice of the English and Dutch physicians, who have recently employed the buchu in Great Britain and on the continent. Very lately it has awakened the attention of practitioners in the United States. Dr. Francis informs me that he first became acquainted with this medicine from information given him by Dr. M'Lean, who had used it in a complex case with great success. Profiting by his remarks, Dr. F., within the last four years, has prescribed buchu tea in a number of cases of chronic catarrh of the bladder, of retention of urine in consequence of

* I believe the best practitioners of the present day do not administer digitalis, nitrate of potash, and other diuretics, in cases of nephritis. With respect to purgatives, Dr. Elliotson prefers those of calomel. The warm bath is also more efficient than partial fomentations. In the event of suppuration, the treatment is to be regulated by the principles applicable to suppuration in general. Anodynes will be required, and uva ursi may be tried, though its virtues are rather doubted by many members of the profession.—E.D.

† In some observations on inflammation of the bladder, inserted by Mr. Coulson in the *Med. Gaz.* for 1833, an attempt is made to lay down the particular symptoms which characterize both these varieties of cystitis.—E.D.

When the urine is actually suppressed, it is usually evacuated by a catheter; but I would strenuously recommend, instead of this, a siphon formed upon the plan of that employed by Mr. Jukes for the stomach, and already described under *dysphagia constricta* (Class I., Ord. I., Gen. III., Spe. 1), with an elastic bottle attached to its outer end, and a stopcock adapted to it; so that, being introduced in its contracted or vacuum state, it may readily be converted into a powerful suction-pump by merely turning the valve. This instrument may also be rendered of great importance in another way; for by charging it with an emollient or anodyne fluid, when the bladder is empty, we may get such preparations to come immediately in contact with the inflamed surface of the bladder, in any degree of strength that may be advisable.*

SPECIES XVII.

EMPRESMA HYSTERITIS.

INFLAMMATION OF THE WOMB.

PAIN, SWELLING, AND TENDERNESS IN THE HYPOGASTRIC REGION; HEAT, PAIN, AND TENDERNESS IN THE OS UTERI; VOMITING; PULSE RAPID.

This species offers us two varieties, according to the condition of the organ at the time of attack:—

α Simplex.	The organ unimpregnated.
Simple inflammation of the womb.	Pain permanent, circumscribed, throbbing; fever a cauma.

weakness or diminished energy of this organ, &c.—and in most cases with the happiest results. It seems to possess several advantages not belonging to the remedies generally used. The buchu leaves are best given in an infusion made by pouring a pint of boiling water on an ounce of the leaves; which quantity may be taken in twenty-four hours. This article is mentioned satisfactorily in the excellent Dispensatory of the United States, by Professors Wood and Bache, of Philadelphia (second edition), 1834.—See also Manuel de Matière Médicale, par H. M. Edwards and P. Vavasour, p. 362, Paris, 1831.—D.

* The plan of appeasing an inflamed bladder by injecting any kind of fluid into it, is one that is now renounced by all men of experience. On this point I will quote a short statement made by Mr. Coulson, in speaking of inflammation of the mucous membrane of the bladder:—"Some recommend the injection of oil and opium, and other substances, into the bladder, by means of a gum-elastic catheter; and in one of my patients this plan had been suggested by an eminent physician, prior to the patient being placed under my care; but no benefit was derived from this treatment. In fact, the pain and irritation which are experienced from the introduction of instruments into the bladder in these cases, are so considerable as to deter me from employing this plan."—(Lond. Med. Gaz. for 1833, p. 666.) This gentleman found some benefit produced by the decoction of pareira brava, after the severity of the pain had been subdued by other means; though he pronounces it to be more applicable to the chronic form of the complaint. He adds, hyosciamus, opium, lime-water, with sirup of poppies, may from time to time be administered.—ED.

β Puerperarum. The organ having lately suffered childbirth. Pain less acute, less circumscribed; inflammation of the womb. flow of urine difficult; fever a synochus or typhus.

The FIRST of these is produced by cold, or any of the other ordinary causes of inflammation, and terminates in resolution, suppuration, scirrhus, or gangrene. The most ordinary termination is that of resolution, the next that of scirrhus, sometimes running into cancer: both which are far more common to women who have never been impregnated than to those who have had families, but rarely appear before menstruation, from the natural quiescence of the organ in this state.—(J. P. Frank, *de Cur. Hom. Morb. Epit.*, tom. ii., § 922, p. 217.) [One symptom is constant, viz., pain in the hypogastric region, which is increased by the slightest pressure, or on the patient's making a deep respiration. The urine is generally voided with difficulty, and in small quantities; and, as the rectum participates in the irritation, a distressing tenesmus is experienced. The bowels are mostly irregular, the tongue white, and the pulse rapid, small, and what some practitioners term wiry. The pain frequently extends with great severity to the loins, and sometimes shoots down the thigh; and, as the stomach sympathizes, there is generally vomiting.]

All the ordinary means already noticed for subduing inflammation, both general and local, should here be put into effect without loss of time; as, copious and repeated venesection, leeches, aperients, emollient injections, both into the rectum and uterus itself, and fomentations or epithems to the hypogastrium. The disease is sometimes relieved by a sudden flow of the menses, with hemorrhage or genuine blood.*

* Inflammation of the womb is sometimes attended with another disease, which has been much overlooked: we allude to *inflammation of the ovary*, which might very properly be introduced into this genus under the term *EMPRESMA OVARITIS*.

Among the causes of this disease may be mentioned, inflammations of the uterus or of the peritoneum, difficult labour, repeated abortion, the indulgence in sexual intercourse before the proper period, shortly after parturition, or when convalescent from diseases of the uterus, disappointment in marriage, &c.

The most prominent symptoms of ovaritis are, pain in one or both sides of the abdomen, increased by pressure; this pain is more severe, also, when the patient walks, but is much less in lying down: sometimes, also, the affected ovary becoming enlarged, a tumour is observed in the side diseased.

Ovaritis is sometimes resolved, sometimes it becomes chronic, and sometimes it terminates in suppuration; the pus collects in an abscess, which opens in the anterior wall of the abdomen, in the Fallopian tube, the vagina, the peritoneal cavity, the bladder, and even into the intestines; it emerges through the vulva, the urethra, or the anus, or it remains incarcerated in a cyst. Mad. Boivin thinks that the adhesion of the inflamed ovaries to the adjacent parts seems to prevent conception, the development of the fetus, and to be a very common cause of abortion.

Ovaritis requires to be treated, like other inflammations, by bleeding, leeches, warm mucilaginous

The SECOND VARIETY, in which the symptoms are alike, but less acute, is usually, though not always, a result of suppressed lochia, or violence sustained during labour, particularly from the use of instruments: the inflammatory action from this cause often extends down the vagina, which is hot, reddened, tense, and tender to the touch; and sometimes the same effects descend so low as to be manifest externally. Bleeding is here to be avoided,* and the inflammation to be attacked with gentle laxatives, diaphoretics, and, where there is much irritability, camphire and opiates; fomentations and injections being employed at the same time.

It is a singular but well-ascertained fact, that the spleen, from some unknown cause, is peculiarly apt to sympathize with the action of the womb, and at times to run into an equal degree of inflammation, suppuration, or even gangrene; and especially in females of a high nervous temperament. And so common is this fellowship of action, that most of the cases of diseased spleen related by Morgagni, are accompanied with an account of some mischief existing in the womb or its appendages. It is, however, to M. Gastellier, of the Hospice de la Maternité, at Paris, that we are chiefly indebted for a knowledge of this peculiar sympathy, and especially in the case of uterine inflammation after childbirth. "La rate," says he, "en a été souvent frappée, mais une fois entr'autres elle a été entièrement détruite, entièrement fondue: il n'en restoit aucune trace, sinon un foyer de fluide sanieux, dans la région, et en place de cet organe."

This passage from M. Gastellier is quoted by Dr. Ley, in a case of a similar kind which recently occurred to himself in the Westminster Lying-in Hospital.—(*Med. Trans.*, vol. v., art. xx.) In this case, the preceding labour seems to have been perfectly natural, and without any difficulty whatever. On the third day afterward the disease seems to have commenced, indicated by intense pain over the whole of the abdominal region, with a slight sense of fulness, but without any considerable degree of tension. The patient sunk suddenly seven or eight days subsequently, and at a time when she was supposed to be in a state of improvement. On examining the body, the peritoneum and intestines exhibited little morbid affection of any kind, and the disease was found limited to the uterus and spleen; the peritoneal covering of both was slightly inflamed, but the internal structure of both had undergone a very extensive destruction. The whole surface of the uterus, when stripped of its tunica, was found to have assumed a gangrenous appearance, was extremely irregular, of a dark, livid hue, and gave forth a highly offensive vapour. The texture of the

spleen was so changed as to resemble an extremely soft piece of sponge, and its cells were filled with an intimate mixture of pus and grumous blood.*

SPECIES XVIII.

EMPRESMA ORCHITIS.

INFLAMMATION OF THE TESTICLES.

PAIN AND SWELLING OF THE TESTICLES; NAUSEA OR VOMITING; DEPRESSION OF SPIRITS; PULSE QUICK, SOMEWHAT LOW.†

INFLAMMATION of the testicle has generally been expressed by the absurd and unmeaning name of *hernia humoralis*; which, however, in its earliest use, applied to only one stage of the disease, namely, the suppurative, and imported an abscess or collection of pus in any part of the scrotum; and, in this sense, the expression occurs in Heister and Dionis, being precisely synonymous with the *empyocoele* of the Greeks. I have revived the Greek term *ORCHITIS*, not only as being far more precise, but as accordant with the general termination of the specific names of the diseases appertaining to the present genus.

The inflammation seems commonly to commence in the tunica vaginalis, and to pass secondarily into the substance of the testis. Dr. Swediaur contends, that the testis never swells in the first instance, and that the disease always begins in the epididymis.‡ The causes

* *Hysteritis puerperarum* is, in fact, the disorder commonly, but improperly, called *puerperal fever*, and described in a former part of this volume, p. 414. Experience has now fully proved, that this disease is not necessarily and essentially peritonitis. This fact is clearly established by the evidence adduced on the subject by M. Tonellé, Dr. Conquest, and Dr. Lee. Dr. Conquest does not think, however, that the morbid appearances are always sufficient to account for death; for sometimes he has only found a Fallopian tube, or an ovary inflamed. In other cases, *hysteritis*, uterine phlebitis, gangrene of the uterus, and agglutination of all the pelvic viscera, are noticed in post-mortem examinations. For further information respecting the morbid appearances, see ante, p. 414, et seq. An excellent account of the different views taken by different men of eminence of the nature and best mode of treating *puerperal fever*, is given in Ryan's *Manual of Midwifery*, p. 635, ed. 3. His description might be much enriched by a notice of the valuable observations of Doctor Lee.—Ed.

† The pulse is quick and hard; the skin is hot; the patient is constipated; and if blood be drawn from the arm, it presents a buffy covering, and its surface is cupped or excavated.—Ed.

‡ According to Sir Astley Cooper, the first symptom of orchitis, when it arises from sympathy with the urethra, is an irritation of the membranous or prostatic portion of that canal, as if some drops of urine still remained in the beginning of the urethra; and this is succeeded by a tenderness in the spermatic cord at the abdominal ring, and by swelling and pain in the epididymis. The testicle next swells, and attains a considerable size, becoming at the same time so tender, that the pressure of the thigh against it can hardly be endured. Its weight is also much increased; the pain and swelling ex-

fomentations, and calomel. For further details on this disease, see Boisseau, *Nosographie Organique*, tome troisième, Paris, 1829, p. 803; Nouveaux *Elém. de Pathol. Médico-Chirurgicale*, par Roche et Sanson, tome première, Paris, 1828.—D.

* There does not seem to be any sound reason for this caution; bloodletting may often be considered as an effectual auxiliary to our means of relief.—D.

are irritation in the urethra, or external injuries. The most common source of irritation is a gonorrhœa [which usually stops, or undergoes a considerable diminution, as the testis begins to swell.] Bleeding, leeches, puncturing the veins of the scrotum (*Sir Astley Cooper*, op. cit., p. 27), the recumbent posture, laxatives, and cold lotions, with a suspensory bandage, form the curative process.* [After two or three days, fomentations and poultices are the best applications.†] Yet we have already observed, that, when all local applications have proved ineffectual, the inflammation has been removed by vomits, in consequence of the close sympathy between the testis and the stomach.

This was a frequent practice of Mr. John Hunter (*On Venereal Disease*), and especially when the inflammation was the result of gonorrhœa. It was successfully employed for the same purpose, and is hence strongly recommended by Rhases (*Continet.*, lib. xi.), and is a common mode of treatment on the continent, particularly in Germany: after which opiates are often had recourse to, as well externally as internally. It may be worth remarking, that the affinity or play of action which thus prevails between the testis and the stomach, does not appear to be the common bond of union that is exhibited between the stomach, as the general centre of sympathy, and most other parts of the system; but a fellowship of a peculiar kind, and which, in fact, does not terminate in the stomach, but extends to the upper extremity of the alimentary tube, and exercises a very high degree of influence over the parotid glands, as is well known in E. PAROTITIS, and has been already noticed in discussing that disease. In treating of E. HYSTERITIS, I have had occasion

tend along the cord into the inguinal canal; and a good deal of uneasiness is felt both in the groin and the lumbar region, especially when the inflamed testis is suffered to hang down unsupported. In severe cases, nausea and vomiting sometimes occur. It is remarked by Sir Astley Cooper, that the epididymis swells more in proportion than the testis, the globus major and minor being more affected, however, than the body of the epididymis, and the former generally very perceptible in front of the spermatic cord. In some cases the pain is periodically and severely increased by spasms of the cremaster muscle.—See Obs. on the Structure and Diseases of the Testis, by Sir Astley Cooper, Bart., 4to., Lond., 1830, p. 9.

* Tepid fomentations of vinegar and water, one part of the former mixed with four of the latter, will often be found very useful: the slippery elm-bark poultice is one of the best local applications.—D.

† Sir Astley Cooper, op. cit., p. 28. This excellent surgeon finds, that there are some constitutions in which depletion will not succeed in relieving orchitis, and, when the pulse is jerking, the patient irritable, and the part painful, he deems it the best practice to give the submuriate of mercury, with the compound powder of ipecacuanha. When matter forms, he recommends it to be discharged by puncture, as the tunica albuginea ulcerates slowly. Frequently the abscess is in the testis itself; often in the epididymis; and occasionally in the spermatic cord.—Op. cit., p. 30.—ED.

to glance at the existence of a like sympathy between the uterus and the spleen: and the physiologist who has time for such pursuits, and judgment enough to guide him to a correct discrimination, would be engaged in no unthrifty employment, if he were to follow up, and arrange in a regular classification, these specific and mysterious relationships which single organs hold with single organs, and which are subordinate to the general harmony of the entire machine.*

GENUS VIII.

OPHTHALMIA.

OPHTHALMIA. INFLAMMATION OF THE EYE.

PAIN AND REDNESS OF THE EYE OR ITS APPENDAGES; INTOLERANCE OF LIGHT; FLOW OF TEARS OR OTHER DISCHARGE.

OPHTHALMIA, from the Greek term ὀφθαλμός, “oculus,” is obviously of very extensive import, and, from its radical signification, may be applied to any morbid affection of the eye, unless limited by common consent. Now, although a sort of common consent has been given, so as to restrain the term to inflammatory action, such consent has not been universally acceded to; and hence ophthalmia has been used in very different senses by different writers. Thus Sauvages, Linnæus, and Sagar employ it as expressive of any ache of the eye, without reference to pyrexia or inflammation. Among all these, therefore, it occurs under their class *dolores*, and runs parallel with cephalalgia, or cephalæa, ache or pain in the head. By Vogel, Cullen, and Macbride, it is limited to inflammatory affections of the eye; the two former arranging it as a genus, and the latter as a species. By Dr. Parr and Dr. Young it is also arranged as a species, and limited to a phlogotic action; the second denominating it ophthalmitis, consonantly with the common termination of names importing inflammatory diseases of a particular description of internal membranes and organs.

In the present system OPHTHALMIA assumes a middle rank: it is limited to inflammatory action accompanied with organic pain, but is arranged as a genus. It might possibly have been placed as a species under the preceding genus, EMPRESMA; but it has various characters peculiar to itself, as well in regard to its symptoms, as to the particular parts of the organ affected, which seem to entitle it to the rank of a distinct genus. And, thus explained, its real meaning will be found in the generic definition; the symptoms of inflammation common to the order, and entering into the ordinal definition, being

* It is remarked by Sir Astley Cooper, that when an acute inflammation of the testicle is sympathetic with the urethra, it rarely advances to suppuration; and he extends the same observation to other sympathetic inflammations. But, when orchitis is the effect of mechanical violence or vicissitude of temperature, suppuration may happen, though not frequently. The symptoms are then aggravated, and rigours occur.—Op. cit., p. 11.—ED.

always understood as a part of the generic character. [Yet, if the words of the definition be strictly adhered to, and no inflammations in the eye be regarded as species of ophthalmia, unless attended with redness and intolerance of light, certain cases, generally admitted to be such by the best modern practitioners, will be excluded. As Mr. Lawrence has correctly noticed, it is impossible to reduce into one description the characters of the various inflammations affecting the several structures of the eye. The truth of this must be evident, when it is recollected that the eye and its appendages exhibit, within a very small compass, a great variety of textures. We find in the visual apparatus, specimens of each of the three divisions of membranes, the mucous, the fibrous, and the serous; the conjunctiva, the sclerótica, with the cornea, and the surfaces containing the aqueous humour, corresponding respectively to each of those classes. It contains also nervous, muscular, and glandular parts; and, besides these, several tissues of peculiar structure, to which there is nothing analogous in other parts of the body; as the iris, the ciliary body, the choroid coat, and the transparent media. Each of the latter has its own characteristic structure; the cornea, the crystalline lens, the capsule of the lens, and the vitreous humour, resemble each other in being transparent. What similarity of character can we trace between inflammations of the conjunctiva, cornea, iris, and retina? Inflammation of the external tunics differs widely from that of the internal. Hence the attempt to embrace all these affections under one head, name, or definition, will only lead to confusion. It may be argued, indeed, that several textures of the eye are frequently inflamed together; yet the affection mostly begins in one, and, if duly treated, may often be wholly or principally restricted to it.* As, in a work of this kind, it can hardly be desirable to enter into a minute description of cases usually regarded as belonging to the department of the surgeon, the editor conceives

* As Mr. Middlemore has well observed, the study of the diseases of the eye is peculiarly interesting; for in consequence of the superficial situation of some of its textures, and the transparency of others, an opportunity is frequently afforded of actually witnessing the morbid process. When the pleura is inflamed, we may infer, from existing symptoms, that serum is effused, that lymph is deposited, or that pus is secreted, as a consequence of such inflammation; but, if the conjunctiva, or any of the superficial textures of the eye are diseased, we can not only see their precise pathological state, but the product of such morbid condition.—(See Lectures on Dis. of the Eye, as published in Med. Gaz. for 1832-3, p. 136.) "Many of the diseases of the eye, and, generally speaking, those of chief importance, are very obscure in their symptoms on cursory examination, and, at the same time, rapidly destructive in their progress; and, unless they are very promptly detected, they may arrive at that degree which no remedies will then affect. To detect, therefore, the degree of inflammation, as well as the particular texture inflamed, affords, in many instances, the only chance of preventing the loss of vision."—Middlemore, op. cit.—Ed.

that a notice of the following species of ophthalmia will suffice, the arrangement being founded on the structure and parts of the eye chiefly affected.

1. Ophthalmitis. Inflammation of the whole Eyeball.
2. Ophthalmia Externa. Inflammation of the External Tunics.
3. ——— Interna. Inflammation of the internal parts of the Eye.

These species, with their varieties, will embrace as much of the subject as can be expected in a work of the present description, rather embracing physic than surgery. Staphyloma, ectropium, and entropium, which were arranged in the early editions as species of ophthalmia, though frequently attended with a greater or less degree of inflammation of the organ, are never considered by any of the best practitioners of the present day as ophthalmiæ. It is therefore only on the principle of their being often associated with a degree of ophthalmia, that their admission into the present genus can be at all justified. The editor, therefore, with some reluctance, suffers them to remain annexed to the foregoing species, and in the place assigned them by the author.]

4. ——— Staphyloma. Protuberant and Opaque Cornea.
5. ——— Ectropium. Everted Eyelid.
6. ——— Entropium. Inverted Eyelid.

For the diseases affecting the SENSE of vision, and unaccompanied with inflammation, the reader must turn to the ensuing class NEUROTICA, Order II., in Vol. II.

SPECIES I.

OPHTHALMITIS.

INFLAMMATION OF THE WHOLE EYEBALL.

INFLAMMATION SEATED IN NO PARTICULAR TEXTURE OR COAT, BUT AFFECTING MORE OR LESS ALL THE TISSUES OF THE EYE; INCREASED SECRETION OF TEARS.

WHEN this general inflammation of the globe is fully developed, it is characterized by very considerable pain, increased external redness, more or less swelling of the part, increased lachrymal discharge, following, however, an earlier stiffness and dryness of the eye, and by redness and swelling of the upper eyelid. The pain is by no means confined to the front of the eye; but is deep-seated, and extends to the surrounding parts, as the brow, cheek, temple, and back of the head. The redness is at first inconsiderable, and seated in the sclerotic coat; but the conjunctiva soon participates in it, and the distention of its vessels produces the bright scarlet redness which conceals the faint pink colour of the sclerótica. The conjunctiva then begins to swell, and a deposition of lymph takes place, not only in the texture of the membrane, but in the loose cellular tissue that unites it to

the sclerotica. This bright scarlet elevation of the conjunctiva, projecting beyond and surrounding the cornea, firm, of considerable breadth, and acutely sensible, is technically called *chemosis*.

The access of light is very offensive to the patient; the pupil contracts to exclude it; and the eyelids are spasmodically closed. As the slightest attempt also to exert the organ produces severe pain, the patient keeps it as completely as possible at rest.—(*A Treatise on the Diseases of the Eye*, by William Lawrence, p. 74, 8vo., Lond., 1833.)

In the second stage, various alterations of structure are noticed. The iris becomes changed in colour, its brilliancy declines, and it no longer exhibits its usual motions in the varying degrees of light. The pupil contracts, and loses its clear black colour. The cornea becomes more or less opaque, and vision is lost. The alteration in the cornea, and in the state of the pupil, as Mr. Lawrence well observes, would account for imperfection or loss of sight; but the latter often occurs while the cornea is sufficiently clear for the transmission of light, and the pupil still open: hence, the evil is then to be ascribed to the mischievous effect of the inflammation on the structure of the retina; which effects, also, no doubt, generally exist, when the above specified causes of the interruption of the passage of light into the eye are present.

When the inflammation has attained its greatest violence, ectropium of the lower eyelid takes place, and a portion of the anterior surface of the eye projects in a denuded state, like a piece of red flesh.

To continue Mr. Lawrence's matchless description, here, however, considerably abridged, the mucous membrane of the eyelids becomes the seat of inflammation equally violent with that of the conjunctiva of the globe, becoming red as well as the skin, and the consequent swelling forms a large convex protuberance on the upper eyelid. The pulse is quick, hard, and full; the face flushed; headache is experienced; the skin is hot and dry; the tongue white; the appetite lost; the patient restless, and his nights sleepless.

The disorder, if not checked, is now attended with aggravation of all the general and local symptoms; the pain becomes throbbing, rigours occur, and suppuration of the eyeball follows; the cornea turns of a dull white, and then yellow colour. The agony is not relieved by the formation of matter, but continues for some days, until the cornea bursts, and the contents of the abscess are discharged, generally with the vitreous humour and crystalline lens. Matter is discharged for a time; the tunics of the eye collapse, shrink into the orbit, and the original form of the organ is completely lost.

When the disease does not proceed so far, the cornea becomes opaque, and remains so; the pupil is either closed or very much contracted, and the aperture filled by a newly-formed adventitious substance. Vision is either completely, or in a great degree lost; but the form of the eye remains.

The most favourable termination that can be expected, is the recovery of the organ, with the cornea clear, and the pupil open; still, in this case, as Mr. Lawrence has observed, the retina has generally suffered so much, that more or less of imperfection of vision is produced.

The present species of ophthalmia is characterized by its commencing, at one and the same time, in the external and internal tunics of the eye. Internal inflammation may spread to the external coats, or external inflammation may extend inwards; but, in this affection, both sets of parts are simultaneously attacked.

The prognosis, as delivered by Mr. Lawrence, is short and instructive. If the affection be seen early, and actively treated, you may expect to arrest it, and to prevent a change of structure in the organ, and consequent injury or loss of sight. But if the inflammation be fully developed, it can hardly be controlled, so as to preserve the powers of the organ unimpaired. When chemosis is actually established, the cornea clouded, the colour of the iris changed, and the pupil contracted, the patient will certainly lose his sight.

With respect to the causes of ophthalmia in general, our limits will permit us only to give a brief enumeration of them. Accidental wounds; surgical operations; and direct injury of the eye by various extraneous substances, mechanical or chymical stimuli, coming in contact with it; immoderate use of the organ; the influence of various states of the atmosphere; dense winter fogs; currents of cold wind blowing directly on the eye; exposure of the organ to vivid light, or its employment in the examination of luminous shining bodies. To use Mr. Lawrence's words, as the eyes are parts of an organic system, connected with the rest by vessels and supply of blood, by nerves, and by reciprocal sympathetic influences in health and disease, the remote and predisposing causes must be the same for them as for the rest of the body. One of the most important of these is fulness of habit, and, more technically, a plethoric condition of the system, arising from excess, or imprudent indulgence in the quantity or quality of food and drink. These indulgences produce and keep up an unnatural excitement, under which accidental circumstances more readily occasion disease, and that disease partakes more of the acute inflammatory character. The effects of all excesses at table will generally be aggravated, if combined with the unhealthiness of sedentary occupations in close and crowded dwellings. Another predisposing cause is the suppression of some habitual discharge, as that of menstruation. When, as Mr. Lawrence observes, we consider that, in a large portion of the community, all these predisposing circumstances are united with the direct exciting influence of excessive or injurious exertion of the organ, we shall cease to wonder at the numerous instances of inflammation in all the textures of the eye, that daily present themselves to our observation.*

* The annexed passage from Mr. Lawrence's work is introduced as conveying, in a small com

In the treatment of all inflammations of the eye, the removal of the cause forms one of the most important and early indications; not, however, that we have it in our power always to trace the precise cause, or, when it is known, to remove it. Its removal, also, will not invariably prevent the disorder from making advance, though certainly it is one of the most likely means of having this desirable effect. Thus, if ophthalmia be excited by the lodgment of any extraneous matter, as a small insect, a particle of gravel, sand, &c., between the eyeball and lid, the extraction of such foreign body must scarcely require any knowledge of surgery to make its necessity plain to any common understanding; the removal of it in particular cases, however, demands surgical skill. The following directions, given by Mr. Lawrence, deserve to be recollected. In order to discover and remove any minute substance that has insinuated itself into the eye, you should first look attentively at the exposed surface of the organ in a good light; if you discover nothing there, you should proceed to depress the under lid, and bring the lower surface of the globe into view, by desiring the patient to look up to the ceiling. If you still find nothing, direct the patient to look in the opposite direction, and raise the upper lid, so as to bring into view the superior surface of the globe. In most instances, the extraneous substances lodge in the concavity of the upper eyelid, and cause exquisite pain. When they are thus situated, you must evert

pass, a great deal of useful information:—"The common or idiopathic inflammation, is distinguished from the specific or sympathetic inflammations, by the following circumstances:—1st, The principal symptoms, that is, redness, pain, swelling, intolerance of light, and lachrymal discharge, are equally developed, and present a correspondence in degree. In the specific inflammations, one symptom is commonly predominant over the rest. Intense external-redness is seen in catarrhal ophthalmia, often without pain or intolerance of light; in scrofulous cases, the highest intolerance, with hot and acrid lachrymation, and spasm of the palpebral muscles, with hardly perceptible redness; in the arthritic and syphilitic, severe pain in the eye and its neighbourhood, with the other phenomena in a slight degree. In the forms just enumerated, the swelling is inconsiderable in comparison to the particular symptoms now pointed out; but is excessive in the purulent and gonorrhœal ophthalmia. 2dly, The symptoms commence at the same time, and in an equal degree, and continue in this equal proportion to each other throughout. Each symptom also exhibits this uniformity in degree and extension. The redness occupies equally the whole surface of the organ. In catarrhal and strumous cases it is partial, consisting in distention of some fasciculi of vessels, or confined to some part of the organ. In syphilitic, rheumatic, and arthritic ophthalmia, the redness is in the sclerotic coat, and usually forms a zone round the cornea. The pain in ophthalmia occupies the whole globe and orbital region. In other ophthalmia, it is often less in the eye itself than in the parts round the orbit. 3dly, The course of the complaint is very regular, proceeding, when it has once begun, to its full development, unless it should be interrupted by active treatment. In the other ophthalmia, the complaint altogether, or particular symptoms, of-

the lid. Take the cilia between your finger and thumb, and draw the lid downwards and forwards; press with a probe steadily against its upper part; then carry the ciliary margin upwards and backwards; you thus turn the lid inside out, and immediately see whether any extraneous body lodges there.* Particles of metal, imbedded in the cornea, should be removed with a cataract-needle.

Another indication is to protect the eye from injurious external influences. Thus, as Mr. Lawrence has observed, employment of the inflamed organ irritates it, and increases the inflammatory disturbance. The eye should therefore remain perfectly at rest; and even in slighter inflammation, active exertion of the organ should be discontinued, as in reading, writing, &c., although passive exercise of it may be permitted. This rule applies to the sound eye, when the other is the seat of violent inflammation. In the worst cases, the patient should be kept in a darkened room; but, in general, it will be sufficient to moderate the light by the ordinary Venetian blinds, and to protect the eye by the common pasteboard shade, covered with green crape or silk. The inflamed eye should never be exposed to cold air, in windy, rainy, or damp weather, and great vicissitudes of temperature should be avoided.

The preceding measures are only to be regarded as auxiliaries to the grand plan to be adopted for stopping the inflammation. To use Mr. Lawrence's expressions, it becomes necessary to institute early, and to follow up steadily,

ten undergo increase or diminution; in some, remissions, and in others, complete intermissions are observed. In catarrhal cases, the patient is often free from complaint during the day; the symptoms return in the evening, and are again diminished or lost in the morning. The symptoms of syphilitic ophthalmia undergo a marked diminution during the day, and show themselves again in severe nocturnal paroxysms. Scrofulous patients, on the contrary, suffer in the day, and are greatly relieved towards the evening. In these cases, too, recoveries and relapses occur suddenly, and succeed each other frequently. 4thly, True ophthalmia is attended with considerable constitutional disturbance of inflammatory character, while the sympathetic ophthalmia are generally without fever, even in many instances where the inflammation runs high."—See Treatise on Dis. of the Eye, by Win. Lawrence, p. 78.—Ed.

* See Lawrence on Diseases of the Eye, p. 99. "The directions given in books respecting extraneous substances in the eye, are in general of little use. Beer is tediously minute in describing every variety of matter by which the eye can be injured, and in laying down rules of treatment (Lehre, b. i., § 158); but he does not even mention the simple proceeding of everting the upper eyelid, which enables us to give the necessary relief in the majority of cases. Injections of water, milk and water, and mucilaginous fluids, under the lids and over the surface of the eye, are recommended: these are of no use, and, indeed, can only add to the irritation which already exists. If any injection could remove the foreign body, the flow of tears which its presence excites would be sufficient; when it sticks to the concavity of the upper lid, injections are wholly ineffective."—Op. cit., p. 101.—Ed.

bold and decisive antiphlogistic treatment, for the purpose of preventing any injurious changes in an organ, the perfect state of which is essential to the comfort and enjoyment of life. The disease must be arrested in its early stage, on account of its tendency to bring on the deposition of opaque matter, and to destroy the transparency of the pellucid textures of the eye. The pleura may become opaque, or adherent, without serious inconvenience; but the cornea cannot be deprived of its transparency, or the iris be rendered motionless (or misshapen by adhesions), without the functions of the eye being permanently injured or destroyed.—(*Middlemore's Lects., Med. Gaz. for 1832-3, p. 136.*)

Here local bleeding alone will rarely suffice; and the patient must be bled freely from the arm. In cases of inflammation affecting the entire globe of the eye, in inflammation of the external proper tunics affecting both eyes, or where it is very severe in one, general bleeding should be resorted to. Mr. Lawrence states, that a single large bleeding will, in general, be sufficient; but he is not inclined to measure the quantity of blood to be taken by ounces, but by the effect produced upon the system. He bleeds till the circulation decidedly feels the loss, and, in severe cases, where the eye is in danger, till fainting is produced.

The next mode of taking blood, in point of efficacy, Mr. Lawrence considers to be cupping, either from the back of the neck or the temple, especially the latter, from which part blood can be obtained quickly, and in large quantity.

Blood may be drawn by leeches applied as near to the eye as possible. The eyelids would be the best situation, were not this practice apt to produce an ecchymosis, that causes for a few days an unpleasant appearance. Copious bleedings by leeches, or cupping-glasses, are usually recommended from the temples; but it has been suggested, that the former may be employed with inconceivably more advantage, if applied directly to the mucous lining of the lower eyelid. We learn from Dr. Crampton, that this method has been pursued with almost universal success in the most severe cases in the Royal Military Infirmary at Dublin;* and it is said to have the great advantage of not being followed by that erysipelatous affection, which so often follows the application of leeches to the external surface of the eyelids, or even to the temples. This mode of using leeches may deserve more extensive trial.

In Mr. Lawrence's opinion, opening the temporal artery is less advantageous and convenient than cupping. We sometimes do not get blood enough in this way, and sometimes there is difficulty in stopping the bleeding. In active inflammation, the practice of scarifying the conjunctiva is decidedly condemned by him, and he thinks that there are very few cases of chronic ophthalmia in which it is beneficial.

The bowels are also to be cleared out by an

active purge of calomel, combined with rhubarb, extract of colocynth, or jalap, and followed by senna, salts, &c. Antimony and nitre may afterward be given to keep up perspiration, and aperients to maintain regularity of the bowels. In all severe cases, the patient should be restricted to fluid, or spoon-diet; and, in milder attacks, fermented liquors and animal food ought not to be allowed.

After these measures have been adopted, blisters may be applied to the back of the neck, or behind the ear. Mr. Lawrence is of opinion, that, in active inflammation, they should never be applied nearer to the organ than these situations.

Large doses of tartarized antimony have been recommended, with the view of keeping up nausea and vomiting, and thus suddenly checking the progress of inflammation of the eye. It seems to have been practised by Dr. Dobson, of Kirkham, as long ago as the year 1773.—(*Edin. Med. Com., iii., p. 411.*) While, however, Mr. Lawrence admits, that the plan diminishes the heart's action, lessens the force and frequency of the pulse, and certainly so far diminishes the degree of any local inflammation, he deems the remedy severe, and not to be depended upon.

After the abstraction of blood, and the evacuation of the alimentary canal, calomel may be given in doses of from two to five grains, alone, or combined with a small quantity of opium, and repeated every six or eight hours. The free exhibition of calomel, after depletion, is observed to have a very favourable effect in preventing the changes of structure, so frequently produced by inflammation.—(*Lawrence on Dis. of the Eye, p. 111.*)

This distinguished surgeon has little confidence in local applications; but he does not object to the use of saturnine collyria, or fomentations, the choice being regulated by the patient's feelings.

SPECIES II.

OPHTHALMIA EXTERNA.

INFLAMMATION OF THE EXTERNAL TUNICS OF THE EYE.

INFLAMMATION SEATED IN THE EXTERNAL TUNICS, ATTENDED WITH INCREASED LACHRYMAL DISCHARGE, IF IN THE SCLEROTICA AND CONJUNCTIVA UNITEDLY; BUT WITH MUCOUS, OR PURULENT DISCHARGE, IF THE INFLAMMATION BE OF A SPECIFIC CHARACTER, AND AFFECT PRIMARILY AND CHIEFLY THE CONJUNCTIVA.

As, under the term external ophthalmia, may be comprised all inflammations affecting chiefly, or primarily, the outer coats of the eye, the proper tunics, as well as the conjunctiva, and sometimes the eyelids, it is here proposed to notice the following varieties:

- α Ophthalmia externa communis. Inflammation of the external coats of the eye.
- β Ophthalmia catarrhalis. Catarrhal, or mucous inflammation of the conjunctiva.
- γ Ophthalmia purulenta. Purulent inflammation of the eye.

* Crampton on the Application of Leeches to Internal Surfaces; Dublin Hospital Reports, vol. iii., p. 223, &c.

δ Ophthalmia Gluti- Affecting the conjunctival
nosa. Psor-oph- lining and edges of the
thalmia. eyelids.

The first variety, as Mr. Lawrence has observed, which is common, or simple inflammation in subjects otherwise healthy, varies considerably in degree, from slight congestion of the conjunctiva to acute inflammation of the same membrane, with chemosis, and similar inflammation of the sclerotica and cornea. Under its various degrees and forms, it has been designated by different names. *Taraxis* denotes the slighter cases; *ophthalmia angularis* refers to a particular seat of the disorder; *xerophthalmia* denotes the dryness of the organ in a particular stage of the affection; and *chemosis* is its most violent or dangerous form, on account of the particular swelling of the conjunctiva often attending it, and described in the foregoing section.

Common ophthalmia may be seated in the conjunctiva only, or in the sclerotica and cornea. Although both cases may, without impropriety, be called external inflammation of the eye, they are very different in their symptoms, progress, termination, and treatment.

Simple inflammation of the conjunctiva is, generally speaking, an unimportant affection. In consequence of its loose texture, the vessels of the membrane yield readily; there is little pain or inconvenience; and no danger to the organ. The firmer textures of the sclerotica and cornea yield to distention with pain and slowness; their vessels do not easily recover, so that inflammation is with more difficulty subdued; and the implication of the cornea, with the ready transition of inflammation to the iris, exposes the organ to serious danger.

The symptoms of inflammation affecting the external proper tunics of the eye, are redness, pain, intolerance of light, increased lachrymal discharge, with more or less febrile disturbance.

To pursue Mr. Lawrence's valuable description, the redness begins on the front of the globe, immediately round the cornea, where it forms a red zone. Numerous bloodvessels may be seen advancing from the posterior part upon the sclerotica, and branching out into numerous ramifications, which are at length lost in the red zone. In inflammation of the conjunctiva, the redness commences in the circumference, the anterior part being at first comparatively free from it, and the sclerotica retaining its natural white appearance. The character of the red tint differs remarkably in the two cases. The vessels distended in sclerotic inflammation, or *scleratitis*, as it is frequently termed, are those seated immediately upon the sclerotic coat; they are therefore covered by the conjunctiva, and, being seen through that membrane, are of a dark rose-red, and sometimes almost of a livid hue, which forms a striking contrast to the bright scarlet tint of the vessels distended in conjunctival inflammation. The zone, seen around the cornea in the early stage, is also of a rose or pink colour. The redness is uniformly diffused through the sclerotic coat; and, when the inflammation is con-

sidcrable, a dense arrangement of vessels may be noticed, lying under the conjunctiva, and occupying the whole surface of the sclerotic coat. In inflammation of the conjunctiva, the vessels are not only of a bright scarlet colour, but lie nakedly on the surface of the membrane. When inflammation, without being very violent, is seated in the conjunctiva and sclerotica at the same time, the marked difference in the situation and tint of the two orders of vessels is very manifest.

When the sclerotic coat inflames, the conjunctiva soon participates in the affection; and the cornea, without becoming opaque, assumes a kind of dull appearance. Other common symptoms are, a sense of stiffness and dryness in the eye in the early stage of the disorder; a burning or aching pain in the organ; a sense of tension, or pressure of it; and a feeling as if sand or gravel were in contact with it, and pain shooting to the back of the orbit and side of the face. Intolerance of light is a marked symptom from the commencement of sclerotic inflammation, and forms another striking contrast between this affection and conjunctival inflammation; for, in the latter, the patient generally opens the eye freely, and experiences no pain from the access of light.

If the inflammation proceed further, the cornea first becomes grayish, and, when chemosis occurs, it turns white, cloudy, and then yellow; a thick, viscid matter, that cannot be discharged by puncture, being deposited in its texture. An effusion of a similar nature also frequently takes place in the anterior chamber, constituting the case termed *hypopyum*. Sometimes the cornea is perforated by ulceration; the aqueous humour escapes; the iris becomes adherent to the opaque cornea, with or without prolapsus; and vision is lost. Inflammation of the external proper coats, then, is distinguished by the redness being originally seated in the sclerotica; by the discharge being lachrymal, not mucous; by the pain and intolerance of light; and by the changes occurring in the cornea. In conjunctival inflammation, there is increased mucous discharge; little or no pain, nor intolerance of light, except at first; and seldom any affection of the cornea. According to Mr. Lawrence, the degree of danger to the eye will depend on the question, whether the inflammation extends to the cornea; and, if it does, on the degree of that inflammation. If the cornea be not involved, there is no risk; or, if the affection of that part be slight, we need not apprehend any injury of vision. The degree of sclerotic redness in the early stage is a criterion, from which we may form an opinion, whether it will be severe or otherwise. If the case proceeds to chemosis; if the cornea becomes gray or white; or, if matter be deposited in its texture, sight will be more or less impaired.

With regard to the treatment, it should conform to the directions given under the first species of the present genus; the extent and rigour of the antiphlogistic measures being regulated by the degree and violence of the inflammation.

The distinct nature of catarrhal ophthalmia,

and its origin from atmospheric causes or peculiarities, are expressed, as Mr. Lawrence has well observed, in the terms *cold* or *blight*, under which it is often popularly mentioned. The expression, *mucous ophthalmia*, designates the increased mucous discharge, which is one of its most striking characters. It is inflammation of the conjunctiva, either of the globe, or of the eyelids, or of both, caused by cold, and it corresponds to catarrhal affections of other mucous membranes, as those of the nose and its sinuses, of the fauces, trachea, and lungs. Catarrhal inflammation frequently goes through all these parts, and commonly so in influenza.

The symptoms of catarrhal ophthalmia, as described by Mr. Lawrence, are at first stiffness and smarting; some uneasiness on exposure to light; and external redness. When fully developed, the disorder is characterized by redness, increased *mucous*, not *lachrymal* discharge; inconsiderable pain, and no intolerance of light. The redness is superficial, and of a bright scarlet colour; and at first generally in patches, the whole surface not becoming uniformly red, till the disorder is fully developed. The redness begins at the circumference of the globe, and gradually advances towards the cornea; but, in the commencement, it is confined to the palpebral conjunctiva. Sometimes little ecchymoses appear on the conjunctiva, and sometimes small vesicles, called pustules, generally situated near the edge of the cornea; but there is nothing like chemosis.

When the lachrymal discharge, noticed in the very commencement, stops, its place is supplied by increased secretion of mucus from the inflamed membrane itself. This is at first thin, afterward becomes thicker, assuming a whitish or yellowish appearance, and sometimes resembling pus. Whenever catarrhal inflammation of the eye is at all considerable, the eyelids participate in the disorder; and a pain and sense of weight are felt about the frontal sinuses and antrum, with headache, disordered stomach, foul loaded tongue, and other febrile symptoms. In the daytime the redness is less; there is no pain nor intolerance of light; but, in the evening, the disorder undergoes an exacerbation.*

Catarrhal is distinguished from purulent ophthalmia by its much milder character; and Mr. Lawrence thinks that they differ rather in degree than in any other essential point, unless it should be proved, which he thinks is not yet the case, that purulent ophthalmia is contagious.

As the affection is not a serious one, and does not produce injurious consequences to the organ, venesection is not in general necessary; but,

in a young subject of full habit, with both eyes severely attacked, a full bloodletting would be proper. In ordinary cases, cupping and leeches will suffice. An active aperient, and, if the tongue be foul, an emetic, will advantageously follow the loss of blood. Saline and sudorific medicines may then be given, and occasional purgatives. The patient is to be kept warm, take plentifully of diluent drinks, and no animal food, nor fermented liquor. The pediluvium, or warm bath, may be useful, and perhaps, after a few days, a blister on the nape of the neck. Where the case seems to depend on a disordered state of the alimentary canal, an emetic, and an active purgative containing calomel, or the latter alone, followed by mild aperients and low diet, will often suffice, without the abstraction of any blood. The best local applications are fomentations. The sticking of the eyelids together during the night should be prevented by inserting a little of the unguentum plumbi* between the tarsal edges in the evening. The eye will not require a shade, unless the light be strong and offensive. Cool air will also be pleasant to the patient's feelings, and tend to remove the sensation of sand in the eye.†

Purulent ophthalmia of adult subjects, the third variety of external inflammation of the eye, here to be treated of, is a case of the most acute kind, attended with an increased secretion, which, in colour and consistence, resembles pus. The affection begins in the lining of the eyelids; extends to the mucous surface of the globe; and, when violent and not checked, it soon attacks the cornea. The whole texture of the conjunctiva then swells and becomes thicker; its vascular texture is developed; and its surface acquires an intensely bright red colour. The mucous surface is rendered villous, pulpy, granular, like the secreting surfaces of the alimentary canal; and, from the secreting surface, thus developed, flows the puriform discharge. This form of disease does not, like others, produce suppuration within the eye.‡

* R. Liq. plumbi acet. ʒss; ung. cetacei ʒj. Misce.

† Some practitioners resort to stimulating applications; thus Mr. Melin dropped into the eye a solution of the nitrate of silver, four grains to the ounce of distilled water twice a day.—(Report of Ocular Diseases, &c., Lond. Med. Phys. Journ., vol. liii., p. 184.) Dr. Ridgway used a stronger solution, ten grains to the ounce. Mr. Mackenzie also puts a large drop of a solution of the nitrate of silver into the eye, in the proportion of from two to four grains to the ounce; foment the eye twice a day with a collyrium of gr. j of the oxy-muriate of mercury in eight ounces of water; and applies to the edges of the eyelids, at night, an ointment, containing gr. iss of red precipitate to the drachm.—(See Mackenzie's Practical Treatise on Diseases of the eye, p. 334.) Mr. Guthrie employs the nitrate of silver ointment, ten grains to ʒj. These stimulating local applications are alleged to supersede the necessity for bleeding. Mr. Middlemore says, however, that he cannot recommend the ung. nigrum for catarrhal ophthalmia.—Lect. on Dis. of the Eye, Med. Gaz., p. 316.

‡ Dr. Vetch never saw the formation of pus in the chambers of the aqueous humour from puru-

* There are exceptions to this statement; a young lady in Bedford Place, whom the editor is now attending (Dec. 1833) for catarrhal ophthalmia, is always considerably better in the evening. This fact is noticed by Mr. Middlemore:—"Sometimes," says he, "the uneasiness occasioned by catarrhal ophthalmia is increased during the day, and much relieved during the night; or, if that be not the case, there will be a distinct remission and exacerbation of the symptoms at regular intervals."—Med. Gaz. for 1833, p. 314.—Ed.

The changes in the cornea are sloughing, ulceration, and opacity. The sloughing and ulceration often expose the anterior chamber, causing prolapsus of the iris, loss of the humours, and collapse of the tunics, so that not only the function, but the very form of the eye is destroyed.

The affection has been described under various names; as *purulent, Egyptian, and contagious ophthalmia*.

In the first stage, there is redness of the palpebral conjunctiva, with some stiffness of the eyelids; and a little whitish mucus is seen on the membrane; but this stage is seldom seen by the surgeon. The disease soon extends to the globe, in what may be called its second stage; and now we see it marked by high vascular action, and bright redness, great tumefaction of the membrane, and profuse discharge. Frequently, there are red patches, apparently of ecchymosis. The swelling of the conjunctiva on the globe often raises it in the form of chemosis, which is sometimes so considerable as completely to hide the cornea. At this period the whole eyelid swells, from an effusion of serum in its texture. At first, a stiffness is felt in the eyelids and globe; and then a sensation is experienced, as if sand or gravel were in the organ. As the inflammation extends to the globe, the pain becomes severe and excruciating; and is deep-seated in the eye, often with throbbing of the temples and headache. "I have seen (says the younger Dr. Frank) the bravest soldiers cry like children for a whole night; and have heard them declare, that they would readily allow the affected eye to be torn out, if they could hereby get rid of the pain."—(*De Peste, Dysenteria, et Ophthalmia Ægyptiaca*, 8vo., Vienna.)

In the third stage, there is a gradual remission of the symptoms: the swelling, pain, and discharge are lessened; the external œdema ceases; and the swelling of the conjunctiva being no longer counterbalanced, the palpebræ are everted, especially the lower.

A thickened and granulated state of the lining of the eyelids, with consequent opacity and vascularity of the cornea, are remote effects of the inflammation when it becomes chronic. Some unnatural redness of the membrane, with slight swelling, and a little discharge, often continues for a long time; and there is a great tendency to relapse.

If the cornea retain its natural transparency, we may expect to arrest the inflammation by vigorous treatment; if it be dull, and deep-seated pain in the eye and head announce extension of inflammation to the globe, the event is doubtful.

This is the disease concerning which so much has of late years been written by French and English surgeons and physicians; which

lent ophthalmia (On Dis. of the Eye, p. 64); and a similar remark is made by Mueller (*Erfahrungssätze*, p. 68; see also Lawrence on Diseases of the Eye, p. 180). Yet, Mr. Middlemore speaks of suppuration of the eyeball as one of the occasional results of the disorder.—See *Med. Gaz.* for 1833, p. 410.—Ed.

proved so extremely destructive to the armies of both nations in their respective expeditions to the banks of the Nile; and the real nature and cure of which have been discussed in modern times with no small degree of acrimony in our own country, but at the same time with much benefit to the public, from the facts and the ingenuity which the controversy has brought to light. There appears little doubt, however, that it has occasionally existed even in our own day, in ships-of-war, antecedently to the expedition to Egypt, of which Sir Gilbert Blane has given two examples (*Select Dissertations, &c.*, p. 215), though it does not seem to have been a subject of much attention at the time.

This disease was at first ascribed to the minute and glassy spiculae of the sands of the Egyptian plains. But it has since been referred, either to a peculiar miasm generated in marshlands, or to sleeping on damp or swampy ground, with insufficient covering, and surrounded by a moist atmosphere. And as these causes exist in other parts of the world than in Egypt, the disease is noticed in other countries, and, as we shall presently remark, appears to have been known in former times. The most contested points, however, in the history of the disease, are, whether, after the disorder has been once produced by the above, or other unknown causes, the matter secreted by the conjunctiva be contagious or not? and whether the extensive spreading of the affection afterward should not be imputed to this circumstance, rather than to epidemic causes!

[The generality of practitioners now incline to the affirmative on both these questions. In a former edition of this work, it was observed by Dr. Good that the matter is impregnated with a specific contagion; and hence the disease is propagated with great rapidity between those who come in contact with each other by sleeping together, or using the same towels. He had known it to be caught by a surgeon's assistant, merely in consequence of syringing the eyes of a patient; a part of the discharge having, from the force of the syringing, spirted into one of the assistant's eyes, which was for some days in a state of danger. Sir Patrick McGregor (*Trans. for the Improvement of Med. Knowledge*, vol. iii.), in the account which he has given of this affection, as it occurred in the Royal Military Asylum, mentions three instances in which the nurses of the establishment caught the disease, either while syringing the eyes of patients, or from having employed sponges used by the children.]

It is curious to find, however, that Assalini, and all the surgeons who accompanied the French expedition to Egypt, never entertained any belief of the contagious nature of the disease. Not long since, Mr. Lawrence also regarded the doctrine of contagion as involved in doubt. In support of the opposite view he remarks, that in all cases where collections of individuals labouring under it have been separated or dispersed, as when troops are disbanded, and go into civil life, the complaint is put a stop to, and does not extend itself. Now,

if it were contagious, and capable of producing a like disease in others, we should suppose that this would be the very way to spread it all over the country; but we find it the most effectual mode of putting a stop to the disorder. There is no dissemination of the complaint in the families or districts to which the soldiers, or other persons so afflicted, return. Yet, in opposition to this statement, it is to be remembered, that the extraordinary and increased prevalence of purulent ophthalmia in the army and elsewhere in this country, since the return of our troops from Egypt in 1801, is ascribed to the importation of the infection by soldiers labouring under the disease. If a healthy regiment also enter barracks which have been quitted by another corps, more or less afflicted with the complaint, experience proves that the new-comers are almost sure to suffer. If the facts of inoculation by contact, mentioned by Sir Patrick McGregor, Mr. Middlemore (*Lectures on Dis. of the Eye, in Med. Gaz.* for 1833, p. 410), and Dr. Good, be unimpeachable, such affirmative amounts to a proof of the infectious character of the disorder, and cannot be in the slightest degree invalidated by the result of Mr. Mackesy's (*Edin. Med. and Surg. Journ.*, vol. xii.) bold experiment of applying to his own eyes a rag, soaked in the purulent discharge from the eyes of three of his patients, but without contracting the disease.

Mr. Lawrence does not, however, venture so far as to assert, that purulent ophthalmia is not contagious; but merely that it is a point requiring further proof. He considers, that there is abundant evidence that the disease arises from other causes than from the application of matter from the eyes of one individual to those of another. Many patients went to the Ophthalmic Infirmary, in whom he could trace no connexion whatever with persons labouring under the same affection, and yet they had decided purulent ophthalmia. According to his experience, purulent inflammation may be produced by the action of common causes, without the application of any morbid matter to the eye. But, when it is once produced, it is capable of propagating itself, under particular circumstances, in a way which we cannot easily distinguish from a contagious propagation. When individuals are crowded together in great numbers in confined habitations, sleeping in the same rooms, and using the same linen and the same utensils, and not carefully attending to personal cleanliness, deleterious influences on human health are known to be produced, though their nature and mode of action are obscure. The bad effects are increased by unwholesome diet, insufficient clothing, and inadequate ventilation. Hence, the only instances of the disorder spreading extensively and virulently, have been in barracks, ships, schools, prisons, and work-houses.*

* "If contagion exist," says Mr. Lawrence, "it must be very different from that of smallpox, scarlet fever, or measles; much less active and certain. At the same time, when I look to the instances in which the affection has prevailed exten-

sively; when I see how the disease has gradually spread through large bodies of men, and how effectually its progress has been arrested in so many cases by insulating the diseased, and preventing all intercourse between them and the healthy, I feel fully satisfied that the disease is contagious under certain circumstances and conditions."—(*On Diseases of the Eye*, p. 200.) Mr. Middlemore makes the following inferences:—1st, That contagion alone will not, except in very rare instances, produce this form of purulent inflammation of the eye, but requires to be aided in its operation by constitutional susceptibility, want of cleanliness, disordered health, exposure to a brilliant sun, or the damp night air, or to dust, or to peculiar conditions of the atmosphere, &c. All, or any of these circumstances, he thinks, will ensure the operation of contagion. 2dly, Purulent ophthalmia may arise without the aid of contagion, as occurs in many instances of relapse, and in some of those cases in which one eye becomes affected as soon as the other has nearly recovered; and, finally, the disease has occurred to a ship's crew during their voyage, whose eyes were not affected at the commencement of the voyage, nor until some time afterward and who had no communication with the men of any other vessel until the completion, or nearly the completion of their voyage.—(*See Med. Gaz.* for 1833, p. 411.) It seems manifest, then, that the disease may begin as an epidemic, and, under certain circumstances, at least, propagate itself also by contagion. In the same way, the Asiatic cholera is now commonly believed to extend itself, both as an epidemic and as an infectious disease.—*Ed.*

In the treatment of purulent ophthalmia, two indications present themselves: the first is, to check the inflammation by antiphlogistic means; the second is, to restore the altered texture of the conjunctiva to its natural state by the use of astringents. In this manner, not only may the ulceration of the cornea and other destructive effects on vision be prevented, but, as Mr. Lawrence observes, you will also avert that chronic thickening and granulation, which are so obstinate and troublesome.]

The earliest mode of treatment pursued by the French, as we learn from the account of Dr. Antonio Savaresi, as well as of Dr. L. Frank, consisted in little more than the general treatment of the common acute ophthalmia; as bleeding from the jugular vein or temporal artery, blisters, saline purgatives, anodyne lotions, and a low diet. The bleedings, however, do not appear to have been very copious. And yet the first writer tells us, that, by this process alone, he was so fortunate, that, out of a thousand or thereabouts, who were confined to the French military hospitals in Egypt under his care, not more than two lost their sight completely, though some others suffered the loss of one eye.

In the hands of our own army practitioners, the plan of treatment, thus limited, completely failed; and the bleeding, which was almost solely depended upon, was carried, from the first day of the attack, and repeated for several days afterward, to as great an extent, not only as fainting, but as life itself would allow. The first accounts we had of this practice seemed to show that it was in the highest degree success-

ful;* but later experience has not justified the representation, and the extensive lists of blind pensioners supported by the Chelsea and Greenwich Hospitals, are a sufficient proof that the success of the evacuating plan was considerably exaggerated. A free abstraction of blood by leeches applied to the conjunctive tunic itself, does not appear to have been tried till of late by Dr. Crampton, in the Dublin Hospital, where it seems to have been of very decided advantage when employed in the first stage of the disease.

[Although bleeding seems not to have been invariably capable of checking the disease, the reason of this may perhaps have depended upon its not being combined with the seasonable employment of other judicious measures, and the impossibility of invariably removing soldiers from those influences by which the disease is kept up. Certainly, at the present day, and in this metropolis, purulent ophthalmia is treated with great success, which is in a great measure ascribed to free bleeding in the early stage. Mr. Lawrence recommends copious venesection, so as to produce syncope, as the first proceeding.† If the symptoms remain urgent, he advises the bleeding to be repeated. Subsequently, cupping may be practised on the temple, or numerous leeches applied round the eye, and repeated. Mr. Middlemore prefers placing them close to the tarsal margin of the lower eyelid. Cold or tepid washes should be used. Brisk purgatives in the first instance, and afterward milder aperients, will be necessary, with low diet and rest. After these plans have been adopted, blisters are to be employed. Such means are to be repeated and continued till the œdematous swelling of the eyelids, the chemosis, and the pain are reduced. The conjunctiva will now grow paler, and assume a relaxed and flabby appearance, the discharge still continuing in abundance.

In this stage, astringent lotions are to be applied to the organ, tonic medicines prescribed, and a better diet allowed. Mr. Lawrence prefers, at first, a solution of alum, and afterward one of the nitrate of silver, or the undiluted liquor plumbi acetatis. Two or three drops of either of the latter liquids should be introduced between the eyelids twice or thrice a day, and the eye may be bathed occasionally in the intervals with the alum lotion. The ung. hydrarg. nitrat. may also be applied to the edges of the eyelids at night. Mr. Guthrie, as is well known, is in the habit of using a strong ointment, composed of 10 grs. of the nitrate of silver, mixed with a drachm of lard, or the ung. cetacei, in nearly every form and stage of inflammation of the conjunctiva, attended with increased discharge from its surface. As an early applica-

tion, however, it is disapproved of by Mr. Middlemore, though he admits that the stimulating plan is extremely useful, as soon as the acute symptoms are subdued.—(See *Med. Gaz.* for 1833, p. 412.) Then also, bark, cascarilla, and dilute sulphuric or nitric acid, with occasional aperients, are the best medicines. At first surgeons should carefully watch the effect of astringents; for, if the pain continue after their use, with an increase of redness, they must be left off, and antiphlogistic measures be resorted to again.

When the cornea is in a sloughing or ulcerating state, accompanied with debility, the patient should have wine, porter, good diet, and the sulphate of quinine, and use local astringents.]

The late Mr. Saunders was the first in the present day to discover that the blindness which is so apt to follow, even after the first attack of virulent inflammation has subsided, proceeds from the friction upon the transparent cornea of innumerable irritating granulations, as he denominated them, thrown forth from the surface of the tunica conjunctiva that lines the interior of the palpebræ, and which become a new source of inflammation, less violent, indeed, but as fatal in its effects; and the disease has hence been very correctly divided into two stages, that of primary and that of secondary or apparently granulating inflammation. Mr. Saunders endeavoured to cut the disease short in its first stage by exciting nausea, and maintaining it for a considerable period of time, so as to lower the living power, and hereby take off the inflammatory action. And where the disease had proceeded to what he called the granulating stage, he removed the minute caruncles from the tunica conjunctiva by cutting them off with a pair of scissors, and afterward applied a solution of nitrate of silver to prevent their sprouting again. Instead of the nauseating process employed in the first stage, Sir William Adams boldly prescribed active and powerful vomiting, continued for eight or ten hours, by giving two grains of tartar emetic at first, and continuing one grain every half hour afterward, through the whole of this period; by which violence a change of action, or new but more manageable excitement, is often produced in the eye, and the disease is stopped in the course of ten or twelve hours from its onset. [The editor need scarcely observe, that, though most inflammations may be checked by the emetic treatment, the plan is severe, and less to be depended upon, than free bleeding and other antiphlogistic remedies.]

Where the second or granulating stage has commenced, Sir William Adams used to cut away the diseased surface of the conjunctiva, instead of the granulating points alone; by which the morbid action is destroyed, not only with less pain, but far more radically and effectually; and he afterward employs a solution of alum, instead of a solution of nitrate of silver, as the latter is hereby rendered unnecessary; not to mention that the agony it excites is often intolerable, and that a new inflammation has

* Account of the Ophthalmia which has appeared in England since the return of the British army. By J. Vetch, M. D.

† "If the symptoms be severe, and the patient tolerably strong, bleed until the pain is relieved, the chemosis diminished, and the sense of tension and throbbing removed."—Middlemore, in *Med. Gaz.* for 1833, p. 411.—Ed.

followed, in some instances, almost as dangerous as the original inflammation itself. Emetics, indeed, have long been occasionally made use of as a means of relieving inflammation in the eyes, but not in the particular kind before us, nor perhaps at any time of the inflammation with the precise object in view proposed by Sir William Adams. Stoll, for instance, employed them successfully in periodic ophthalmia (*Nat. Med.*, part ii., p. 102); and Dobson, as already observed, in ophthalmia of a like chronic kind, accompanied with nervous debility; the bark being interposed between their repetition. —(*Med. Comm. Edin.*, vol. iii., p. 444.) The nearest approach, however, to this practice, which I have met with on medical record, is Dr. Dobson's case, already noticed in the foregoing pages.

Yet, though the emetic plan carried to this extent, and employed for the express purpose just stated, does not appear to have been had recourse to in this form of ophthalmia till our own day, it has been very clearly shown by those who have critically and historically examined into the subject, that this very affection was long ago known to the world, and has been rationally as well as successfully treated in different ages. As the Greeks were much better acquainted with Egypt than ourselves, it is hardly to be supposed that it could have escaped their notice, and it has hence been suggested, with much probability, that it is referred to by them under the term *PLADAROTIS* (*Galen. Isag.*, 215, c. 6, vol. v., fol. 1542); while it is ingeniously affirmed by a learned critic of our own day to have been described by the old surgeons of our own country under the expressive appellation of the *MULBERRY EYELID*. —(*Quart. Journ. of For. Med.*, vol. i., p. 403.) There can, however, be no question that the ophthalmia before us was well known to them under whatever name described; and that even the *granulations* of the second stage, as they are incorrectly denominated, and which are rather enlarged and indurated cryptæ of the conjunctiva, had not only been noticed by them, but were even removed by some of the most approved methods of modern surgery; since it is expressly recommended by Read, who flourished nearly a century and a half ago, that, "if they be thick and gross, they must be cut away dexterously with the point of a lancet, and afterward let the place be touched with a little fine salt, alum, or copperas-water."* This, however, is not mentioned with a view of deducting from the merit of Mr. Saunders or of Sir William Adams; since the practice, and even the name of its original inventor, seems to have been long lost sight of in the annals of surgical science, and consequently the revival of such a practice, and a detection of its benefits, are as much a discovery now as it was in the time of Read. [At the present day, the practice

of cutting away the granulations is less frequently adopted than that of touching them with nitrate of silver or sulphate of copper; experience having proved that they are more apt to grow again after the use of the knife or scissors than after that of astringents* or mild escharotics. The eversion of the eyelid, frequently remaining after an attack of purulent ophthalmia, may also be speedily cured by touching the surface of the thickened conjunctiva with these applications, which have the effect of restoring to it a healthy surface. The plan, however, is only right in the perfectly chronic stage, or rather a stage subsequent to those of the original complaint.

With respect to the *purulent ophthalmia of new-born children*, it usually comes on within a week from birth. Both eyes are mostly affected, but they are not first attacked exactly at the same time. In the first stage, it is confined to the mucous lining of the eyelids, which are remarked to adhere together when the child wakes. Their edges are redder than natural, especially at the corners; and the access of light to the eye produces pain, and makes the child shut it. If at this period the eyelids be everted, their lining will be found to be red and villous, and a little white mucus will be seen lying on the inside of the lower eyelid.

In the second stage, the inflammation extends from the palpebral conjunctiva to that covering the eyeball; the vascular congestion and redness are much augmented; the eyelids swell and become red even externally; from the inflamed membrane there is a copious secretion of purulent fluid, which glues the edges of the eyelids together, and then accumulates under the latter parts, or pours out over the face, staining the cap and linen. As the light is very painful, the child keeps the eye constantly shut, even if the swelling of the eyelids should not already close it. In this second stage, the whole of the conjunctiva is swollen, of a uniform bright scarlet colour, and presents a villous surface. It is further remarked by Mr. Lawrence, that the close adhesion of the membrane to the tarsi prevents the palpebral conjunctiva from swelling much; but the loose folds between the lid and the globe become greatly enlarged, forming red tumid rolls, finely granulated. These folds, pressed on by the orbicularis, evert the tarsi, causing ectropium of one or both eyelids. This eversion particularly takes place when the child cries, or the surgeon attempts to examine the eye by separating the eyelids. Sometimes the upper eyelid is so swelled that it hangs completely over the lower. During the night, the eyelids become so adherent to each other that they cannot be opened in the morning till after they have been soaked with warm water. When they are separated, the eye is completely concealed by the discharge; we wipe it away with a soft rag, and

* Short but exact Account of all the Diseases incident to the Eyes, Lond., 2d edit., p. 96, 1706. See also Quarterly Journ. of Foreign Med., ut supra.

* Mr. Lawrence gives the preference to solutions of alum, sulphate of copper, or lunar caustic, or the liquor plumbi acetatis.—On Dis. of the Eye, p. 216.—Ed.

there is still enough to cover the globe and hide the cornea. If the disease should not be checked, it extends to the cornea, and thus may reach the interior of the globe. Some one or more of the following changes are now produced: general or partial sloughing of the cornea; ulceration or opacity of the same part; adhesion of the iris to the inflamed or ulcerated cornea, or suppurative of the eyeball, which last occurrence, Mr. Middlemore says, has been denied by Mr. Saunders on very insufficient grounds.—(*Middlemore's Lect. on Dis. of the Eye, as published in Lond. Med. Gaz. for 1833, p. 508.*) In the third stage, there is a gradual abatement and cessation of all the symptoms; the redness, swelling, and discharge are diminished; the child opens the eyes more readily to the light; and no ectropium takes place. The opportunity of seeing whatever changes may have been produced by active inflammation is now afforded.

When the complaint is severe, the infant becomes restless, and its bowels are disturbed; and the sloughing stage is attended with paleness and debility.

With regard to the causes of purulent ophthalmia in infants, it appears, that in a large proportion of instances, the mother is affected with some kind of vaginal discharge, to which the child's eyes have been exposed during parturition. Hence the natural inference is, that the disorder is excited by the actual contact of the matter: and the tolerably regular appearance of the disease on the third day corroborates this notion. Indeed, some facts mentioned by Mr. Lawrence and Mr. Middlemore* also tend to confirm this view of the subject. Yet, the former observes, purulent ophthalmia is often seen in children of healthy mothers, or mothers who at least declare themselves to be free from any kind of discharge. A declaration of this sort, however, coming from a woman whose child is attacked about three days after birth, is of course incorrect. Whatever may be the fact with regard to contagion being an exciting cause of this purulent ophthalmia, Mr. Lawrence adverts to other circumstances, which undoubtedly promote its occurrence. He says, that it is most frequent and destructive in weakly children, and such as are exposed to bad air, cold, insufficient clothing, and deficient nutrition. It is more frequent in premature children than in those born at the full time; in twins than in single children; in newly-born infants than older children; and in those than in adults. It is more frequent in damp and cold than dry warm weather; and among the children of the poor than those of the upper classes. In the Foundling Hospitals of Paris, Vienna, Petersburg, and Mos-

cow, which receive all infants presented, the disease is particularly prevalent and unmanageable.

When the cornea remains clear, the prognosis is always favourable; but if this membrane has sloughed, or ulcerated extensively, loss of sight is unavoidable. Even if the cornea be of a dull white, or has begun to lose its transparency, vision may be lost or injured, as it is most likely that ulceration and prolapsus of the iris, or permanent opacity will ensue.]

I cannot say that in any instance that has fallen within my own range of practice, I have seen all the benefit from the use of Bates's powerful and stimulant astringent, known by the name of aqua camphorata, which Mr. Ware ascribes to it. I have known it at times check the discharge, but do almost as much mischief from the pain it excites, and the irritation produced by very long fits of restlessness and crying, which are sure to follow.

The plan that has proved most effectual, in my own course of observation, is to syringe the eyes thoroughly, so that the whole of the purulent discharge may be washed out, with a solution of alum in water, in the proportion of not less than a grain to an ounce: to continue this syringing three times a day, to keep the bowels open, scarify the gorged vessels of the conjunctiva where it can be done, or apply leeches to their under surface, and surround the forehead lightly and loosely with folded linen, wetted with a lotion of an ounce of the liquor ammoniæ acetatis mixed with seven ounces of water, and kept cold in a bucket of ice. [Mr. Lawrence has seldom found it necessary to use more than one leech, which he applies to the red swelling of the upper eyelid: even this, he says, sometimes renders the infant quite pale. In the most robust children, he would not advise more than two leeches; one to each eyelid, or to the upper eyelid of each eye.] The child, in order to receive the full benefit of the solution of alum, should have its head laid flat between the knees of the operator, with the face uppermost: the lids should be separated from each other by the fingers, or, if necessary, as it almost always is, by the assistance of a blunt silver spatula, or some other blunt instrument, and the point of the syringe, loaded with the astringent lotion, should then be introduced between them and convey its contents all around: the syringing being repeated till the whole of the collected matter is washed away. The pain produced by the use of this solution is trifling, and the child ceases to cry almost as soon as the operation is over.

[In the early stage, Mr. Lawrence prefers a saturnine lotion made with rose-water. He also directs the bowels to be kept open with castor-oil or magnesia; and when the inflammation is active, and the tongue white, he lets the purgative medicine be preceded by a grain or two of calomel. He does not approve of blisters for young children.

The agglutination of the eyelids is to be prevented, and the exit of the discharge promoted, by frequently bathing them with tepid water, or milk, and applying a little lard, or fresh butter, to their edges.

* Lond. Med. Gaz. for 1833, p. 508. "All infants," says he, "are subject to the same change of residence, exposure to light, and to cold, &c., although only a small portion, it is presumed, are destined to pass, in their exit from the uterus, through a canal moistened with morbid secretions." The conviction of Mr. Middlemore is, that this disease is produced by the contact of morbid vaginal secretions.—ED.

The inflammatory stage having been subdued, astringents are to be employed. Mr. Lawrence uses a solution of alum, in the proportion of from two to ten grains of alum to each ounce of water, according to circumstances. This lotion is to be carefully injected under the eyelids, three or four times a day, so as to cleanse out all the purulent secretion; and, in the intervals, a piece of rag, wetted with the same wash, may be laid over the eye. If the alum lotion ceases to have effect, a solution of nitrate of silver, in the proportion of two grains to each ounce of water, may be dropped into the eye two or three times a day.*]

If, when the inflammation begins to subside, an ulcer be detected on any part of the cornea, and especially if it be over the pupil, a solution of nitrate of silver, in the proportion of a grain to an ounce of water, should be dropped into the eye night and morning after the syringing is over, and the eye be kept open for about half a minute, so that the solution may not be wiped away suddenly by the closing of the lids, but may fairly lie upon the ulcer and float over it for this period of time. The sulphate of quinine should also be given, dissolved in a small quantity of water, to as great an extent as the infant can bear it [for the extract of bark, broken down and blended with milk, may be prescribed, as advised by Mr. Lawrence]; and if looseness be produced, it should be checked by a drop or half a drop of laudanum in each draught. Prussiate of potash is also a very good astringent for contracting the area of the ulcer, and expediting the healing process; and may be used instead of the solution of the nitrate of silver, in the form of an ointment, by means of the unguentum cæcæi. By a careful perseverance in this process, I have not only seen ulcerations on the cornea heal speedily, but, in one or two instances, without leaving any cicatrix to impede vision, even where the ulceration has been seated over the pupil.

[The varieties of purulent ophthalmia said to arise from metastasis of gonorrhœa from the urethra to the eyes,† and from the inadvertent application of the urethral discharge to the eyelids, hardly require a particular description in a work of this nature.]

δ *Ophthalmia glutinosa*, so called in the present work, is the psor-ophthalmia of Plenck and

* The practice of using powerful stimulants in the early stage is strongly condemned by Mr. Middlemore. "Let the acute stage pass by; let the secretion become diminished; and the tense, florid state of the conjunctiva be exchanged for a comparatively pale, flabby appearance of that membrane, and then," he admits, "either the undiluted liq. acetatis, or the strong nitrate of silver ointment (ten grains to a drachm), may be advantageously employed."—See Middlemore's Lect. on Dis. of the Eye, as pub. in Med. Gaz. for 1833, p. 511.—Ed.

† This particular cause, which is admitted by Richter, Scarpa, and Beer, is rejected by Mr. Lawrence, because "gonorrhœal ophthalmia may occur while the discharge from the urethra continues, and since it does not take place when that discharge is stopped."—On Dis. of the Eye, p. 229; see also his Treatise on the Venereal Dis. of the Eye.—Ed.

Mr. Ware [the idiopathic inflammation of the glands of the eyelids, of Beer, and the catarrhal inflammation of the eyelids, of various modern writers]; and consists in an inflamed state of the small sebaceous glands, whose ducts, arranged in a row on the edge of each eyelid, pour forth a viscid matter that incrusts and hardens. [It appears to Mr. Lawrence, however, that the mucous membrane is the primary seat of the disease, and that the Meibomian glands, if diseased at all, are affected secondarily.—(Lawrence on Dis. of the Eye, p. 158.)] During sleep, when the lids have been for some time in contact, the matter glues them together so firmly, that they cannot be separated without many a painful effort. This matter, instead of being mild and lubricant, as in health, is now not only viscid, but acrimonious and erosive; whence the eye is irritated, and the edges of the lids ulcerated; and the complaint is apt to become chronic, and will sometimes last for years, or even for life, in which state it is termed lippitudo.

The disease is not unfrequently produced by smallpox and measles; occasionally by common ophthalmia from cold or any other causes, and in a few instances, though rarely, from a sty. Sometimes it appears to be the result of a scrofulous habit.

[In the acute stage, cupping or leeches, tepid lotions, mild ointments, and active aperients, are called for, followed up, if necessary, by a blister.] In the chronic stage, it is best attacked, and perhaps only to be cured, by such local stimulants as may excite a new action or inflammation, that may be more manageable. The practice of M. St. Yves was here very bold: he touched the ulcers on the edge of the eyelid with lapis infernalis, and thus cauterized the morbid surface. The unguentum hydrargyri nitratis, or the older form entitled unguentum hydrargyri nitrati, has of late been used with equal success, and with far less danger of injuring the ball of the eye. The best way of using it is to take up a little of it with a camel-hair pencil, and apply it along the edge of each eyelid.* Or a drop of spirits, as vinum opii, ether, or Riga balsam, may be allowed to fall into the eye in the same manner, and be repeated daily. [Besides local applications, the compound calomel pill, and other alterative and aperient medicines, are frequently necessary.]

SPECIES III.

OPHTHALMIA INTERNA. INFLAMMATION OF THE INTERNAL PARTS OF THE EYE.

ACCOMPANIED WITH LESS EXTERNAL APPEARANCE OF DISEASE THAN THE PRECEDING SPE-

* Other applications in common use are Janin's ointment, composed of Armenian bole and tutty, of each ʒij. white precipitate ʒj. and lard ʒss.; Singleton's, or the golden ointment, the active ingredient in which is orpiment, or the sulphuret of arsenic; and ointments containing the red precipitate in various proportions. Mr. Mackenzie puts from twelve to twenty grains of it to an ounce of lard.—See Practical Treatise on Dis. of the Eye, p. 138.—Ed.

CIES; ITS COMMENCEMENT AND PROGRESS FREQUENTLY INSIDIOUS; AND OFTEN ATTENDED BY LITTLE OR NO EXTERNAL REDNESS.

[INFLAMMATION may be confined to one of the internal structures, or all of them may be involved. The close connexion between the different internal parts and their common vascular supply, is sufficient to account for the extension of inflammation from one to another. If inflammation commences in the iris, it readily extends to the ciliary body, choroid coat, vitreous humour, and retina. On the other hand, it may spread forward to the anterior part of the eye, so that a case of iritis often involves in its progress the greater part or the whole of the internal tunics, and also the external parts. Inflammation, beginning in the retina, spreads in like manner to the vitreous tunic, choroid, iris, &c.—(Lawrence, op. cit., p. 268.) Mr. Lawrence treats of four varieties of internal ophthalmia; namely, inflammation of the anterior and posterior chambers of the eye; inflammation of the iris; inflammation of the internal tunics generally; and inflammation of the posterior tunics of the eye.]

As this work is not designed to convey a minute account of ophthalmic surgery, the first variety must here be omitted, and our remarks confined to

- α Iritis. Inflammation of the iris.
β Inflammatio tunicarum. Inflammation of the choroid coat and retina.

As in the arrangement of inflammation of the eye adopted in this edition, inflammation of the iris is classed as a variety of internal ophthalmia, and not as a species, no particular definition of it is placed as a leading head at the beginning of this section. Yet, as that inserted by Dr. Good is correct and instructive, it may be as well here to repeat it.]

Inflammation commencing in the iris; colour of the part changed to green or reddish; fibres less moveable, and shooting dentiform processes into the pupil; pupil irregularly contracted and grayish.

Dr. Schmidt, of Vienna, to whom we are chiefly indebted for an accurate description of this species, has denominated it *Iritis* (*Ueber Nachstaar und Iritis nach Staaroperationen*, Wien, 1801); and under this name it has of late years been described by many practical surgeons in our own country. The termination, however, is unclassical, and if the derivative be retained, it should unquestionably be *iritidis*, instead of *iritis*; but ophthalmia *iritidis* is better, as the disease is very clearly a species of a connective genus of diseases, rather than a distinct genus itself. It is the more singular, however, that *iritis* should ever have been used by its inventor, as the Germans have long employed the more correct relative compounds of *iridotomia* *iridectomy*, and *iridodialis*.

The exact change of colour which the inflamed iris assumes, first in its less, and then in its greater circle, depends upon the peculiar colour it possessed when in health. If this were grayish or blue, the morbid hue will be

green; if brown or black, it will be reddish. The grayish or cloudy appearance of the pupil is produced by the secretion of coagulable lymph, which spreads over it in a fine flake like a cobweb. If the inflammation do not yield to the curative treatment, a yellowish-red tubercle forms in some part of the surface of the iris, commonly where the greater and less circles of the membrane meet; it enlarges, projects still forwarder, and is distinctly seen to be an abscess, which at length bursts and discharges its contents into the anterior chamber.

[Iritis is an adhesive inflammation; that is, an inflammation attended with deposition of new matter, indiscriminately called by the not very precise term of coagulable lymph. The chief character of the affection is this effusion of lymph, either into the texture of the iris, or in distinct masses on its surface, or in a more or less fluid form. This effusion of coagulable lymph, besides changing the colour and general appearance of the iris, impairs and destroys its motions; frequently renders it adherent to surrounding parts; alters the form and size of the pupil; and obstructs that aperture, so as to produce more or less impairment of sight. But, though the inflammation is called adhesive, and the substance effused is commonly lymph, it appears, pus may be poured out from the inflamed iris, or, at all events, a fluid of a yellowish colour, that sinks to the bottom of the anterior chamber, and cannot be distinguished from pus; and where the inflammation is violent, even blood itself may be effused.—(Lawrence, op. cit., p. 285.)]

In the beginning, there is some intolerance of light; the sclerotic coat participates more or less in the inflammation; and there is consequently a greater or less degree of increased sensibility. If the inflammation be not relieved by proper treatment, Mr. Lawrence finds that an opposite state succeeds, or dimness of sight, caused by other changes which now take place in the pupil and cornea. From the commencement there is generally more or less pain, which varies in degree according to the acuteness of the attack, and often extends around the orbit, and sometimes to the front or back of the head. The pain is often characterized by nocturnal exacerbations.

In the enumeration of the symptoms of iritis, however, what most particularly deserves notice is the redness, which appears in the form of a zone around the cornea, and consists of the vessels on the forepart of the sclerotica. In the beginning, a pale pink blush of sclerotic redness is perceptible, and, although the conjunctiva is not altered, the trunks of the vessels of the sclerotica may be observed to be in a state of distention. If the affection continue to increase, the inflammation spreads from the iris to the corpus ciliare, choroid coat, and retina, with increase of pain and fever, and ultimately with irrecoverable loss of vision. At the same time, the mischief is propagated forward, the cornea becomes more opaque, the conjunctiva more inflamed, and great external redness is added to all the other symptoms.

After the active inflammation at length abates, the permanent disorganization and changes of structure remain; as general adhesion of the iris to the cornea, with opacity of the latter, and even staphyloma; or adhesion of the edge of the pupil to the capsule of the lens; a motionless contracted state of the pupil, &c.

A change of colour in the whole iris, with considerable contraction of the pupil, and an opaque substance in it, with intense external redness, great and deep-seated pain, and complete insensibility to light, are circumstances denoting, according to Mr. Lawrence's experience, a hopeless case. When the inflammation is recent, confined to the iris, and unattended with permanent changes of structure in the iris, cornea, or retina, or adhesions, and irregularity of the pupil, the prognosis is favourable.]

This distressing affection sometimes follows an operation for the cataract; in which an irritation is often excited, either by endeavouring to press out the lens through too small a wound in the cornea, by suffering some pieces of the lens to remain in the posterior chamber, or from too frequent an exposure of the internal surface to the air, by unnecessarily raising the flaps of the cornea. And the disease was hence, in our country, till of late, most absurdly denominated *secondary cataract*. [It also originates from accidental injuries, and irritation, and immoderate exertion of the eye.

Iritis is particularly apt to occur in certain states of the constitution, and, as Mr. Lawrence mentions, it has even been doubted whether there is any such thing as idiopathic iritis, except as the result of direct mechanical injury. The unhealthy condition of the constitution, promoting attacks of iritis, are those produced by morbid poisons, as in syphilis, or those occurring in individuals who are subject to gouty and rheumatic complaints. Iritis is rare in young subjects, in whom these states of the system do not exist.]

Where a patient is labouring under an arthritic diathesis, and is accidentally affected by a common ophthalmia, this species is apt to be ingrafted upon it. It is also an accompaniment of several cutaneous eruptions, especially those connected with an abuse of mercury.

The medical treatment should consist in free venesection, leeches, active purgatives, and low diet: blisters are then to be applied successively to the temples, behind the ears, and on the nape of the neck. [The body is to be kept perfectly at rest, as well as the organ; and the eye protected from all injurious external influences. According to Mr. Lawrence, local applications cannot be of much service in so serious an affection of parts comparatively internal. Tepid washes, he says, will perhaps be most soothing; but cold applications may be used if the patient prefer them.

The foregoing antiphlogistic measures will moderate the violence of the inflammation; but the effusion of lymph proceeds, and the above-mentioned alterations of structure are the result. For the stoppage of this destructive action, the free and prompt use of mercury is

necessary, which not only stops the further deposition of lymph, but promotes the absorption of what is already effused. Two, three, or four grains of calomel, joined with one fourth or one half of a grain of opium, should be given every eight, six, or, in urgent cases, every four hours. When calomel disagrees, the blue-pill or mercurial frictions may be employed.]

Whether iritis be a primary affection, or connected with other diseases, even with syphilis, or induced by the action of mercurial preparations, Mr. Travers estimates mercury as almost a specific remedy.

[Belladonna is also to be used for preventing that contraction of the pupil, to which there is such a powerful tendency in iritis. If the inflammation be violent, Mr. Lawrence smears the moistened extract upon the eyebrow; when the organ is less irritable, he drops a solution of the extract between the eyelids. This part of the treatment is of the greatest importance, not only in preventing further contraction of the pupil, but because the influence of belladonna on the iris is so great, that, where adhesions have already taken place, if the effusion be very recent, the contraction of the iris will elongate the masses of effused lymph, stretch them out, and often completely liberate the margin of the pupil. The case, however, must be recent, and the belladonna assisted with the operation of mercury.]

Mr. Travers distinguishes also inflammation in the iris from that in the cornea, by regarding the latter as suppurative, and leading to an abscess, and the former as adhesive alone. And he tells us, that inflammation of the cornea so strictly maintains this character, that if it spread to the iris, and in this case become merely secondary, it still preserves its adhesive power.

This species is also sometimes a concomitant of cutaneous eruptions, decidedly not syphilitic; and especially of those produced by a very extensive use of mercury; constituting what has been denominated by some writers *erythema mercuriale*, and hydrargyria, as we shall take occasion to notice under syphilis.

In the syphilitic or arthritic affection, however, a particular attention must be paid to the primary disease, since otherwise no local remedies can be of any avail.

Inflammation of the internal coats of the eye is a disease that has generally been overlooked by writers, and scarcely discriminated by practitioners. We have seen, that inflammation commencing in the iris, may extend to the internal coats of the organ, and even to the whole of the eyeball; but sometimes those coats become primarily inflamed.

The leading symptoms of the first stage are, a dull, deep-seated pain in the organ, aggravated by light, or exertion of the eye; impaired vision; with originally, and often throughout, but little external redness. The pain soon extends to the brow, occiput, and other parts of the head. The pupil may be either rather contracted, with a quick motion of the iris, or somewhat dilated, with sluggish motion of the latter part. The former, according to Mr.

Lawrence, is the earlier state, denoting excitement of the retina; the latter a later condition, indicating more advanced changes, attended with loss of sensibility in the nervous structure. The disorder is accompanied with febrile symptoms. As the disease proceeds, more sclerotic redness shows itself round the cornea; the iris changes colour and expands; and the sight becomes weaker and weaker, and is soon lost; after which misfortune the patient is troubled with various false luminous appearances.

In the second stage the iris closes, and projects in a convex form towards the cornea; and hypopium is produced by the effusion of matter in the anterior chamber. Complete amaurosis, suppurating, and collapse of the eyeball, and closure of the pupil, are the result of bad cases.

Greatly impaired vision, produced quickly, with pupil still clear, and not much contracted, Mr. Lawrence says, may be restored; but if sight should have been totally lost before the pupil has closed, or, if that opening be much contracted, and vision gone, there is no hope.

The treatment should be antiphlogistic, and followed up by the prompt and free use of mercury, combined with the local employment of belladonna. Bleeding and other antiphlogistic means may check the inflammation; but, unassisted by mercury, they are not adequate to prevent those changes in the retina which lead to blindness.

SPECIES IV.

OPHTHALMIA STAPHYLOMA. PROTUBERANT EYE.

PROTUBERANCE AND PARTIAL OR COMPLETE OPAcity OF THE CORNEA; OR AN UNNATURAL PROTUBERANT STATE OF SOME PART OR PARTS OF THE SCLEROTIC COAT; SIGHT ABOLISHED OR IMPAIRED.

THE term STAPHYLOMA is derived from *σταφύλη*, "*uva*," a *grape*, from the resemblance of the tumour of the cornea to the pulpy and semi-transparent appearance of this fruit. [The expression, *protuberant eye*, adopted by the author, is not precisely applicable, because the eye may be rendered protuberant by various other diseases.

The definition introduces us to the division into two species:—

- a Staphyloma corneæ. Staphyloma of the cornea.
- β Staphyloma tunicæ scleroticæ. Staphyloma of the sclerotic coat of the eye.

The term *staphyloma corneæ* is applied to a projecting and opaque state of this part of the eye. The whole of the cornea may be involved in the unnatural protuberance, or only a portion of it may be concerned. Hence, the varieties of *staphyloma totale*, and *staphyloma partiale*. In the first case, sight is in general completely lost; the cornea opaque; and the axis of the eye greatly lengthened; but, in the partial staphyloma, if it does not cover a large portion of the pupil, a considerable degree of vision may remain. When the disease em-

braces the whole pupil, or is accompanied with general opacity, sight is altogether destroyed. The protuberance of the eye interferes with the closure of the eyelids, by the friction of which against the forepart of the eyeball, and by the exposure of the organ to the atmospheric irritation, frequent attacks of pain and ophthalmia are excited, and even the other eye becomes weak and irritable.

Staphyloma of the cornea is mostly preceded by severe inflammation of the eye, particularly such as produces sloughing ulceration, and a consequently weakened state of the texture of the cornea, disposing it to yield to the distention of the contents of the eyeball. The case is likewise attended with an increased accumulation of the aqueous humour; to which circumstance, indeed, some writers mainly refer the origin of the disease. The irritation has often a sympathetic influence on the other eye, rendering it weak, irritable, and even inflamed.

The treatment is either palliative or radical. The palliative consists in the removal of the inflammation by antiphlogistic treatment, or by diminishing the volume of the swelling by puncturing the cornea with a cataract-needle, and letting out the aqueous humour. The repetition of this plan has even sometimes led to a radical cure; the protuberance permanently subsiding, and the eye becoming quiet. But, if the patient continue to suffer severely from frequent returns of inflammation, and especially if the other eye should be affected by sympathy, the radical treatment becomes indispensable. It consists in cutting away the staphylomatous protuberance with a common cataract-knife.

When the inner coats of the eye are the seat of considerable inflammation, it sometimes happens that the disorder so weakens and thins certain points of the sclerotic coat, that they afterward yield to the distention of the contents of the eyeball, and bulge or project in a greater or lesser degree, and the protuberance is either single, or more or less multiplied. The disease is particularly apt to occur in that part of the sclerotic coat which is near the ciliary body. The case is invariably accompanied with total loss of sight.

SPECIES V.

OPHTHALMIA ECTROPIUM. EVERTED EYELID.

EYE WEAK AND WEEPING, WITH SLIGHT BUT CHRONIC INFLAMMATION; TARSUS THICKENED AND RETRACTED, WITH A PERMANENT REDNESS ON ITS VERGE.

THIS species is usually a relic or sequel of some form of ophthalmia, in consequence of ill treatment or neglect.* [The eversion may be either temporary or permanent. The former is common in the purulent ophthalmia of children, and other inflammations, in which the conjunc-

* Vetch, on Diseases of the Eye, 8vo., 1820. It may likewise accompany chemosis and also most stages of ophthalmia: our author's definition, therefore, is not unobjectionable.—Ed.

tiva is much swelled. The eyelid in these cases may be easily restored to its proper position again by the manual assistance of the surgeon, and, indeed, the part generally rectifies itself, as soon as the child ceases to cry.] Ectropium may be contemplated under two varieties: or, according to Scarpa, two species:—

- α Lippitudo. The ciliary edge red, thickened, and highly irritable; the retraction simple; conjunctiva unexposed.
 Blear-eye.
- β Nudum. The upper or lower tarsus completely everted, the conjunctiva exposed and turgid, with red vessels.
 Naked ectropium.

The bloodvessels visible in that part of the conjunctiva which covers the inside of the eyelids, are far more numerous than those observable in that part of it which covers the globe of the eye. And hence, in various species of ophthalmia, the interior of the eyelid is peculiarly apt to become turgid, and very highly inflamed; and, from turgescence, thickens at its edges, and is often so considerably everted as to expose a very large portion of the conjunctiva. And if these effects of inflammation be not duly attended to, both the thickening and eversion are apt to remain and become permanent; nor is this all, for the exquisitely tender membrane of the eyelid, constantly exposed to irritation from cold, sharp winds, dust, a strong light, and excoriating tears, increases in tenderness, is never free from some degree of inflammation, and at length becomes highly vascular, florid, fleshy, and carunculate (*ectropium sarcomatosum*), and exhibits a very hideous deformity; the everted eyelid sometimes becoming adherent to the cheek. [The frequent occurrence of ectropium in the lower eyelid as the result of lippitudo, is particularly noticed by Mr. Lawrence, who observes, that when the mucous membrane of the eyelid has been long inflamed and thickened, and when the irritating discharge has excoriated the skin, the latter shrinks under the repetition of such attacks, becomes shortened, and draws the margin of the eyelid outwards.]

In the commencement of the BLEAR-EYE, or vascular turgescence, the vessels should be scarified with a lancet; and it will be sometimes expedient to repeat the plan several times; for the operation itself produces a new and more healthy action, and gives a disposition to contractility. The edge and interior of the thickened tarsus should then be attacked with gentle stimulants and astringents; as a solution of alum, zinc, lead, or camphire; or applications of the best brandy, vinum opii, or the nitric oxyde of mercury, in the form of the college ointment. [The treatment recommended by Mr. Lawrence, consists in freely applying the red precipitate ointment to the thickened and everted conjunctival surface, as well as to the ciliary margin of the eyelid. It reduces the swelling of the conjunctiva, and rectifies the secretion of the tarsal glands. In this way, he says, ectropium may often be re-

movcd, even when accompanied with much thickening of the conjunctiva. If the latter affection do not yield readily, the part may be lightly touched with nitrate of silver. The shrinking thus produced on the internal surface of the conjunctiva, draws the edge of the eyelid into its natural situation. When the case is more obstinate, and resists the foregoing plans, the excision of the surface of the thickened membrane is to be performed, after which, in proportion as the wound heals, the eyelid is drawn into its right position again.]

The SECOND VARIETY, or EVERTED EYELID, when of long standing, is accompanied with a hard or horny cicatrix [and frequently with such a change in the figure of the tarsus, in consequence of its having been long in a stretched state, that, even if the eyelid were replaced, it would not properly adapt itself to the convexity of the globe]. In such cases, the only cure seems to be that recommended by Sir William Adams, of cutting out, with a pair of scissors, a strip of the tarsus in the form of the letter V; afterward separating the eyelid from the cheek whenever it adheres to it; and, finally, supporting the lid, now raised into its proper place, and confining the edges of the cut eyelid, brought into a state of juxtaposition, by a proper bandage.—(*Pract. Obs. on Ectropium, &c.*, chap. i.) The divided edges heal by the first intention; and the cure is often completed in a fortnight, with a restoration of the eyelid to its healthy form.

Sir W. Adams recommended the same process for the simpler and earlier stages of everted eyelid, or where there is no hard or horny cicatrix, but a morbid turgescence of the internal membrane of the eyelid, often accompanied with granulations; yet, as Mr. Guthrie has given ample evidence, after Beer (*Lehre von den Augenkrankheiten*, band ii., p. 144, Wien, 1817), in both these cases, a skilful application of a very small portion of sulphuric acid to the internal conjunctiva, upon the end of a probe, will of itself suffice to effect a cure, will destroy the minute caruncles, and produce almost any degree of contraction throughout the extent of the eyelid, even to that of an inversion of the ciliary edge, if carried too far (*Operative Surg. of the Eye, &c.*, p. 56, 8vo., Lond., 1823), the operation just noticed should, perhaps, always be reserved for the examples above specified.

SPECIES VI.

OPHTHALMIA ENTROPIUM.

INVERTED EYELID.

TARSUS DRAWN INWARD; CILIARY HAIRS BENT AGAINST THE CONJUNCTIVA; AND PERMANENTLY IRRITATING AND INFLAMING THE EYE.

This disease is sometimes known by the name of trichiasis. The evil it produces is the reverse of that just described, and consists in an internal traction of the tarsus above or below, in consequence of which a perpetual irritation is produced in the conjunctiva, by the friction of the hairs of the eyelid, thus thrown

out of their natural line of growth. The inflammation is in time communicated to the cornea, which becomes opaque, and is frequently ulcerated. When the disease has acquired a chronic state, the integuments appear redder than usual, the eyelid is thickened, the conjunctiva is contracted at its commissures, and the tarsus assumes an unnatural curvature.

[Entropium may be either temporary or permanent; partial or complete. According to Mr. Lawrence's interesting description, temporary inversion, particularly that of the lower eyelid, is apt to occur in chronic external ophthalmia, and sometimes even in acute cases. Permanent ectropium may happen from two causes: there is frequently, in elderly persons, a relaxation of the integuments; the skin of the eyelid loses its elasticity; falls into wrinkles; the fat is absorbed from the surrounding parts; and thus loose folds are formed in it. The balance between the external surface and the mucous lining of the eyelid is lost, and inversion is the consequence. In another form of the disease, the cause is seated in the tarsus and mucous lining of the eyelid; these parts being corrugated and shortened in consequence of repeated chronic ophthalmia. The temporary ectropium may generally be remedied by putting a small compress against the lower portion of the eyelid, and retaining it there for twelve or twenty-four hours, by a strip or two of sticking-plaster, after which time the disease will not return.]

Various plans have been devised for the cure of the permanent form of the defect from the time of Celsus, or rather of Hippocrates. Of these the chief have consisted in a careful attention to remove, and, if possible, prevent the future growth of hairs, either by pulling them out, or destroying their roots with sulphuric acid; a removal of a fold of the skin, and producing an artificial retraction by drawing the extremities of the wound together by sutures or strips of adhesive plaster, as recommended by Scarpa; the plan of destroying a similar portion of skin with caustic, or concentrated sulphuric acid; and, lastly, an entire removal of the edge of the eyelid, including the cilia, as proposed by Jäger, and since performed with little variation by Mr. Saunders.

Of these methods, the first, which is the simplest, rarely, if ever, as Beer has justly observed, produces a permanent cure; [the second and third answer very well in ordinary cases; but the fourth is peculiarly unsightly in the issue.

When the tarsus is permanently shortened and corrugated, common methods sometimes fail, in which event either Mr. Crampton's plan may be followed, or the modification of it adopted by Mr. Guthrie.] Its principle consists in taking off all contraction, by slitting up the eyelid at each angle, and then producing a sufficient degree of permanent retraction, by taking away a small slip of the affected tarsus as near the edge as may be, and afterward uniting the margins of the wound, as already noticed, by small sutures, the threads of which are to be fastened with sticking-plaster to the

eyebrow, so as to keep the edge of the eyelid duly everted, till the sutures are removed.*

GENUS IX. CATARRHUS. CATARRH.

INFLAMMATION OF THE MUCOUS MEMBRANE OF THE FAUCES, OFTEN EXTENDING TO THE BRONCHIA, AND FRONTAL SINUSES; INFARCTION OF THE NOSTRILS; SNEEZING; AND, FOR THE MOST PART, A MUCOUS EXPECTORATION, OR DISCHARGE FROM THE NOSE.

CATARRH is a Greek compound, and imports "defluxion;" from *κατὰ*, denoting, as stated in the table of significations to the affixes and suffixes of medical terms in the Nosology, "augmented action," and *ῥέω*, "to flow." Catarrhus, however, like ophthalmia, has been used in various senses and latitudes by different authors. The old pathologists distinguished between three separate terms, which are now regarded by many writers as synonymous:

"Si fluit ad pectus, dicatur rheuma CATARRHUS; Ad fauces, BRONCHUS; ad nares, esto CORYZA."

This couplet is, perhaps, founded upon Galen's account of these affections.

Sauvages has only deviated from the rule contained in the above Latin couplet, by omitting bronchus and employing catarrhus in its stead, and rheuma in the stead of catarrhus; so that with him RHEUMA imports a cold, or febrile defluxion of the chest; CATARRHUS, the same affection of the fauces, and adjoining organs; and CORYZA, the same malady of the head or nostrils.

Cullen has regarded rheuma, coryza, bronchus, and catarrhus as synonymous terms, scarcely indicating varieties of the same disease. The arrangement of Dr. Cullen, moreover, did not allow him to place *bex*, *tussis*, or cough, anywhere else; and, being obliged to yield to the force of necessity, he has made cough also a synonyme of catarrh, and has treated of it under this genus. It is here the present system differs from Dr. Cullen, as it does likewise in separating coryza from the list of phlogotic affections. Cough is not necessarily a pyretic or inflammatory disease, though it may be occasionally a symptom of such disease. Cough, therefore, under the Greek term *bex*, we have already considered, as well as CORYZA, under the second or PNEUMATIC class; where they will probably be allowed by most nosologists to occupy more correct and natural posts, than in the present place. Catarrh, thus explained, embraces the two following species:—

1. Communis. Cold in the Head or Chest.
2. Epidemicus. Influenza.

Under neither of these species can catarrh be regarded as a dangerous or very serious dis-

* Operative Surgery of the Eye, &c., p. 33, 8vo., Lond., 1823. Quadri, *Annotazione pratiche sulle Malattie degli Occhi*, Napoli, 1819. Travers, *Synopsis of the Diseases of the Eye*, 1810. Becr, *Lehre, &c.*, ut supra.

order, unless neglected or treated improperly; or it occur with great severity in persons of delicate lungs, or possessing a consumptive diathesis; in all which cases its result may be very mischievous, and lead on either to pneumonitis, bronchlemitis, phthisis, or dropsy of the chest, though in itself, and separate from such concomitants, by no means alarming.

SPECIES I.

CATARRHUS COMMUNIS.

COLD IN THE HEAD OR CHEST.

FEVER SLIGHT; MUCOUS DISCHARGE CONSIDERABLE.

THIS is the *pose* of old English writers, a term precisely synonymous with the *gravado* of Celsus, which is also employed in the earlier medical works of our own country. To *pose* is still used in the sense of to stupify, and the real meaning of *posy* is a "narcotic charm," and hence a nosegay of tranquillizing odour inducing repose or sleep. The common symptoms of this species are a sense of fulness in the head, and of weight over the eyes, which are inflamed and lachrymose. The nostrils are obstructed, and pour forth a thick acrimonious ichor, which excoriates the skin as it descends, accompanied with frequent sneezing. The voice is hoarse, the fauces sore, and the lungs loaded, often producing a troublesome cough.

Its usual cause is suppressed perspiration from cold; whence Dr. Cullen conceives, that cold is the constant and only cause, and would in every case be detected to be such, were men acquainted with, and attentive to, the circumstances which determine cold to act upon the body.

From the similarity between the fluid exhaled from the skin and that from the lungs, he conceives that, whenever the former secretion is obstructed in its flow, it is transferred to, and passes off with the latter; the cough being produced by the stimulus of the increased action, and exhalation.

There seems, however, to be, in many cases at least, something more than this; for neither cold nor suppressed perspiration will account for every instance of common catarrh. There are few practitioners, perhaps, but have sometimes known persons thus affected who have been bedridden from chronic lameness or some other cause, and have had their chamber warmed night and day by a fire. Some ladies always catch a cold in the head on quitting the town for the country; and others on quitting the country for the town. Something must therefore depend on the actual state of the constitution at the moment; and something upon the variable quality of the atmosphere; and a change in both frequently perhaps concurs in producing the affection of a common catarrh.

Where the attack is slight, medical aid is not often sought for or needed. A few days of domestic repose in a warm but not a close atmosphere, diluent drinks, with an abstinence from animal food, and vinous or other fermented

liquors, a sudorific posset at night, with an additional blanket thrown over the bed to encourage perspiration, usually succeed in carrying off the complaint. But if there be a sense of oppression on the chest, or of fulness in the head, with the ordinary signs of fever, constituting what is often called pulmonary catarrh, the bronchitis of Dr. Badham, venesection should be had recourse to, and a smart purgative immediately afterward, while the preceding process is still continued. If the cough should be troublesome at night, it will be best allayed by a dose of Dover's powder, which will take off the irritation, and determine to the surface.*

Catarrh is also found, occasionally, as a symptom in measles, smallpox, worms, dentition, and rheumatism.

SPECIES II.

'CATARRHUS EPIDEMICUS.

INFLUENZA.

THE ATTACK SUDDEN; GREAT HEAVINESS OVER THE EYES; FEVER STRIKINGLY DEPRESSIVE; EPIDEMIC.

THIS species differs chiefly from the preceding in the abruptness of its incursion, the severity of its symptoms, and very generally in the rapidity of its transition. It probably also differs in the nature of its remote cause.

It commences, according to Dr. J. C. Smith, who has accurately given us its progress as it appeared in 1781 and 1782, with the usual catarrhal symptoms, in conjunction with others that are far more distressing to the patient, and often not less alarming to the physician; such as great languor, lowness and oppression at the præcordia, anxiety, with frequent sighing, sickness, and violent headache. The pulse is peculiarly quick and irregular, and at night there is often delirium. The heat of the body is seldom considerable, particularly when compared with the violence of the other symptoms; the skin is moist, with a tendency to profuse sweating; the tongue moist, but white or yellowish. Sometimes there are severe muscular pains, general or local; at other times, erysipelatous patches or efflorescences on different parts of the body, which, in a few rare instances, have terminated in gangrene and death. From the onset, for the first twenty-four or forty-eight hours, the symptoms are extremely violent, far beyond the danger or duration of the distemper. For the most part, it attacks the healthy and robust; children and old people either escape entirely, or are affected in a slighter manner.†

* Dr. Corrigan believes that there are two species of catarrh; one not extending its effects to the bronchia, and curable by camphire mixture and opium in twenty-four hours; the other affecting the bronchial tubes, and demanding the same treatment as bronchitis.—See Dublin Journ. of Med. and Chymical Science, No. i.—Ed.

† In the influenza of particular years, the mortality has been chiefly in children and aged individuals. The last visitation of this disorder in London proved fatal to a great number of old persons.—Ed.

Pregnant women, however, are disposed to miscarry, and the flooding is in some cases fatal. Patients, also, subject to pulmonic complaints, suffer much from the cough, difficulty of breathing, and other peripneumonic symptoms, which occasionally lead on to dissolution.—(*Med. Communications*, vol. i., p. 71.)

Such is the general progress of influenza in most of the periods in which it has shown itself. But, in every period, its symptoms have considerably varied in severity in different individuals. In many instances, they have scarcely exceeded the signs of a common cold; in others, the pleuritic pain has been very acute, or the headache intolerable, shooting up to the vertex with a sense of splitting; the pulse has been a hundred and forty, and often considerably more, in a minute, with incoherency or delirium from the first night. Yet cases of real danger are very few; and the violence of the disease is over frequently in forty-eight hours; sometimes in twenty-four. Those who have suffered appear to be insusceptible of a second attack during the continuance of the epidemic, though they have no indemnity against the next that may appear. In many cases, however, the general debility, induced on the system, does not terminate with the catarrh itself, but remains for weeks, perhaps for months, afterward, and is sometimes removed with great difficulty.

The disease has been known and described from the time of Hippocrates* to the present day; and is dwelt upon at great length by Sydenham, who regarded it in the autumn of 1675 as a general cough, produced by cold and moist weather, grafted upon the autumnal epidemic, and varying its symptoms; whence the fever, which had hitherto chiefly attacked the head or the bowels, now transferred its violence to the thorax, and excited symptoms which had often a semblance to those of genuine pleuritis, but in reality were not so, and demanded a different and less evacuant treatment, the patient being uniformly made worse by copious and repeated bleedings; though a single moderate venesection was often useful, and, in a few instances, a second: beyond which Sydenham always found it mischievous to proceed. And in proof that this was the real nature of the case, he observes, that "these catarrhs and coughs continued to

the end of November, after which they abated, but the fever still remained the same as it was before the catarrhs appeared;" meaning that it then returned to its essential character: "although," he continues, "it was neither quite so epidemic, nor accompanied with quite the same symptoms; since these incidentally depended upon the catarrhs."

Influenza, however, as we shall have occasion to show presently, has not only occurred in the autumn, but in every season of the year, whether hot, cold, damp, or temperate; and when there has been apparently no other constitutional distemper with which it could unite itself. The chief returns of the disease which have been remarked in this country since the above of Sydenham, are those of 1732, 1762, 1775, 1782, 1803, and 1831: the duration of the epidemic was in every instance from a month to six weeks. That the disease is an epidemic, cannot be doubted for a moment: yet this is to advance but a very little way towards a knowledge of its origin or remote cause; for we have still to inquire into the nature of epidemics, their sources, diversities, and means of diffusion; often, as in the case of spasmodic cholera, in the very teeth of periodical winds and other meteorological phenomena that we might fairly conclude, if we did not know the contrary, would irresistibly oppose their progress, or disintegrate their principles, and consequently abolish their power.* Dr. Sydenham, with the modesty which peculiarly belongs to himself, and always characterizes real knowledge, freely confesses his ignorance upon the subject, though he is rather disposed to ascribe them to "some occult and inexplicable changes wrought in the bowels of the earth itself, by which the atmosphere becomes contaminated with certain effluvia, which predispose the bodies of men to some form or other of disease;" while Hippocrates, who had pursued the same recondite subject with an equally indefatigable spirit upwards of two thousand years before, resolves them, with a devotional feeling which would do honour to the philosophy of the present day, but which the philosophy of the present day has not always evinced, into a present divinity, a providential interposition; for such, as Galen informs us, is the actual meaning of his *TO ΘΕΙΟΝ* (*De Prognos.*, lib. i.), and not some unknown and latent physical principle of the atmosphere, as various expositors have conceived:—"non enim quæcunque causas habent incognitas et abditas DIVINA vocamus; sed ubi admirabilia videntur duntaxat."—(*Comment. in Progn. Hipp.*)

An epidemic, however, or state of the atmosphere capable of producing any general disorder, whether originating specially or in the ordinary course of nature, may depend upon an intemperament, or inharmonious combination of the elementary principles of which it consists, or upon some foreign principle accidentally combined with it, and which has of late years more

* This statement is at variance with other accounts of the subject: thus, in the *Cyclop. of Pract. Med.*, it is alleged, that we find no medical description of the epidemic catarrhal fever before the year 1510. "It was called coccoluche, because the sick wore a cap close over their heads." Schenck observes, that physicians then looked upon it as a new disease. Its course seems to have been in a N. W. direction from Malta to Sicily, Spain, Italy, Germany, France, and Britain; and Short says, that "it attacked at once, and raged over all Europe, not missing a family, and scarce a person, and that none died except some children. In some it went off with a looseness; in others, by sweating."—(See Short's *Chronol. Hist. of the Weather*, &c., vol. i., p. 204; and *Dict. des Sc. Méd.*, art. *GRIPPE*.) Tozzetti's *Cronica Meteorologica Toscana*, a work referred to by Cullen in relation to influenza, was published, however, in 1323.—Ed.

* Like cholera, the influenza has also generally extended itself from the east towards the west, and from the south towards the north; which is a curious coincidence.—Ed.

especially been called a miasm or contamination. It is possible, that both these may be causes of different diseases; and, in this case, the term epidemic might be more correctly limited to those which issue from the first cause than from the second: and Dr. Hosack has endeavoured thus to limit it. But as it is rarely that we can distinguish between the two, and especially as the term has been very generally applied to diseases arising from both sources, it is not worth while to alter its common signification.

In the disease before us, many writers have endeavoured to trace it to the first of the above causes, and particularly to the atmosphere's being in a state of negative electricity; and Weber, fully confiding in this cause, has recommended, somewhat whimsically, the use of socks made of the most powerful non-conductors, as oiled silk, or paper covered with sealing-wax, as a certain prophylactic.—(*Rahn, Briefwechsel mit seinen ehemaligen Schülern*, band. ii., Zürich, 8vo., 1787.) Others, without undertaking to determine in what the atmospheric temperament consists, have regarded it as a mere exciting cause of catarrhs, or, in other words, as merely rendering the body more susceptible of the ordinary causes of this disease, and hence converting a sporadic into a general distemper.

More commonly, however, catarrh, as well as other epidemics, has in modern times been contemplated as dependant upon the second of the aerial causes just adverted to, namely, the existence of a specific miasm, or morbid principle of a peculiar kind, in the atmosphere, distinct from any change in the combination of its proper elements;* and hence, Professor Frank (Op. cit., p. 118-19), after adverting to the "in ambiente nos aëre mutatio," adds, "non sine magnâ latentis contagii suspitione." There is much, indeed, to support this opinion; for in many cases, as in intermittent and remittent fevers, we can manifestly trace such an origin; and, as we have already shown that contagions and miasms are often identic or nearly so, the former may be brought forward as abundantly confirming the same view.

This identity, or approach to identity, between contagions and miasms, is closely connected with the present subject, and must be a little examined into for its clear elucidation.

In treating of the origin and laws of febrile miasm we observed, that it is of two distinct modifications, or proceeds from two distinct sources; that, in its ordinary course, it first appears as the result of a decomposition of dead organized matter, operated upon by the common auxiliaries of putrefaction; but that afterward, "during the action of the fever thus produced, the effluvia from the living body is loaded with miasm of the same kind, completely elaborated as it passes off, and standing in no need of the decomposition of the effluvia for its formation;

under which form it is commonly known by the name of contagion."

I may now add, that, as primary febrile miasm is not the only miasm generated in the atmosphere, so it does not seem to be the only miasm that gives rise to contagion: that both are very numerous in their kinds, and that specific contagions are, though perhaps not always, yet far most generally, a result of specific miasm produced as above. This seems especially to be the case in respect to influenza; for though most individuals labouring under it are evidently affected from an atmospheric taint, many, as we shall show presently, appear, as in the case of remittent or typhus fever, to receive it from personal contagion: nor is there, in fact, any reason why a puriform discharge from the mucous membrane of the nostrils may not be contagious, as well as a puriform discharge from the mucous membrane of the eyelids in ophthalmia, or from the urethra in blenorrhœa, or, as we shall shortly have to notice, from the rectum in dysentery. Among dogs and horses we perceive the same disease, in many instances highly and extensively contagious, and accompanied with so violent a degree of fever as to be peculiarly dangerous, especially to the young of these kinds. In South America, in particular, this affection is so violent, that half the dogs pupped there are supposed to die of it while sucklings. Whence, in common language, it is called emphatically the *distemper*, though vulgarly, the *snuffles*, or rather *snuffles*, from the state of the nostrils. In nosology, it is commonly called *catarrhus caninus*.

Generally speaking, specific miasms and contagions, capable of affecting one kind of animals, are incapable of affecting any other kind; or, at least, rarely extend their influence any farther. In a few febrile pestilences, quadrupeds and birds seem to have been fellow-sufferers with mankind, as we have already had occasion to notice under EPANETUS MALIGNUS, or malignant remittent fever. But this is not common; and, in some instances, is well known to have depended upon the general dearth of a country, or the insalubrity of the preceding harvest. A few of the exanthems, as cowpox, are capable of propagation from one species to another; but the greater number of them are not, or only with great difficulty. When a putrid fever has broken out among a ship's crew, the live stock has never been known to suffer from it: and it has happened occasionally, when large numbers of sheep and hogs have been stowed in a ship for the purpose of exportation, sometimes the former have been attacked with infectious fever, and sometimes the latter; but the sheep have never communicated it to the hogs, nor the hogs to the sheep, nor either of them to the ship's crew. "It seems to be a general law of nature," observes Sir Gilbert Blane, "at least among the mammalia, that accumulation and stagnation of the exhalations of the living body produce disease. The glands of horses arise only in large stables, and the distemper of dogs in kennels. During the American war, it was proposed to send live sheep from England across the Atlan-

* See especially De Merten, *Observ. Med.*, tom. ii., p. 4; and Simmons, *Lond. Med. Journal*, 1788, part iv.

tic. In a few weeks, in consequence of being crowded in a ship, they all died of a febrile disorder."—"In the expedition to Quiberon in 1795, several horse-transports had their hatches shut for a length of time in a storm, by which means eight horses were suffocated. Those which survived became affected with the glanders soon after they landed. Professor Colman saw twenty of them under this disorder; a considerable number had been previously destroyed."—(*Med.-Chirurg. Trans.*, vol. iv., p. 89, 475.) It does not appear, that, in either of these instances, the respective disorders were communicated from one genus or species of animals to another.

That the catarrh before us possesses not only an epidemic character, but is dependant on atmospheric influence, is established by so many well-known proofs, that it is hardly worth while to give examples. Of a dozen persons in perfect health in the same room, ten have often been attacked as nearly as possible at the same time. In the influenza of 1782, three families, consisting of seventeen persons, arrived on the same day at a hotel in the Adelphi, all in perfect health. The next day they were all affected with the symptoms of the reigning disease.—(*Med. Trans.*, vol. iii., p. 59.) In an hospital containing a hundred and seventy persons, more than a hundred were on one occasion attacked within twenty-four hours; and few of the remainder escaped afterward.

We have said, however, that the middle-aged, the strong, and the robust, are affected soonest, and suffer most severely, while the young and the old are less susceptible of its influence. In proof of this we may advert to the fact, that healthy and well-disciplined soldiers suffer peculiarly. In 1782, this was especially the case at Aberdeen: at Dublin, there were, at the same period, seven hundred soldiers confined under it in their barracks at once, and incapable of doing their duty (*Dr. Hamilton, Mem. Med. Soc. of Lond.*, 1782); while at Utrecht, the number amounted to not less than three thousand. On the contrary, out of seven hundred boys in Christ's Hospital, during the same epidemic, only fourteen had the disease, and all of them in the slightest manner.*

The proofs of communication by personal contagion are not less decisive. "The first," says Dr. Hamilton, describing the influenza of 1782, "who were seized with it at Norwich were two men lately arrived from London, where it then continued to rage. A sergeant of grenadiers in the 10th regiment of foot went to London on furlough: the disease then raged in the capital. He returned in a few days to St. Albans, affected, and communicated it to the people in whose house he had his billet. This was the first of its appearance there, and from thence it spread rapidly all over the town."†

* *Med. Trans.*, vol. iii., p. 56. It has been already noticed, that when the influenza visited this country in the spring of 1833, old persons suffered with peculiar severity, so that many of them were cut off.—Ed.

† *Mem. Med. Soc. of Lond.*, ut *suprà*. The

Dr. Cullen in his Synopsis has followed the more striking returns of influenza, from the fourteenth century down to the present times; or rather from the Cronica Meteorologica Toscana of 1323, by Targioni Tozzetti, to Saillant's Tableau des Epidémies Catarrhales. "In all these instances," says he, "the phenomena have been much the same: and the disease has always been particularly remarkable in this, that it has been the most widely and generally spreading epidemic known. It has seldom appeared in any one country of Europe, without appearing successively in every other part of it." And, in some instances, the infection has passed the Atlantic with little or no remission of its severity, and attacked Americans who had not had the slightest intercourse with Europeans.

And hence we are capable of tracing it at sea as well as on land. In the epidemic of 1782, Lord Howe sailed in the month of May with a fleet for the Dutch coast; and Admiral Kempenfelt for that of France. The crews of both fleets were, well on sailing: but, in the same month, both were attacked very generally, and the latter was obliged to return home. The previous state of the air, with respect to any of the sensible qualities of heat, cold, electricity, or damp, seems to have exercised but little power. Influenzas, as already observed, have recurred at every different season, in every state of the barometer, thermometer, and hydrometer.

Thus the influenza of 1762, one of the severest on record, producing effects which continued, in many instances, for two or three years afterward, was preceded by weather uncommonly warm; while in that of 1767, being the next in rotation, which was also very severe, though productive of less durable mischief to the constitution, the weather was remarkable for being unusually cold.—(*Dr. Heberden, Med. Transact.*, i., art. xviii.) We know nothing of the country from which the disease has at any time taken its rise; but it has frequently seemed to proceed from north to south, though it has occasionally travelled from west to east. That of 1781 and 1782 is said to have originated in China, and to have travelled through Asia into Europe; whence it crossed the Atlantic, and arrived the ensuing year in America. But this assertion wants confirmation. If we allow its materies to depend upon specific miasm floating in the atmosphere, we can only account for its preserving its agency so long, and operating in such distant theatres, by supposing that its particles are with great difficulty dissolved or decomposed in the air, even when in its purest state or highest degree of agitation by tempest. Of the specific miasms we are a little acquainted with, some seem to dissolve or lose their power

opinion on this point, delivered by the author of the art. INFLUENZA in the Cyclop. of Pract. Med., is, that the disorder generally arises from, and is propagated by, some general cause, subsisting in the atmosphere; "but that it is probable a limited propagation also takes place, by personal intercourse, under the influence, and during the prevalence, of the epidemic constitution."—Ed.

much more readily than others, and hence spread their influence through very confined peripheries; while others are only dissoluble in a pure atmosphere, and consequently retain all their virulence in an air already saturated with other foreign elements.

The chief influenzas that have visited Europe within the last three centuries, occurred in the following order of time:—1510; 1557; 1580; 1587; 1591; 1675; 1709; 1732-3; 1743; 1762; 1767; 1775; 1781 and 1782; since which period, the return of the disease has been little noticed in respect to extent or violence.*

The remedial treatment needs not detain us long, notwithstanding the violence with which the disease makes its assault. Bleeding, as we have already observed, is rarely required, and, from the debility so soon induced, should be avoided, except in urgent pleuritic pains, which are not common. It was tried copiously by many practitioners in 1782, but they soon reverted to the cautionary track of Sydenham. Quiet, diluent drinks, and the promotion of that easy breathing perspiration which Chenot has distinguished by the name of *diapnoë*, will usually be found sufficient, if the bowels be kept free from confinement.† If the chest be much loaded, an emetic will afford the best relief. And, if the cough be troublesome, and the breathing laborious, both which, however, are generally alleviated by an emetic, small doses of *ipeacacuanha*, with or without *oxymel* of squills, will promote an easy expectoration, and take off the sense of oppression. Dr. Cullen joined these with opium, and was particularly attached to the use of Dover's powder in all catarrhal affections, asserting that there is no disease in which opium has been found more useful.‡ But it generally agrees better in common catarrhs than in influenza. The subsequent debility may be removed by a free use of the bark, gentle exercise, pure air, cold bathing, and a liberal regimen; which last, indeed, should be con-

tinued through the disease itself. The cough occasionally produced remains sometimes as a sequel, long after the other symptoms have disappeared: and, in this case, opium with camphire, or the resinous balsams, or the extract of hemlock, or of hyoscyamus, prepared in a steam-heat, often affords essential relief, and especially at night; yet it has not been found that even the symptom of a cough has proved any impediment to the use of the bark, or even that of cold bathing, or been augmented by the practice, as influenza has rarely terminated in phthisis, and, according to Dr. Carmichael Smith, is less disposed to produce this complaint than a common catarrh.*

GENUS X.

DYSENTERIA.

DYSENTERY. BLOODY FLUX.

INFLAMMATION OF THE MUCOUS MEMBRANE OF THE LARGER INTESTINES; GRIPING AND TENESMUS; FREQUENT AND OFTEN BLOODY DEJECTIONS; THE FECES IRREGULARLY DISCHARGED.

DYSENTERY is far more frequent in the autumnal months than in any other season of the year. The animal frame is at this time generally relaxed and debilitated by a long exposure to the stimulus of a high atmospheric temperature, and, in many cases, to that of the direct rays of the sun. The digestive organs and intestinal canal necessarily partake of this debility, and are more easily irritated and thrown out of the order of health, than at any other time. Hence diarrhœas and colics, and that hepatic flux which by some writers has been regarded, but erroneously, as a variety of dysentery. And hence, also, proper dysentery; which, in a particular state of the intestinal canal, is excited, rather than any of the rest, by causes that are perhaps common to the whole.

These causes may be DIRECT OR SYMPATHETIC: and, as most of these are peculiarly incidental to hot climates, we may readily perceive why dysentery should be more prevalent in them than in other situations.

THE DIRECT CAUSES are chiefly those of diet; and may consist of any sudden application of cold to the stomach very much below its actual temperature, as drinking cold water or eating com-

* The influenza of 1831, which occurred subsequently to the author's decease, was generally mild in its character, though almost universal; for it seems to have appeared in both hemispheres, in India as well as the United States of America. About a month before the epidemic cholera broke out in Warsaw it prevailed in that city, and in the spring and autumn it also swept over great part of England, Scotland, and Ireland. Late in the autumn it attacked Paris, the south of Spain, Gibraltar, and Italy, with more severity than the British Islands.—See art. INFLUENZA, in *Cyclop. of Pract. Med.*—Ed.

† Strong purgatives are generally objected to in cases of influenza, on account of the tendency to a morbid state of the mucous coat of the bowels, usually accompanying the complaint.—Ed.

‡ *Mat. Med.*, part ii., ch. vi. At the commencement of the disease opiates are frequently found hurtful, increasing the febrile heat, aggravating the headache, and stopping the expectoration; but in the decline of the complaint, they may be more advantageously given. Our author has not noticed blisters, which often afford great relief. A solution of gum ammoniac, with oxym. of squills, is in these cases a valuable medicine.—Ed.

* The reader will find much information in regard to the epidemic catarrhs and other diseases which have prevailed extensively in the United States, contained in Webster's *Hist. of Pest. Diseases*, Mitchell and Miller's *N. York Med. Repository*, Coxe's *Phil. Med. Museum*, Chapman on Epidemics, in the *Phil. Journ. of Med. Sc.*, Yandell's *Pennsylvania Journ. of Medicine and the Associate Sciences*, Hosack and Francis's *Am. Med. and Phil. Register*, the *New-England Journal of Medicine and Surgery*, Barton's *Med. and Phys. Journal*, the *Am. Journ. of Med. Sc.*, the works of Dr. Rush, Williams's *History of Vermont*, Belknap's *History of New-Hampshire*, Chalmers on the Weather and Diseases of South Carolina, Ramsay's *History of South Carolina*, Gallup on the Epidemics of Vermont, the Collections of the Mass. Historical Society, &c. &c.—D.

fectionary ices when in a state of considerable heat; eating flatulent herbs, unripe or sub-acid fruits, and especially to excess; or food of little nourishment and difficult of digestion; drinking impure water, and especially when impregnated with the decomposing elements of animal or vegetable substances. In this last case, as well as in one or two of the preceding, the disease is often endemic, and extends to almost every one who is under the influence of such a cause; of which a striking example occurred, not many years ago, among the soldiers stationed in the old barracks at Cork. While the disease was raging with great violence, it was observed by Mr. Bell, the temporary surgeon, that the troops were supplied with water contaminated by an influx from the public sewers, and rendered brackish by an intermixture with the tide. He instantly changed the beverage, and had the barracks supplied by water-casks from a spring called the Lady's Well, when the disease almost immediately ceased.—(*Dr. Cheyne in Dublin Hospital Reports, &c.*, vol. iii., p. 11.)

We meet with various examples of a like kind. Thus Rolander, while residing with Linnæus, was repeatedly attacked with this affection, which he ascribed to drinking stagnant water contained in a cistern of juniper-wood. In this cistern was discovered a species of acarus, which Linnæus, who was fond of resolving almost all diseases into an animalcular origin, immediately regarded as the source of the complaint, and specifically distinguished by the name of *acarus dysentericæ*.—(*Aman. Acad.*, vol. v., p. 82, et alibi.)

The SYMPATHETIC CAUSES are those which operate on the intestines through the medium of other organs, chiefly of the skin or the lungs; as exposure to currents of cold air when the body is heated; wet clothes and wet feet, producing, like the last, a sudden suppression of perspiration. And hence a damp marshy soil, or sudden changes in the atmosphere from hot and dry to cold and moist. And as in the autumnal months we find the bowels apt to be directly affected by water contaminated with peculiar impurities, we have reason to believe that they are also apt to be affected by air contaminated in a particular manner, though we cannot easily trace the specific nature of the taint. And hence the disease assumes an epidemic, as in the former case an endemic range.

But the autumn, which thus peculiarly favours the origin of dysentery and other intestinal affections, gives a like tendency, as we have already seen, to various fevers, and especially to bilious and intermittent. With all these dysentery is particularly disposed to combine, by which the disease is rendered far more complicated; or excites in them a transfer of action, so as to turn aside, in many instances, their regular tenour, and run away with their violence.

When dysentery is accompanied with atonic fever, and a copious discharge of mucous, purulent, bloody, or filmy matter, evidently the result of intestinal ulceration, it is frequently presumed to be contagious; but whether the matter

of contagion is thrown forth from the body of the sick, or from the putrescent recrements, has been a disputed point. But the grand question is, whether dysentery ever exists without contagion! or, in other words, whether, when the disease exists without those virulent symptoms which are deemed indicative of contagion, it is entitled to the name of dysentery?

Dr. Cullen, who, if he did not first start this controversy, has followed it up with a more peremptory opinion than perhaps any other writer, has contended for the negative of the question; and has hence not only arranged the disease under his class PYREXiÆ, but generically distinguished it by his character of PYREXiA *contagiosa*: asserting in his Synopsis that he has never met with more than one species; and still more distinctly in his First Lines, that "the disease is always contagious," and that the contagion is probably at all times specific.—(Part i., book v., chap. ii., sect. MXXXV.)

[On the other hand, Sydenham makes no mention of any contagion attending the epidemic dysentery which he has described; and Willis, who speaks of the same epidemic, expressly asserts that it was not contagious.]

Although Dr. Bateman believed dysentery to be contagious in camps and hospitals, he never found the disease, as it occurs in this metropolis, to partake of this character. He states that the disease was common in London in a sporadic form in the autumn of 1808; yet, that he never once knew it to pass to a second person in any family, while its origin could be often satisfactorily traced to exposure to cold and moisture. He was therefore disposed to consider Cullen's doctrine as erroneous.—(*Rees's Cyclopædia*, art. DYSENTERY.) The epidemic dysentery which prevailed at Glasgow in the autumn of 1827, and which has been described by Mr. Brown, is also stated by that gentleman not to have been infectious.—(*Glasgow Med. Journ.*, vol. i., p. 55.)

Dr. Parr and Dr. Young make a nearer approach to the general opinion of Dr. Cullen, than any other nosologists that I am acquainted with. They regard the disease as an inflammatory affection; but differ from Dr. Cullen, inasmuch as they do not believe it to be essentially and at all times contagious: the former limiting himself to the expression that it is *generally* so; the latter, that it is *often* so.

The earlier nosologists, however, have laid little or no stress on either the pyretic or the contagious character of the disease; and hence in Sauvages, Linnæus, Vogel, Sager, and Macbride, it occurs as a genus under the division, not of fevers, but of fluxes, without any notice of fever or contagion, except as a distinctive symptom in some of their species.

The practitioners in warm climates, and even the monographic and clinical writers of our own country to the present moment, are as little agreed upon the subject of a specific contagion. Pringle, Hunter, Harty, Balfour, and Chisholm, contend strongly for the existence of such a principle; the last of whom asserts that "few diseases are more apt to become contagious."—

(*Climate and Dis. of Trop. Countries*, p. 54, 8vo., 1822.) Johnson, Ballingall, Bamfield, and Dr. L. Frank, either deny it altogether, or have not met with any instance of it in their own practice. [Dr. Renton also, in his description of the dysentery of Madeira, distinctly affirms, that "the disease is certainly not contagious. The lower orders of the inhabitants, its principal victims, live huddled together in close crowded sties; but (says Dr. Renton) I have never seen two cases in the same family at the same time."—(*See Med. Chir. Trans. of Edinburgh*, vol. ii., p. 376.)] So in the late alarming attacks of this disease in Ireland, it was not regarded as contagious at that time at Cork by Dr. Barry (*Dublin Hospital Reports*, &c., vol. iii., p. 10), or at Limerick by Dr. Perston (Id., p. 81): while Dr. Halloran, practising also at Cork (Id., p. 9), observes, that it was obviously contagious on many occasions; Dr. Poole that it was contagious at Waterford (*Dublin Hospital Reports*, &c., vol. iii., p. 7); Mr. Dillon that it was the same at Clonmell (Id., p. 5); and Dr. Cheyne, to whom we are indebted for the best, as well as the most extensive, clinical history of this disease, that it was at Dublin in some cases contagious, and in some not: being decidedly so when connected with continued fever; and uncontagious in its simple form, or when combined with an intermittent. This last opinion harmonizes most with the present author's experience: and especially when the disease has been epidemic or endemic.

This view has the full countenance of another very able and experienced writer of our own day, Dr. O'Brien, of Dublin. He has never found the disease decidedly contagious; but supposes it may become so when the disease is epidemic, and the accompanying fever, in camps or other crowded stations, assumes a malignant or typhous form (*Obs. on the Acute and Chronic Dysentery of Ireland*, &c., Dublin, 1822); being, in effect, the opinion offered concerning it many years ago by Dr. Harty.—(*Obs. on Simple Dysentery and its Combinations*, 8vo.)

In truth, we meet with a like associate process in influenza, from an inflammatory affection and increased secretion in the mucous membrane of the nostrils, instead of in that of the colon: for we have already seen that the disease, at first simply epidemic or atmospheric, at length becomes contagious, and is capable of communicating its like to whatever distance the patient may be removed from the line of tainted atmosphere. And we are hence enabled to enter fully into the following variety of causes, traced out on the spot by Dr. Cheyne in the late extensive call upon the whole of his judgment and talents. "I have analyzed ninety-eight cases. Thirty-three arose during recovery from fever: fifteen while the fever was in progress: fifteen from cold, or cold and wet: four from indigestion. The rest were doubtful: but many had been exposed to febrile contagion, and nine in close communication with patients labouring under dysentery: four had been nurses in wards where the disease had occurred: four

had slept with dysenteric patients, of whom one had used the same night-chair."—(*Medical Report*, &c., p. 18.) We may here readily subscribe to his own language, and say, "it has rarely fallen to the lot of a physician in civil life, possessing all the advantages of books, and of consultation with skilful and experienced colleagues, to witness dysentery upon such a scale."

[In a later paper on the subject, Dr. O'Brien speaks of one of his patients, who supposed that he caught the disease either by lying near another person affected with dysentery, or by using the same night-chair. One other instance occurred, Dr. O'Brien remarks, in which a tolerably strong presumption at least existed of the propagation of the disease by contagion; viz., the case of Kelly, the whole of whose family, amounting to six in number, were attacked in succession. But Dr. O'Brien has met with no other strong or probable instance of the communication of the disease by contagion.*] Dr. Cheyne tells us, that Dr. Prevost, of Geneva, at that time one of the clinical clerks of the Whitworth Hospital, conceived he had contracted the disease he was then labouring under in the dissecting-room, where he spent much of his time hanging over the bodies of those who had died of dysentery.—(*Dublin Hosp. Rep.*, vol. iii., p. 18.)

When the disease has run through its acute stage with great severity, but without destroying the patient, and not unfrequently, perhaps, when it has been something less severe, but unskilfully treated, it assumes a chronic character, exhibits symptoms peculiar to itself, and, as Sydenham observes, will continue to afflict the patient for several years. In this case, the structure of the liver, as well as that of the intestines, is almost always injured. If the lesion be not considerable, the patient may at length recover; but very generally the termination, though protracted, is still fatal. Dr. L. Frank, indeed, regards it as even more fatal than in the acute form.

It is not always that the disease under this shape is a sequel of acute dysentery, and especially among those who have predisposed themselves to it by an antecedent life of intemperance. Dysentery has, on this account, of late years, by many writers, both at home and abroad, been divided as a genus into the two species of acute and chronic, the pyretic form being contemplated as a variety of the acute division:—

1. Dysentery Acuta. Acute Dysentery.
2. ———— Chronica. Chronic Dysentery.

* Trans. of King's and Queen's College of Physicians, vol. v., p. 227, Dublin, 1828. Dr. Elliotson observes, that the sporadic cases which are occasionally met with in this country among persons who have returned from hot climates, are certainly not contagious. Without denying that the disease may be contagious in warm countries, he expresses his belief that it is not so in England.—Lectures at the Lond. Univ., as published in Med. Gaz. for 1833, p. 555.—Ed.

SPECIES I.
DYSENTERIA ACUTA.
ACUTE DYSENTERY.

FECES DISCHARGED WITH DIFFICULTY, MOSTLY IN SMALL QUANTITIES, AND ALTERNATING WITH MUCCOUS OR BLOODY DEJECTIONS; PAIN OR TENDERNESS IN THE ABDOMEN: TERMINATING WITHIN A MONTH.

WE have already observed, that the atmospheric temperaments chiefly calculated to produce severe bowel complaints are those of summer and autumn; when the liver is excited to a larger secretion of perhaps more pungent bile, from the greater heat of the weather; the skin is exposed to more sudden transitions from free to checked perspiration; and the exhalations that rise so abundantly from marshes and other swamps too often give an epidemic character to the atmosphere, and lay a foundation for intermittent and remittent fevers: and we may hence see why dysenteric and other bowel affections, like intermittents, were far more common in our own country about a century ago than they are at present; the soil being more generally drained, and the atmosphere less humid.

We have here also sufficient ground for local and general affection, and may readily see how it is possible, from the operation of one of these causes singly, or of two or all of them jointly on an irritable state of the intestines, for all or any of the local symptoms to be produced which enter into the generic or specific definition of the disease before us; as also how it is possible for these symptoms to be combined with fevers and other disorders of various kinds and various degrees, so as to render the complaint peculiarly complicated and dangerous; though we have not yet been able to find out what are the precise causes, that, operating locally, produce the distinctive symptoms of dysentery, rather than those of diarrhœa, cholera, or any other irritation or spasmodic action of the intestinal canal. This may, perhaps, sometimes depend upon idiosyncrasy, sometimes upon accident, and, in the severer cases, upon contagion or a specific miasm.

The symptoms, however, already noticed, sufficiently point out the general seat of the disease: the tormina or griping pains, the region most affected by them; and the costiveness or nodules of feces that are dejected, the existence of spasmodic constriction in or about the colon, or the upper part of the large intestines. And while such is the state of the canal above, the excessive straining or tenesmus, accompanied with a discharge of simple or bloody mucus, shows as distinctly the existence of great irritation in the sphincter or its vicinity. In some cases, one of these parts is more affected, and in some another: and hence the origin of most of the disputes concerning the precise spot of the disease.

The ordinary exciting cause, however, of acute dysentery, under all its varieties of fixation, there can be little question, is suppressed perspiration, or a sudden chill applied to the surface, acting in conjunction with the predis-

posing cause of an atmosphere varying rapidly from heat to cold, and from moist to dry; but by what means this exciting cause operates upon the larger intestines rather than upon any other cavity, or produces the symptoms of dysentery rather than those of diarrhœa, cholera, or colic, we seem to be incapable of determining. We perceive, however, in the events of every day, that sudden chills on the surface are possessed of a revellent power, and throw the action which is lost on the skin on various internal organs, and especially on cavities of mucous membranes, which, in consequence of this excitement, become inflamed, and pour forth an additional secretion. Such is especially the case in rheumatism and catarrh, both which terms are derived from the same Greek root, and import defluxion. And, from this common character, the three diseases have by some pathologists been conceived to be so much alike, that dysentery has been regarded as an intestinal rheumatism by Cælius Aurelianus, Akenside, Stoll, and Richter; and is actually set down by Dr. Parr as a species of catarrh, in his nosological classification.

We also see why dysentery, like catarrh, may be either sporadic or epidemic; as also why, in each case, it may be either slight, and pass off without any serious evil in a few days, or accompanied with great inflammatory action and continued fever; thus giving rise to the two following varieties:—

- | | |
|--|--|
| <p>α Simplex.
Simple acute dysentery.</p> | <p>Feces often discharged without considerable pain; of a natural quality and affording ease: abdominal tenderness unheeded.</p> |
| <p>β Pyretica.
Pyretic dysentery.
Dysenteric fever</p> | <p>Stools frequent: in every way diversified, both in colour and consistence: severe pain in the abdomen: fever considerable, mostly a synochus.</p> |

• These are the two varieties under which acute dysentery is described by Sydenham, who indeed limits himself almost entirely to these forms of the disease, since, though he notices the second species, or chronic dysentery, he merely glances at it in a kind of postscript to his chapter. Yet his description of both is so accurate, and his general mode of treatment so judicious, that they have received the sanction of the most approved pathologists from his own day to the present.

As the local inflammatory action is more usually traced in the colon than elsewhere, Stoll (*Rat. Med.*, part iii., pp. 294, 326) and various other writers have fixed upon this intestine as its proper seat; and hence Dr. Ballingall has distinguished it by the name of *colonitis*.*

Although, in dysentery, the primary seat of inflammatory action is the intestines, yet the functions of the skin and of the liver are from

* In the *Dict. de Méd.* it is described under the name of *colite*.—See tom. v.—Ed.

the first, as well as throughout the whole course of the disease, considerably disturbed by sympathetic excitement. The liver, however, suffers in many instances, not only on this account, but from a continuous spread of the inflammatory action through the medium of the biliary ducts, and becomes injured in its organization as well as in its function. Some pathologists, as Dr. Chisholm, conceive that they can trace this extension of the inflammatory process to the liver by particular symptoms, as a fixed pain at the stomach, a constant headache, and frequent dejections at the commencement of the disease; and they have consequently given us a distinct division of it, under the name of *hepatic dysentery*. It is sufficiently ascertained, however, that the structure of the liver has been often considerably affected, and even destroyed, when neither these or any other peculiar symptoms have presented themselves; and hence it is a distinction which can be made no use of. A frequency of dejections at the commencement is rather an anomalous fact than a pathognomonic sign: while, as to the other two indications, it is admitted by Dr. Chisholm himself, that they are "apparently not characteristic symptoms;" in other respects, says he, "the disease does not seem to differ from the idiopathic or common dysentery."

Some writers, however, as Piso (*Discours sur la Nature, &c. des Maladies accompagnées de Dysenterie*, 1623) formerly, and Dr. James Johnson in our own day (*Influence of Tropical Climates*, &c., edit. 3, p. 197), have carried this view of the subject considerably farther than my late learned and venerated friend Dr. Chisholm ever intended; for they have boldly reversed the general opinion that has prevailed, and especially since the days of Sydenham, and contended that the liver itself forms in every instance the primary seat of the disease, the intestines being only affected secondarily. Whence the latest of these two distinguished authors has ventured a scoff at the pathology of Sydenham, "who," says he, "it is our firm belief, never examined a dead body after he left his academical studies; at least he has given us no indication of pathological knowledge in any of his works."—(*Med.-Chirurg. Rev.*, March, 1823, p. 830.)

I value Dr. Johnson's friendship, and have an equal value for his talents; but I cannot concur with him in thus tearing from the temples of an illustrious countryman the wreaths of honour he has so deservedly earned, and which have been bestowed on him by our best foreign as well as domestic judges, from Boerhaave and Sauvages, in the middle of the last century, to the younger Frank in the present day. His language, indeed, is tinged with the prevailing errors of the humoral hypothesis, which at that period it was impossible altogether to avoid, and which is again rising into notice in some quarters; but, sifted of this, his pathological doctrines are those of the present day, to which in the main they have given rise; and better stand the test of dissection than those of Dr. Johnson himself. "His observations," says Dr. Bostock, "will be commonly found to be correct, although his

hypotheses are too often fallacious."—(*Physiology*, vol. i., p. 448, 8vo., 1824.) These "observations" teach us, in few words, that dysentery is an inflammatory affection of some part of the larger intestines, which, in its idiopathic and milder state, subsides without serious evil in a few days; but which, occurring in the autumn, is apt to associate itself with whatever febrile epidemic is then prevalent, to become a far more important and complicated malady, and to ravage over a much larger field of organization; the fever aggravating the dysentery, and the dysentery the fever; while, not unfrequently, a metastasis ensues, and the fever is thrown upon the intestinal canal, and expends its violence topically: during which vehemence of action a peccant material (the contagious principle of Dr. Cullen) is elaborated in the constitution and thrown out on the surface. To oppose all which, he lays down a therapeutic plan which evinces an equal degree of judgment; and consists in bleeding, purging, diaphoresis, and opium; in other words, in taking off congestion and inflammatory action, in allaying irritation, and restoring to the circulatory system its proper balance. It may perhaps be said by some modern writers, that he did not always carry these principles far enough. Possibly not in every instance; but this must altogether depend upon the severity of the disease. And we have a proof, in his own success, that he carried them far enough in general; while his great merit consists in the establishment of such principles, and in squaring a correct line of practice to a correct pathology. It may also be objected, that calomel does not appear to have entered into his list of deobstruents. That he did not use it among other *cathartics*, shows evidently that his cathartic catalogue might have been improved; but to have employed it as a *sialagogue*, and to have depended upon curing the disease *almost exclusively*, as his loudest opposers have endeavoured to do, by ptyalism—however valuable such a process may be in a few instances, would not, I fear, have added to his reputation, or increased the number of his followers.

Had the animadversion, indeed, which I have thus felt it my duty to notice, been delayed but a few months, it is most probable that it would not have been advanced at all. For while the learned writer who has made it had already to struggle with perhaps a majority of the most judicious tropical writers, in denying the existence of contagion at all times, and regarding the very opinion as absurd (*Influence of Tropical Climates*, edit. 3, p. 223), he would have found in the admirable treatises on dysentery which have since been furnished us from Ireland, not only that this opinion, as already observed, seems to have a firm foundation under particular circumstances, but that his favourite doctrine, that the liver is the primary seat of the disease, is completely unhinged; as also that his favourite plan of treatment has as little succeeded here as it did in India under Dr. Balingall, or, as Dr. Frank informs us, it did in his hands in Egypt during the occupation of that country by the French army.

The diagnostics of the first variety, or SIMPLE ACUTE DYSENTERY, unaccompanied by the prevailing fever of the season, are thus accurately laid down by Sydenham :—

“But frequently there is no appearance of fever; for the host of gripings take the lead, and the dejections follow. The gripings are always severe, and a sort of painful descent of the bowels accompanies every evacuation. The discharges are chiefly mucus, but an excrementitious stool sometimes intervenes without considerable pain. The mucous stools are generally streaked with blood; but, in some cases, there is no such appearance through the whole course of the disease. Nevertheless, if the stools be frequent, mucous, and accompanied with gripings, the disease may as justly be called a dysentery as if blood were intermixed with them.”

These constitute the ordinary symptoms of the simple variety. And to the same effect Dr. Cheyne :—“When dysentery was unconnected with continued fever, which apparently was often the case, there was nothing peculiar in its origin. The patients generally assigned cold, damp, fatigue, hardships, indigestible food, as the causes of their disease, which began with confinement of the bowels, chills, pyrexia, tormina, unsatisfactory stools, and tenesmus.”—(*Dublin Reports*, vol. iii., p. 18.) It is correctly observed by Dr. Chisholm, that, “when, after the straining has continued for a few days, the stools are intermixed with blood, the blood never thoroughly combines with the slime or mucus so as to produce a uniform colour” (*Climate and Diseases of Tropical Countries*, p. 54), but, as Sydenham observes, “appears distinctly or in streaks.”

It is remarked by several of the practitioners in India, and especially by Mr. Bampfild, that the dejections are more frequent during the night, and especially towards morning, than at any other period of the twenty-four hours: and that the attacks and relapses of the disease are more common at new and full moon, than at any other period of the lunar revolution: and the influence of the heavenly bodies is referred to as the cause of these peculiarities.—(*On Tropical Dysentery*, 8vo., 352, 1819.) The remark does not seem to be sufficiently established.

In its most favourable course, the symptoms gradually subside in a week or ten days, and sometimes even sooner, the skin becoming soft and moist, and the circulating fluid recovering the natural freedom of its current. If the symptoms augment, all the local mischiefs of ulceration and gangrene follow, which we shall have to describe presently, or the disease will become CHRONIC.

In the SECOND VARIETY, OR DYSENTERIC FEVER, as it is called by many writers, all the preceding symptoms are highly aggravated, and others are superinduced by the action of the fever itself.

The preceding variety may occur at any season of the year, though, for reasons already stated, the disease, under every form, is most

frequently to be met with in the estival and autumnal months: it is very rarely, however, that the pyretic variety is to be found in any other than these two seasons; nor even in these, unless there be some endemic or epidemic fever prevailing, with which dysentery can combine.

Of its readiness to do this, and even to convert almost all the other diseases of the season into its own form, so forcibly pointed out by Sydenham, the late ravages in Ireland have furnished us with the most undeniable proofs. “The bilious fever of the autumn,” says Dr. Cheyne, “continued till near the termination of winter; consequently it existed as long as the dysentery was prevalent in the hospitals and the House of Industry, or the symptoms were often exchanged for those of dysentery, the irritation from the mucous membrane of the stomach and small intestines probably extending to the large.”—(*Dublin Reports*, vol. iii., p. 17.) And again, “dysentery was sometimes converted into fever, while, *vice versa*, fever was converted into dysentery: in short, these forms of disease were convertible the one into the other; so that the opinion of Sydenham, that dysentery is a *febris introversa*, or turned in upon the intestines, received support from our observations. And it is not unreasonable to suppose, that as these patients in my wards, in common with most of the poor in the city, had been exposed to the contagion of fever; this CONTAGION, according to the condition of the system at the time of its application, or some other modifying circumstance, may have produced at one time fever, at another dysentery.”—(*Id.*, p. 19.)

And so of other diseases as well as the prevailing fever of the season. “In early autumn, cases of cholera degenerated into dysentery, and, in the spring following, symptoms of dysentery accompanied the measles, then epidemic in many parts of Ireland.”—(*Id.*, p. 16.)

It is from the peculiar tendency which dysentery has to unite with other diseases, and especially fevers, or to convert them into its own nature, that many pathologists of considerable name have regarded it as nothing more than fever with a peculiar “local mode of action,” to adopt the language of Dr. Jackson. And they hence endeavour to show that, when dependant upon a cause of endemic fever, it is often intermittent; when dependant upon a cause of contagious fever, it is contagious (*Jackson, Hist. and Cure of Fever*, part i., ch. xiii., p. 324); and, when dependant upon a cause of typhus fever, it is malignant or putrid;—in the language of Dr. Balfour, as applied to the dysentery of India, a “*putrid, intestinal, remitting fever*.”—(*On Sol-lunar Influence*, p. 17.)

Most of the French writers of the present day describe dysentery as essentially an atonic or adynamic disease, and hence peculiarly apt to fall into this last form: and Dr. L. Frank represents this as the form it assumed, with little deviation, among the French army in Egypt, and believes it to be the ordinary form of hot climates.—(*Consult.*, lix., T. H., p. 135.) And we can hence see, where there is much fibrous debility with but little fever, and especially

where this is produced by poverty of diet, that it may occasionally connect itself with that kind of scorbutic affection which appeared some time ago among the convicts of the Millbank Penitentiary, and laid a foundation for such a form of the disease as was long ago denominated *dysenteria scorbutica* by Cirigli and Brambilla (*Phlegm.*, tom. ii., p. 337), and has been distinguished by the same name, in our own day, by Mr. Bampffield.—(*Practical Treatise on Tropical Dysentery*, &c., 8vo., 1819.)

In the pyretic variety, therefore, the fever is found to vary according to the diathesis or surrounding circumstances. The functions of the liver and skin are disordered from the commencement, and continue so till the termination. In the dysentery at Dublin, in the autumn of 1818, the skin was obstinately dry, hot, and pungent; and, “judging,” says Dr. Cheyne, “by the appearance of the stools, the biliary secretion was often suspended for many days.”—(Op. cit., p. 22.) Scybala were here never found in the discharges, nor often in the intestines; and they by no means appear so frequent as have been represented by many writers; inasmuch, indeed, that it has of late been doubted by some authorities whether they are ever to be traced at any time or in any country. Dr. Johnson has freely imbibed this doubt (*Johnson*, op. cit., &c., p. 223, et passim): Dr. Ballingall tells us that “it is comparatively a rare occurrence in India (*Practical Obs. on Fever, Dysentery, and Liver Complaints*, &c., 2d edit., Edin., 1823): while Dr. Chisholm speaks of them, on the contrary, as an ordinary symptom, and particularly adverts to the case of one patient under his care, who, “on the tenth day of the disease, after a paroxysm of excruciating torture, attended by cold sweats and delirium, spontaneously discharged at three evacuations a quantity of scybala sufficient to fill a common-sized chamber-pot.”—(*Climate and Diseases of Tropical Countries*, &c., p. 56; see also *Cleg-horn on the Diseases of Minorca*, p. 252.) There is hence no reason to question their occasional formation, notwithstanding they are rarely to be traced on many occasions in the dysentery of any climate: their production, indeed, is easily accounted for, from the spasmodic constrictions which so often run through a very considerable range of the intestines: and there is hence, *primâ facie*, more reason for anticipating than for not expecting them. Mr. Pack, who had formerly witnessed them in the Mediterranean, was surprised at not meeting with the same appearance at Kilkenny, in the epidemic of 1818, and could not avoid adverting to the dissimilarity of the disease in this respect in these distant quarters.—(*Dublin Reports*, &c., ut suprà, p. 20.)

The patient, on going to stool, whatever be the discharge that ensues, has always a feeling of something remaining in the bowels which ought to be dejected; while the dejections themselves, according to the extent and violence of the inflammatory action and its effects, evince every combination of materials: being in consistency watery, like beef-washings, slimy,

mucous, purulent, bloody; in hue, drab-coloured like flummary, bright green like conserva, and, after opium and calomel, deep green; sometimes pitchy (*O'Brien on Dysentery*, p. 58), and extremely fetid: and sometimes loaded with shreds of detached membranes; while occasionally a feculent motion is thrown down, of a natural colour, and nearly of a natural spissitude. Meanwhile, to adopt the description of Sydenham, the strength is much exhausted, the animal spirits dejected; there are all the signs of an ill-conditioned fever; intolerable sickness and excruciating pains, and a deadly coldness of the extremities; insomuch that the disease, in many instances, and especially when unskilfully treated, endangers the patient's life much earlier than in most other acute diseases. But, if the patient should escape death in this way, still numerous symptoms of different kinds succeed. Sometimes, in the progress of the disease, instead of the membranous shreds which are usually mixed with the stools at the commencement, pure blood, unmixed with mucus, is profusely discharged at every evacuation, which of itself threatens death, as manifesting an erosion of some of the larger vessels of the intestines. Sometimes a fatal gangrene seizes the intestines. Towards the close of the disease, aphthæ frequently affect the interior of the mouth, and generally foreshow imminent death.

The rapidity with which acute dysentery, when connected with fever, rushes on to destruction, is particularly noticed by Dr. Cheyne, who ascribes the fatal issue in this case to the violence of the fever itself, rather than to the proper dysenteric symptoms: though he adds, that sometimes sudden death ensued from an escape of the contents of the intestines into the cavity of the peritoneum, in consequence of ulceration.—(Ubi suprà, p. 20.)

The afflux of hot acrid matter alluded to by Sydenham is not unfrequently derived from the liver, and indicates a very morbid condition of this organ; and to the same effect Dr. Johnson:—“We sometimes see a partial, ill-conditioned sweat on the surface, which is productive of no benefit; while from the liver an occasional gush of vitiated bile, like so much boiling lead, throws the irritable intestines into painful contortions, and then the termina and tenesmus are intolerable.”—(*Influence of Tropical Climates*, ut suprà, p. 194.) There is occasionally, at this time, a formation of black vomit, the stomach discharging frequently a dark fluid, with a precipitate like coffee-grounds.—(*Dublin Reports*, vol. iii., p. 32.)

Dr. Chisholm observes, that the principal signs of the disease having extended to the liver are, a “pain at the pit of the stomach and a headache, a considerable anxiety at the præcordia, and a sensation as of a continued pressure in the right hypochondrium, with frequent stools, composed of a fluid like the washings of raw meat.”—(Ubi suprà, p. 59.) But he admits, as we have already noticed, that these are not idiopathic, and, consequently, are not to be depended upon for this purpose. They prove, however, that the disease has made an exten-

sive inroad upon the constitution. Not unfrequently the lungs themselves are affected, not merely in their function, but in their structure: for their respiration, observes Dr. Cheyne, was sometimes suddenly suppressed in the advanced stages; there was pain in the chest, a teasing, dry cough, showing a translation of the disease to the lungs; an exudation of puriform mucus in the cavity of the bronchia being detected on dissection.—(Suprà, p. 25.)

"A harsh, dry, opaque, dirty-looking skin; a florid, clear, varnished tongue; vigilance; a hollow eye, and pallid, wasted, faded cheek; pains in the knees; cramp in the legs; fits of dyspnoea; tendency to œdema and ascites—belonged to the more advanced stage, but not to the last, which was characterized by extreme emaciation, supine posture, involuntary stools, a thin reddish secretion, flowing without check; sordes on the teeth; hiccough; tendency to delirium; difficulty of swallowing; thread-like pulse."—(Suprà, p. 23.)

The mortality is often dreadful. At Clonmel, in 1818, where, however, it was far less severe than in many other parts of Ireland, Mr. Dillon calculated the deaths at one in ten; at Cork, during the same year, Dr. Barry estimated it at one in three at the least. "I never," says he, "witnessed so fatal a disease." And to the same effect, in general terms, Dr. Cheyne, while practising at Dublin: "I had often witnessed obstinate cases of dysentery, but I had not formed an adequate conception of the horrors of that disease, until I saw the patients who were congregated in the wards of Whitworth Hospital." [Sir James M'Grigor, in his *Account of the Diseases of the Army in the Peninsula*, mentions that, in three years, the loss from the ravages of dysentery was 4717; and Dr. O'Beirne (See *Trans. of King's and Queen's Coll. of Physicians*, vol. iv., p. 407, Dublin, 1824), calculates that the number of cases was 40,000. According to Desgenettes, dysentery made more havoc among the French troops in Egypt than the plague; for while, in a given period, 1689 were carried off by the plague, 2468 perished from dysentery.]

POST-MORTEM EXAMINATIONS were made in the dissecting-room of the Whitworth Hospital upon a very extensive scale, and gave evident proof, first, that the primary and CHIEF SEAT OF THE DISEASE WAS THE INTESTINES; though the liver often participated in the general lesion; and, secondly, that the intestinal canal was very variously diseased, according to the length or severity of the attack, or the peculiarity of the patient's constitution.

In some cases, the canal was prodigiously distended; in others, the coats were greatly injured, but without any thickening; in others, again, they were considerably thickened, as well as otherwise diseased.

Where distention prevailed, the small intestines were in a few instances found to be not less than seven, and the large not less than nine inches in circumference.

Where the intestinal coats were *without incassation*, the inflammation of the mucous mem-

brane was sometimes still very extensive, and reached from the stomach to the rectum; being, however, more obvious as the larger intestines were approached; though occasionally this last intestine was still pretty sound for three or four inches above the sphincter. The vascularity of the mucous membrane was sometimes increased without abrasion or ulceration; sometimes the same part was covered with coagulable lymph; sometimes simply abraded of its epidermal coat; sometimes partly ulcerated, and irregularly exposing the muscular coat; the intervening portions being of a natural appearance.

Where the intestinal coats were *thickened*, the mischief seems to have been generally more severe; the internal surfaces were often rugose as well as ulcerated, exposing the muscular fibres more extensively, which often hung in shreds as if sphacelated. The process of thickening, moreover, belonged to the more protracted cases, and often measured the duration of the disease.—(*Medical Report*, &c., pp. 28, 34.)

This incassation is traced chiefly in the colon, which Dr. Chisholm has found sometimes a quarter of an inch thick, and full of minute abscesses, and small steatomatous excrescences. (*Climate and Diseases of Tropical Countries*, p. 56.) These last appearances are particularly noticed by Dr. Cheyne, but described differently: "they are not," says he, "small ulcers, but minute pinholes formed out of the enlarged ducts of mucous glands; they were found very numerous, but especially in the rectum and lower part of the colon." By Dr. Baillie they are described as excrescences resembling warts.—(*Morb. Anat.*, fascic. iv., pl. iii., p. 73.)

"THE LIVER," says Cheyne, "IN A MAJORITY OF CASES, WAS SOUND, but often otherwise. In two cases there were abscesses; and in many, great sanguineous congestion."—(*Medical Reports*, &c., p. 36.) To a like effect Dr. O'Brien, writing from the same capital at a later period: "Generally," says he, "the liver was unaffected; though the gall-bladder was always distended with deep-brown or dark-yellow bile."—(*Observ. on the Acute and Chronic Dysentery of Ireland*, Dub., 1822.) Both these appearances were particularly observed by Dr. Chisholm in the West Indies, thus again harmonizing the nature of the disease in climates of different temperatures. "Where the colon was thus diseased, it was prodigiously distended with air. All the rest of the intestinal canal was healthy, the liver was equally so; but the gall-bladder was of a most uncommon size, and full of yellow bile."—(*Climate and Diseases*, &c., p. 57.) The same undeviating show of mischief in the intestinal canal, with only an occasional appearance of morbid structure in the liver, occurred to Dr. Ballingall in India, and to Dr. L. Frank in Egypt: so that the real source of the disease can be no longer a matter of doubt. "The dissection of every subject," says the former, "who died of dysentery in the regimental hospital of Penang (with one solitary exception), proved the disease to consist entirely in an inflammatory affection of the

large intestines, without a trace of disease in the structure of the liver.”—(*Pract. Obs. on Fever, Dysentery, and Liver Complaints, &c.*, Edinb., 1823.)

[In a late essay (See *Trans. of King's and Queen's College of Physicians*, vol. v., p. 249, Dublin, 1828) on the present subject, Dr. O'Brien has recorded the dissections of twelve dysenteric patients. The summary is as follows: liver diseased in six; spleen in three; small intestine (chiefly ileum) inflamed, or ulcerated on its mucous surface, in eight; great intestine diseased in twelve; gangrenous in one; much contracted in two; ulcerated and inflamed in all; colon and rectum parts most diseased.]

The MEDICAL TREATMENT of dysentery has given rise to much warfare of opinion. Not, however, in slight cases of the simple acute disease; for such usually give way in a short time to the ordinary evacuates and sedatives. “In cases,” says Dr. Cheyne, “not attended with much fever or pain, and in the first few days of disease, a purgative in the morning, ten grains of Dover's powder in the afternoon, and again at bedtime, with low diet, restored many.”—(*Medical Report, &c.*, p. 42.)

Sydenham generally commenced with bleeding, gave an opiate at night, and a pretty active purgative in the morning: the purgative consisting of a drachm and a half of rhubarb, two drachms of senna, with half an ounce of tamarinds, infused in a sufficient quantity of water, with manna and sirup of roses. The purgative was repeated twice every other day, and in every instance followed up with an anodyne of sixteen or eighteen drops of his own potent laudanum, to take off whatever additional excitement the purgative might produce. The same anodyne was constantly given with a warm diaphoretic, every night and morning, even on those days when the aperient was not employed.

Where this was insufficient, the sedative was repeated every eight hours to the amount of twenty-five drops at a dose, and a perspiration was still further attempted to be promoted and maintained by drinking freely of whey or the white decoction, and the use of warm emollient injections; the perspiration being continued for at least twenty-four hours at a stage, the only beverage allowed in the meanwhile being tepid milk.

The tormina and bloody stools usually gave way after the third or fourth injection. But where the morbid secretion ran into a chronic character, he varied the form and intention of the injection; and, with a view of introducing a new and less unhealthy action, compounded it of half an ounce of Venice turpentine dissolved in a pint of cow's milk, which was thrown up daily; thus anticipating, in a very considerable degree, the modern practice of obtaining the same effect by the balsam of copayva, which is only a terebinthinate of another kind.

The principles of this practice it is not easy to improve upon; though they have since been modified and often extended with considerable advantage.

As a general rule, the lancet was had recourse to with too much timidity; though its present

indiscriminate and lavish employment forms an extreme that ought equally to be avoided.

Where the fever is considerable, the pulse hard and full, and particularly where there is much general pain and tension over the belly, indicating an inflammatory diathesis, blood should be drawn copiously and with all possible speed, and repeated as long as the same symptoms may require; for here we have no time to lose; the inflammation may run rapidly into gangrene, and the patient sink from mortification or loss of blood in a day or two; perhaps in a few hours. There is nevertheless no disease that requires the exercise of a sounder judgment upon this point than dysentery; as the fever, if not typhous from the first, has a general tendency to pass into this type. [The statement of Dr. Renton, who has given a description of dysentery as it appears in Madeira, corroborates the necessity of great caution; for he says that he was once in the habit of using the lancet freely and repeatedly, and of trusting to it and other antiphlogistic means; but every case so treated terminated fatally.*]

In his cathartic plan, Sydenham would have been considerably aided by the use of calomel; of all the purgative deobstruents the most valuable; and the more so, as exercising its evacuating power over all the scernents of the body. It has of late, indeed, been most extensively employed in quite a different way, and for a very different object; that, I mean, of curing by a specific action upon the immediate seat of inflammation; being persevered in for this purpose in doses of from five or ten to twenty or twenty-five grains, two or three times a day; assisted, where there is much torpor of the absorbents, by mercurial friction, and continued till ptyalism is produced, which, as in the case of yellow fever, is the alleged test that the constitution is sufficiently loaded with it, and that the disease is about to give way.

It is impossible to contemplate the conflicting opinions which are given us respecting this mode of treatment by the monographic writers on tropical diseases, without astonishment: and the only mode of reconciling them is, to suppose that the constitution is very differently affected by the use of mercury under different circumstances; and that, while in some epidemics and sporadic cases it produces all that benefit which *à priori* we should expect generally, in others it entirely fails, or even proves mischievous. Dr. Jackson, Dr. Ballingall, and Mr. Bampfield, feel justified in employing calomel merely as a purgative; while the second, though he regards it as of the highest importance in chronic dysentery, found even ptyalism itself unsuccessful in the acute form. Dr. John-

* Edin. Med. Chir. Trans., vol. ii., p. 381. In acute dysentery, a decidedly antiphlogistic plan is recommended by Dr. Elliotson:—“It may be necessary to bleed vigorously in the arm; to apply leeches freely and repeatedly to the abdomen; to give mercury, and get the mouth sore; to apply cataplasms of hot moist bran to the abdomen,” &c.—Lect. at Lond. Univ., as published in *Med. Gaz.* for 1833, p. 556.—Ed.

son esteems it of high importance as a purgative, but of the utmost moment as a sialagogue. He unites it occasionally with bleeding, with anodynes, with diaphoretics, or with all; but each of these is subsidiary to its powers, and may often be dispensed with.—(*Influence of Tropical Diseases*, &c., p. 202.) Mr. Annesley unites it in the same manner, but takes every method in his power to prevent it from becoming a sialagogue. In any of the diseases for which he prescribes it, as fevers, dysentery, and liver-complaints, he gives it in scruple doses in each. "I never wished," says he, "to see the mouth in the least degree affected. Whenever this happened, I considered the salutary effects of calomel interrupted, because its use must be then discontinued; and it was my object to act upon the secretions of the intestines, to diminish muscular action in the intestinal canal, and not in the most remote degree to act upon the salivary glands."

—(*Practical Observations on the Effects of Calomel on the Mucous Surface*, &c., Lond., 1825, 8vo.) Mr. Cunningham, late surgeon to the Sceptre in the East Indies, boldly employs it alone, and regards every thing else as impeding its course. He does not even stand in need of alvine aperients of any kind, and prefers scruple doses to smaller proportions, because it does not in this form so readily excite the alvine discharge, so as to be carried out of the system by stool: and, administered in this way, he fearlessly asserts, and the tables of his practice seem to justify his assertion, that "it is an almost certain remedy for dysentery, in hot climates at least." [Dr. Renton, of Madeira, after having given a trial to almost all the various modes, from copious bloodletting down to the oil of turpentine, feels himself justified in stating, after some years' experience, that, in the treatment of the dysentery of that island, "mercury, given boldly and perseveringly, until the mouth becomes decidedly affected, is the remedy chiefly entitled to confidence."—(*Renton, in Edin. Med. Chir. Trans.*, vol. ii., p. 377.) His plan is to give calomel every three or four hours, until the gums become sore.] And, finally, for it is not worth while to pursue the discrepancy further, Dr. L. Frank assures us, that, in his practice, the large doses of calomel given so generally by the English surgeons in India, proved dangerous in the French army in Egypt; and that the plan most successful in his hands, was that laid down by Sydenham, which consisted, says he, in removing irritation by gentle aperients, the use of emollient injections, mucilaginous and diluent drinks, diaphoretics, and laudanum.

Sydenham employed laudanum as a cordial and diaphoretic, as well as a sedative; so as to take off that fearful depression of the animal spirits by which dysentery is so peculiarly characterized, and to give a breathing moisture, and consequently a refreshing coolness, to the parched and burning skin, as well as to allay local irritation; his chief auxiliaries for the last purpose being diluents, tepid injections, and the warmth of the bed. Modern practice has greatly improved upon this plan, by combining

some relaxant with the opium; and, in many instances, by premising an emetic, which, independently of its often exciting a perspiration, which nothing else can accomplish, has the additional benefit of enulging the ineseaeric or mesenteric vessels by the act of vomiting. The antimonial preparations form the best emetics for this purpose, whether the glass of antimony, at one time so powerfully recommended by Sir George Pringle (*Edin. Med. Essays*, vol. v., art. xv.), tartarized antimony, or Dr. James's powder. Sir George Baker, Dr. Adair, and Dr. Saunders, concurred in strongly recommending the emetic tartar as a diaphoretic or relaxant; the first alone, the second with calomel, and the third with opium; all which, nevertheless, have, in our own day, often yielded to Dover's powder, which is certainly entitled to a very high degree of praise. Much, however, of the benefit to be derived from Dover's powder, as a sudorific, depends upon its proper administration, and the care taken to promote its influence by a proper adjustment of clothing. Dr. Cullen advises, that the patient should, from the first be wrapped in a flannel shirt, and laid between the blankets alone, by a removal of the linen sheets, so that he may be surrounded by nothing but a woollen covering. Mr. Dewar's recommendation (*Obs. on Diarrhœa and Dysentery*) of a broad flannel swathe or cumberland bound round the abdomen, is, however, better entitled to practice, as it affords support as well as warmth: Sir James M'Grigor found it very useful.*

Dr. Darwin amuses us with a singular mode of producing the same result, and one which, if continued long enough, might probably prove as powerful a revellent as any of those already noticed, but which we should not always recommend, nor find our patients disposed to carry into effect. "Two dysenteric patients," says he, "in the same ward of the Infirmary at Edinburgh, quarrelled, and whipped each other with horsewhips a long time, and were both much better after it."—(*Zoonom.*, cl. ii., i., 3, 19.)

If the flux of blood, or any other morbid material, continue and be considerable, and especially if there be still an intermixture of sanious grume and shreds of membranes, evidently proving vascular disintegration and the approach of gangrene, astringents and tonics must enter into the plan of treatment. And, in this case, great benefit has been obtained from mineral acids, in union with sulphate of zinc or with opium.

The former combination was a favourite medicine with Dr. Moscley, who, of the mineral acids, preferred alum, and varied the proportions according to the strength or age, the degree of costiveness or of hemorrhage, of the patient: sometimes giving two or three grains of each at a dose, to be repeated three or four times a day; where the hemorrhage is considerable, increas-

* *Medico-Chir. Trans.*, vi., 433. Dr. Elliotson has not a favourable opinion of the emetic plan, neither has he ever been able to discover the soothing effects of ipecacuanha. He has not judged it necessary to give preparations of antimony.—ED.

ing the alum; and, where feculent evacuations were required, diminishing it, or even omitting it altogether. The preparation is valuable, as it unites a powerful metallic tonic, which is a true character of the sulphate of zinc, with an acid which has the singular virtue of proving astringent to the sanguineous and secernent system, while it produces little effect upon the peristaltic motion, and by some physiologists is thought rather to quicken it. Dr. Adair employed alum alone; but it is greatly improved by the addition of the sulphate of zinc. Dr. Jackson recommends either, or both conjointly; and both himself and Dr. Moseley employed injections at the same time, composed of a solution of acetate of lead, and apparently with great benefit. [Whether small doses of the sulphate of copper, joined with opium, would prove as useful in these cases as they were found by Dr. Elliotson (*Med. Chir. Trans.*, vol. xiii., p. 451, &c.) to be in chronic diarrhœa, future experience must determine: they should not be given on an empty stomach, as they would be likely to produce vomiting; but after breakfast. The smallest dose is a quarter of a grain; the largest, three grains.]

A like beneficial effect, however, has been derived from uniting the mineral acids with laudanum. The sulphuric, though the pleasantest to the taste, is more apt to irritate the bowels than the nitric. But the best mode of giving the latter, is by combining it with muriatic acid in the proportion of two thirds of the former to one of the latter, imitating hereby the chrysulea of Van Helmont, or the aqua regia of later chymists, the nitro-muriatic acid of the present day, in doses of two drops of the nitric, one of the muriatic, and ten minims of laudanum, intermixed with infusion of roses or that of the more powerful astringents, logwood, catechu, and gum kino. I have employed this medicine with peculiar advantage, not only in dysenteric, but in many other loosenesses and hemorrhages of the bowels, increasing the proportion of the acid or the laudanum as the urgency of the symptoms requires.*

When, however, the thirst is considerable, and acidulous drinks are called for, we may for this purpose use the sulphuric acid as the most grateful; though, in this case, the citric acid will usually be preferred, and the patient may be allowed to exercise his choice. Yet the one or the other of the above compounds should be continued, without any alteration in consequence of such a beverage.†

* See likewise Th. Hope's Obs. on the powerful Effects of a Mixture of Nitrous Acid and Opium in curing Dysentery, Cholera, and Diarrhœa.—*Edin. Med. and Surg. Journ.*, No. lxxxviii., p. 35.

† Many of the eminent physicians in different parts of the United States have recommended active antiphlogistic means in the treatment of dysentery: these embrace bleeding, mercurials, the saline cathartics, and the milder aperients. As the hepatic system is sometimes deranged in this disease, emetics, and particularly ipecacuanha combined with antimony, have been used by some to unlock the biliary secretions: blisters are employed by many practitioners, who apply them

Since the second edition of this work, the medical world has been favoured with the opinion and practice of Dr. Baillie, in a printed but unpublished volume of his writings. And if there be individuals who object to the practice of Sydenham on account of its defective energy, they will have infinitely more reason to accuse this eminent physician of tameness. He recommends bleeding, indeed, as what is *frequently* of service, but local alone and by leeches; as cathartics, "mild purgative medicines, of which," says he, "I think castor-oil upon the whole the best;" and opiates and astringents to be delayed till "natural fluid motions" have been obtained.—(*Lectures and Observations on Medicine*, 1825.) Never was man more suspicious of the powers of medicine, or more entitled to the character of an expectant physician, than this eminent pathologist.

As the disease declines, there will often be found a very considerable degree of debility, and a chronic diarrhœa, with occasional discharges of blood, from the excoriated state of many of the minute bloodvessels of the mucous membrane of the intestines, or perhaps from a simple relaxation of the mouths of the capillaries. And in this situation, and especially where the disease has assumed a highly malignant character, many of the bitters of the *Materia Medica*, as the cinchona, columbo, simarouba, or extract of chamomile; and, perhaps, the *Nerium antidysentericum* of Linnæus may be resorted to, in connexion with acids, with great advantage. They have, indeed, occasionally been given from the first; and in a few very slight cases and very infirm constitutions, the practice may have succeeded; but as a general rule it is highly rash, and has rarely been tried without repentance.

In conjunction with this process, the very great tenderness of the interior of the larger intestines, from erosion or abrasion, will often, for a long time, demand peculiar local attention; and demulcent or bland oleaginous injections, as the infusion or oil of linseed, or olive-oil with a little wax and soap dissolved in it, together with a grain or two of opium if there should be much pain (the whole not to exceed three or four ounces in quantity), will often be found of great assistance.

Opium alone, in the form of a small pill or suppository, as recommended by many practitioners, will be generally found too harsh; and, where there is much tenesmus, it will be im-

early, and the compound powder of ipecac. and opium (Dover's powder) is prescribed very generally. When dysentery exists as an epidemic, the depletory method of treatment must be pursued with great care; the physician ever regarding the rapid manner in which the powers of life are prostrated and destroyed by this typhoid condition of the system.

Prof. Geddings, of Baltimore, has recently published some remarks on the use of nux vomica in dysentery. From some experience with this drug, Dr. G. considers it as a useful adjuvant, to be used after suitable depletion, and especially when the disease is verging to a chronic form.—See N. A. Archives of Med. and Surg. Science, Baltimore, vol. i., p. 128.—D

possible to retain it. The only mode in which I have found it useful in this way is to rub it into an impalpable pulp with a little of the oil or butter of the coconut, and to mould it into small pastils of a sufficient consistency to bear the touch.

In long-protracted and chronic cases, lime-water, drunk freely, has occasionally also proved useful. The coat of the intestinal canal is here, however, sometimes very considerably thickened and indurated. And in such cases, the best remedy we can have recourse to is mercury.

The liberal and experimental practice pursued at the Dublin and various other hospitals in Ireland, during the late severe attacks of epidemic dysentery, and its general though often discrepant effects, may be appealed to in confirmation of the mode of treatment thus far laid down.

Such was the fatal ravage of the disease, that no one plan, hitherto devised, offered more than a very unsatisfactory success;—and hence almost every plan was tried in its turn.

From the treatment by mercury much was at first expected; and in many cases it seems to have been of use; but it "did not succeed," says Dr. Cheyne, "so well as I expected. Calomel, tried in every proportion and distance of time, often failed with me and my colleagues."—(*Report, &c.*, p. 41.) And he adds shortly afterward, "Mercury could not be depended upon, and did not relieve in numerous instances where the mouth was affected; and sometimes seemed to increase the disease."—(*Id.*, p. 45.) And even where the symptoms distinctly pointed out a morbid organization of the liver, the result of this treatment was unsatisfactory. "Mercurial frictions," says Dr. Cheyne, "were tried in all the forms over the region of the liver; but the advantages were not so extensively beneficial as I had reason to suppose, from finding that in every dissection the liver was in its structure more or less destroyed."—(*Id.*, p. 89.)

Venesection and opium seem to have been more beneficial. "The lancet," he further adds, "has repeatedly afforded great temporary relief where ulceration seemed to have taken place; and the relief proved permanent from blisters, mild aperients, and anodynes. Where the lancet was not allowable, leeches were also highly useful."—(*Id.*, p. 47.) Free venesection, we are told in another place, often procured a large feculent stool, where even purgatives failed. In conjunction with a blister, it often removed even the alarming symptom of dyspnoea when timely applied.—(*Id.*, p. 26.)

Dr. Cheyne's sheet-anchor seems to have been opium, and to this he shows as strong an attachment as Sydenham, who only preferred the liquid to the solid form of this medicine, as he expressly tells us, on account of its more easy sub-action. Dr. Cheyne, however, carried his practice here, as well as in bleeding, to a considerably larger range, at least in severe and alarming cases. "The mercurials," says he (p. 44), "with opium, sometimes seemed to answer: but in future I should chiefly depend upon opiates in doses of four or five grains, as this seemed chiefly to arrest the progress of in-

flammation, diminished agony, and sometimes proved of permanent benefit."

In less violent assaults, he at length fell back still more fully into the practice of former times. "In the middle stages," he tells us, "I preferred to the treatment of mercurials, *the old proceeding*; venesection, purgatives (chiefly the saline), bath in the evening, diaphoretic at night. This was frequently successful in an early stage." The blood drawn on the first use of the lancet, was from thirty to forty ounces or more; which was repeated as often as necessary. With the saline purgative was often intermixed emetic tartar, to act on the stomach as well as on the bowels; and to these were added, in more violent cases, emollient injections, and, as already observed, blistering.

Castor-oil, so highly prized by many writers, rarely acted kindly, and very frequently aggravated the tormina and tenesmus. It succeeded best when united with opium.

Generally speaking, injections did not answer so well as was expected. The most successful were the terebinthinate clysters—the Venice turpentine of Sydenham being merely exchanged for the oil of turpentine or the balsam of copayva. The local action was hereby frequently changed and meliorated. And even the griping property of castor-oil was softened, instead of augmented, by combining it with the rectified oil of turpentine.

The other kinds of injections chiefly employed, were diluted solutions of nitrate of silver and acetate of lead: the last united with opium. This combination was in high repute, on account of its decided success in various cases. Dr. Barker has since improved upon the principle, by giving to the joint materials the form of pills; under which modification it seems to have been still more effectual.

The ordinary astringents, in addition to the above, were, the chalk mixture, or infusion of catechu combined with laudanum.

In protracted cases, the medicines chiefly had recourse to were Dover's powder, small doses of ipecacuanha, and calomel. [The generality of army surgeons consider small doses of ipecacuanha serviceable. The utility of this medicine, and of small doses of hydrarg. cum cretâ, has been noticed by Dr. Bright.—(*See Bright's Reports*, p. 176, 4to., Lond., 1827.)] The treatment, where the disease ran into a chronic form, we shall notice presently.

[Dr. O'Beirne has related several cases in proof of the great efficacy of fomenting the abdomen with an infusion of tobacco, made by pouring two quarts of boiling water on two ounces of Virginian leaf-tobacco, and allowing it to stand for twenty minutes before use. Tobacco clysters, owing to the irritable state of the rectum, were not found to answer. Dr. O'Beirne usually lets the use of the fomentation be preceded by a mild purgative, like castor-oil; and, indeed, he lays it down as a good general rule, that purgatives should be continued with the fomentation, until perfectly natural and feculent discharges be permanently established. The fomentations were sometimes repeated more

than once in the day, and generally not discontinued, until some disturbance of the stomach and head had been experienced.—(*Trans. of King's and Queen's College of Physicians*, vol. iv., p. 336, &c.)]

SPECIES II. DYSENTERIA CHRONICA. CHRONIC DYSENTERY.

STOOLS FREQUENT, LOOSE, AND FECAL: OFTEN WITH LARGE DEJECTIONS OF PURE OR GRU-
MOUS BLOOD, AND ESPECIALLY WHERE THERE IS SEVERE TENESMUS; MORBID PROGRESS SLOW AND INSIDIOUS; MOSTLY WITH HECTIC FEVER.

The genuine symptoms noticed under the preceding species, are for the most part rapid and violent: and, when they have run through their course, if the constitution generally, or the alvine organs more particularly, be reduced to a state of extreme debility and relaxation, the disease, instead of yielding to a return of health, is extremely apt to pass into the present species of dysentery.

But it not unfrequently happens, that the causes of the disease are feeble and slow, though persevering in their mode of action; or that the organs on which they operate locally are already in an infirm or undermined state, so as to possess scarcely energy enough to evince any vehemence of excitement; and in either of such cases, chronic dysentery is produced without the intervention of acute, and becomes a primary malady.

The causes are chiefly a repeated exposure to a cold, damp air, and especially in warm weather, by which the perspiration of the skin becomes frequently and suddenly suppressed; and an habitual irritation of the alvine canal, by a daily indulgence in highly stimulant food, and particularly spirits.

In this species the inflammatory action spreads insidiously from one organ to another, till all the viscera subservient to the digestive process are implicated in a common chain of disease; and especially the liver, which is usually, indeed, in a state of great irritability and weakness from the first; as are also the mesenteric glands.

Hence, the symptoms must vary according to the progress of the disease, and the extent of the structural injury, from a simple relaxed state of the bowels, producing diarrhoea, uniformly accompanied with a greater or less degree of tenesmus, to a permanent ulceration, pouring forth purulent matter, or a more compound colluvies, sometimes watery like the washings of raw flesh, sometimes coagulated like dirty cream, and sometimes black and tenacious as pitch; and in most cases intolerably fetid.—(*O'Brien on Dysentery of Ireland*, p. 58, Dublin, 1822.) Occasionally, indeed, there is a dejection of sordid pus in considerable abundance, in consequence of the bursting of an abscess that has been long forming in the liver or some other organ, and has discharged its contents immediately or intermediately into the intestinal canal.—(*R. W. Bampffield on Tropical Dysentery*, &c., p. 3,

London, 8vo., 1819.) And we may hence see abundant cause for those colliquative sweats, dry, distressing cough, and other symptoms of hectic fever, which so frequently accompany this form of dysentery.

Chronic dysentery may, therefore, in its simplest and mildest state, be regarded as a GLEET of the larger intestines, produced, as urethral gleet is, by a morbid relaxation of the mucous glands of the part affected, and accompanied with that sort of irritation which is the usual cause of increased secretion in debilitated organs.

If the irritation be of any considerable extent over the intestinal canal, the peristaltic action is often permanently excited, and we have then an obstinate and weakening diarrhoea, pain at the pit of the stomach, with loss of appetite, and other dyspeptic symptoms.

If the same irritation ramify, whether by sympathy or continuous action, to the liver, we often find this organ also stimulated to a very considerable excess of secretion; when there is a frequent flow of bilious fluid from the rectum, sometimes nearly pure, but more generally depraved, and intermixed in its passage with other materials, constituting that variety of the disease which, by practitioners in the east, has been often denominated BILIOUS or HEPATIC FLUX.—(*Curtis on the Diseases of India*.)

Not unfrequently, however, the discharge from the rectum is pure or depraved blood, instead of bile; the relaxed and debilitated capillaries of the organs chiefly affected pouring forth this fluid in great abundance by anastomosis, or a gangrenous erosion of the tunics of larger vessels. This case is correctly denominated BLOODY FLUX.

In the late epidemic dysentery in Ireland, Dr. O'Brien included all those cases under the present species which ran on to a longer period than six weeks, and were accompanied with little or no fever. The most numerous sufferers were the aged and infirm, who had previously laboured under diseases of the liver, or some other abdominal organ.

From the extensive range of the morbid action, the impoverished state of the constitution, and, consequently, its difficulty of rallying, it is not often that a patient recovers from this form of the disease, when it has once passed from its mild or simple stage into a severer or more complicated course; and, on this account, Dr. L. Frank has asserted that it is essentially more fatal than the acute species.

Post-obit dissections have given nearly the same appearances as we have already noticed; there is abrasion or ulceration of the mucous membrane of the intestines;—the colon is very generally found thickened and contracted through its whole extent, but particularly in its lower flexure. The smaller intestines are rarely traced in a state of ulceration; but patches of a deep-red colour are found in scattered plots, and especially on the ileum. The liver is not always affected in its structure, though more frequently than in the acute form: the gall-bladder is usually distended with deep-brown or

dark-yellow bile, evincing a paresis or obstruction in the cystic duct.

The THERAPEUTIC INTENTIONS are here to change the nature of the morbid and irritable action; to diminish the exhausting discharges; and to give tone to the languid and impoverished frame.

For the first purpose, the most effectual medicine is calomel, either alone or intermixed with opium. "If, in treating of the *acute* form of flux," says Dr. Ballingall, "I have refrained from an indiscriminate, and, as I conceive, unmerited commendation of this powerful medicine, it is only in hopes of being able to urge its employment with double force in the form of disease now under consideration; and to recommend an implicit reliance on it in the chronic form of flux; to ascribe to it an almost unlimited power in the disease; and to express an opinion that it will seldom disappoint our most sanguine hopes." Its effects in India, where torpidity and congestion are more frequent and more excessive than in cooler climates, seem to give full sanction to this unqualified recommendation, and authorize its employment in large doses. In our own country, though very far from affording universal success, it is of pre-eminent importance; but, as it requires a long perseverance in its use, it will be found an error to load the system with it suddenly. In Ireland it was most beneficially employed in the form of the blue-pill, combined with opium and a minute appendage of emetic tartar.*

Here, too, the terebinthinate preparations may frequently be had recourse to with some confidence; as may, also, for the same purpose of improving the local action, the essential oil of turpentine and the balsam of copayva. As an aperient, oil of castor may generally be employed with less excitement of griping than in the acute form; but, whatever laxatives are had recourse to, they should always be of as mild a character as possible; and hence rhubarb in combination with small doses of calomel or Epsom salts, is often preferable to castor-oil.

By keeping the bowels free from irritation in this gentle manner, we indirectly check the morbid discharges of whatever kind by which the disease is so peculiarly distinguished. And, where more direct and powerful means are necessary, the compound chalk mixture with opium, various preparations of kino or catechu, or the acetate of lead, in solution or pills, or small doses of the sulphate of copper, joined with opium, may be tried.†

The diet should be bland and nutritious, composed chiefly of milk, as recommended by Sir John Pringle, or of vegetable mucilages, as rice, arrow-root, sago, and salep. And, as soon as the local irritation has manifestly subsided, a more cordial and tonic plan should be entered upon; animal food be allowed; the warmer bitters and metallic corroborants be prescribed, as cascarrilla, columbo, sulphate of zinc; and such exercise and change of air as may best comport with the patient's constitution and station in life. Dr. O'Brien judiciously recommends him to try a warmer climate if his home be the British Isles, and a colder if he be a resident between the tropics. In all situations, he must be especially careful to avoid sudden changes of temperature, and particularly a cold, damp atmosphere, and maintain a healthy excitement on the skin by flannel socks worn on the feet, and flannel swathing around the body.*

GENUS XI.

BUCNEMIA.

TUMID LEG.

TENSE, DIFFUSE, INFLAMMATORY SWELLING OF A LOWER EXTREMITY; USUALLY COMMENCING AT THE INGUINAL GLANDS, AND EXTENDING IN THE COURSE OF THE LYMPHATICS.

This genus is new to nosological classifications: but it is necessary, in order to include two diseases which have hitherto been regarded by most writers as totally unconnected, and treated of very remotely from each other; but which, though occurring under very different circumstances, are marked by the same proximate cause, in most instances affect the same organs, and demand the same local treatment. They consist of the following species:—

1. Bucnemia Sparganosis. Puerperal tumid leg.
2. ——— Tropica. Tumid leg of hot climates.

As the present genus is new, it has been necessary to distinguish it by a new name; and,

cases, of course, require depletion by venesection, &c., and some occasionally demand the use of means to unload the intestines; but commonly the mucilaginous diet and blue-pill afford almost immediate relief, and soon effect a cure." The same treatment has been pursued with success by other practitioners.—D.

* If there be any tenderness about the abdomen, Dr. Elliotson recommends leeches to be put on the anus and front of the belly, for the alleviation of the tenesmus, which may then depend upon inflammation. When this symptom arises merely from irritation, he approves of an injection of forty or fifty drops of laudanum, mixed with not more than four ounces of a solution of starch, or with what Sir James M'Grigor found afford great relief in the Peninsula, a solution of the acetate of lead. Dr. Elliotson has not found it necessary to prescribe mercury in the kind of chronic dysentery met with in England; but he speaks favourably of the plan of applying straps of adhesive plaster round the trunk, and a flannel bandage over them.—See Lect. at the Lond. Univ., as published in Med. Gaz. for 1833, p. 558.—Ed.

* In the Peninsula mercury was found by Sir James M'Grigor to be injurious, except when the liver was diseased.—See Med. Chir. Trans.—Ed.

† A valuable paper on Chronic Dysentery, by Dr. S. K. Mitchell, is published in the Am. Journ. of Med., &c., vol. ii., p. 323. From numerous cases occurring in his own practice and that of his friends, Dr. M. feels confident that "most cases of chronic dysentery are remediable by the exclusive use of inueltage without sugar, and of the blue-pill given in from three to five grain doses, not more frequently than once in twenty-four hours, nor less frequently than once in forty-eight hours. Some

on this account, the author has made choice of that of *Bucnemia*, from βου, a Greek augment, probably derived from the Hebrew בָּעַ or בָּעָה "to swell, augment, or tumefy," a particle common to the medical vocabulary; and the Greek noun κνήμη, "crus," or "the leg," literally, therefore, "bulky or tumid leg."

SPECIES I.

BUCNEMIA SPARGANOSIS.

PUERPERAL TUMID LEG.

THE TUMID LIMB PALE, GLABROUS, EQUABLE, ELASTIC, ACUTELY TENDER; EXHIBITING TO THE TOUCH A FEELING OF NUMEROUS IRREGULAR PROMINENCES UNDER THE SKIN; FEVER A HECTIC; OCCURRING CHIEFLY DURING THE SECOND OR THIRD WEEK FROM CHILDBIRTH.

THE tumid leg of childbirth has mostly been contemplated as a very different affection from that of hot climates, and has rarely been treated of in connexion with it. In the present author's first edition of his Nosology, the ordinary arrangement was so far adopted, that the two species were placed remotely from each other, though a distinction between elephantiasis and the tumid leg was strongly enforced.

The tumid leg of lying-in women has been described by different authors under a variety of names, as *phlegmasia dolens*, *phlegmasia lactea*, *ecchymoma lymphatica*, and by Dr. Cullen as *anasarca serosa*; few of which express the real nature of the affection, and some of them a source obviously erroneous.

By Dioscorides it was denominated *sparganosis*, from σπαργώ, "to tumefy and distend:" *tumeo et distentus sum*, as rendered by Scapula; and, as the term is sufficiently expressive, it has been preferred on the present occasion. By most writers, till within the last twenty or thirty years, the swelling has been ascribed either to a suppression of the lochia, or a redundancy of milk, and a morbid deposition in consequence of such redundancy. Mauriceau regarded it as a metastasis of the lochia, and Puzos as a metastasis of the milk; whence the French practitioners call it, to the present day, *dépôt laiteux*, or *lait répandu*; and the Germans *milchstreichen*. A minuter attention to the subject, however, has sufficiently shown that this complaint has seldom any connexion with the milk, perhaps never. It has occurred where the breasts have been destitute of milk, and where they have overflowed; where suckling has been relinquished, and where it has been continued. It is not long since that I was consulted by a young woman labouring under it, who was suckling her infant, without any complaint of the breast whatever.

It is as little influenced by the state of the lochia as by that of the milk. It attacks women of all ranks and of all habits, the healthy and the diseased, the lean and the corpulent, the sedentary and the active, the young* and

the middle-aged. It also occurs in all situations, and has never perhaps been known to appear in any other part of the body than the lower extremities.

My esteemed friends Dr. Hosack and Dr. Francis, of New-York, have, however, ingeniously contended that it has also been found in the upper* as well as in the lower limbs, and in males as well as in females; and they especially appeal to one case communicated to them by Dr. Heermans of Ontario, which, could it be relied on, would go far to settle the question; but, as it appears to me that this, like various similar cases that have occurred to the present author, was an instance of erratic or metastatic rheumatism rather than sparganosis, we are not at present authorized to deviate from the ordinary character assigned to the disease, or to generalize it in the manner which this more extended view of its occurrence would demand of us. Other local affections, indeed, make an approach to it, of which Dr. Denmark has described one that occurred in a male, which, however, he prudently avoids calling a *phlegmasia dolens*, contenting himself with saying that it resembled it; while Dr. Davis, as we shall have to observe presently, seems to have mistaken for this complaint an inflammation of one of the larger veins in the pelvis or its vicinity.

[The editor is happy in having here an opportunity to remark, that Dr. Davis only attempted to show the grounds he had for thinking that *phlegmasia dolens* was essentially connected with inflammation and obstruction of the iliac veins; and he has undoubtedly proved by dissection, that, in some particular instances, corresponding, as he judged, though not as our author believed, to the latter disease, those veins were inflamed and obstructed. Whether such affection of the veins exists in all or most cases of *phlegmasia dolens*, can only be determined by further pathological investigations.† In the meanwhile it may be right to mention, that Dr. Davis's view has already received material support from three cases recorded by M. Velpeau, in all of which the sacro-iliac symphysis on the diseased side was more or less affected; accompanied with purulent effusions in the peritoneum, and about the genital organs; and a mixture of pus and coagulated blood in the veins of the limb, with evident traces of inflammation of their coats in two of the cases. It is true, that the alteration of the sacro-iliac symphysis

* In Mr. Fraser's case, the left thigh and arm were considerably larger than the right.—See Edin. Med. Journ., No. xc., p. 17.—Ed.

† In the case reported by Mr. Fraser, no traces of disease were found in the iliac vein; and he is inclined to regard *phlegmasia dolens* as a modification of diffuse inflammation of the cellular membrane, as described by Dr. Duncan. On the other hand, Dr. Lee proposes to substitute the term *crural phlebitis* for *phlegmasia dolens*; "as it has been demonstrated by the researches of recent pathologists, that the swelling of the affected limbs, and all the other local and constitutional symptoms of this affection, invariably depend on inflammation of the iliac and femoral veins."—Cyclop of Pract. Med., art. *PHLEGMASIA DOLENS*.—Ed.

* A case of this kind, occurring in a young woman, is mentioned by Hazeltine.—(See Comm. to the Mass. Med. Soc., vol. iii., Boston, 1819.)—D.

is regarded by Velpeau as the occasion of all the other disorder, and so far he differs from Dr. Davis; yet the fact of the veins being inflamed and obstructed, in the examples alluded to, is certainly an important coincidence with what was noticed in the cases adduced by Dr. Davis.*

Neither does it appear to the editor that satisfactory proof has been given, that phlegmasia dolens is exclusively a disease of the female sex. He visited, in the military hospital at Cambray, in 1816, a soldier who was under the care of Dr. Booty, and was afflicted with a swelling of one of the lower extremities, which that gentleman, an army practitioner of considerable merit, confessed that he knew not how to discriminate from phlegmasia dolens. Had the editor had no difficulty in joining the author in the supposition, that any eminent physician could have mistaken rheumatism for phlegmasia dolens, he should yet have had to overlook the foregoing facts, as well as the interesting case of inflammation of the iliac and femoral vein, related by Dr. C. Forbes.—(*Med. Chir. Trans.*, vol. xiii., p. 296.) "The morbid appearances observed in this instance," he says, "were very similar to those which have been described by Dr. Davis. Had the subject of the disease been a woman in the puerperal state, would it not," he asks, "have been considered phlegmasia dolens?" This example, be it observed, is an additional corroboration of the statement respecting the condition of the veins. A peculiar swelling of the lower extremity coming on after fever, and corresponding very much in its character and progress to phlegmasia dolens, was lately described by Dr. Tweedie, who points out its differences from common œdema of the limb, and represents it as an inflammation of the cellular tissue.†

* In January, 1823, several cases and dissections were published by Bouillaud, in which the crural veins were found obliterated in women who had had a swelling of the lower extremity after delivery. Although these cases were printed four months before Dr. Davis's paper was read, "it does not admit of dispute," says Dr. Lee, "that Dr. Davis was the first who proved by dissection, that phlegmasia dolens depended on inflammation of the iliac and femoral veins."—(See *Cyclop. of Pract. Med.*, art. PHLEGMASIA DOLENS.) The numerous cases and dissections of which Dr. Lee has since published the histories in the *Med. and Chir. Trans.*, and in a recent work on the "Pathology and Treatment of some of the most important Diseases of Women," offer a still more complete explanation of the subject; demonstrating that if inflammation be excited in the uterine branches of the hypogastric veins, it may spread from them to the iliac and femoral veins, and by the morbid changes induced in them, give rise to all the usual symptoms.—Ed.

† *Edin. Med. Journ.*, No. xcvi., p. 258. In the spring of 1833, a case of chronic dysentery in a man came under the observation of Dr. Macann, in which phlegmasia dolens took place before death. On dissection, the common iliac, the external iliac, and femoral veins of the left side, were found to be completely obstructed, and their coats extensively disorganized by inflammation. The preparation is in the possession of Dr. Lee, to whom it was given by Dr. Forbes. In the male

In about twelve or fourteen days after delivery, according to the common course of the disease, the patient complains of pain in the groin of one side, accompanied with the general train of pyretic symptoms, but without the precursive shivering. The part affected soon becomes swelled and distended, the swelling usually extending to the labia pudendi of the same side, and down the inside of the thigh to the leg and foot; in a day or two, the limb is double its natural size, is hot, exquisitely tender, and moved with great difficulty. It has not, however, the ordinary external signs of inflammation, but is hard, smooth, glabrous, pale, and equable, except where the conglobate glands are situate, which are corded and knotty, as in the groin, the ham, and the back and fleshy part of the leg. There is occasionally an uneasiness in the loins, and in the region of the pubes on the same side. The swelling has sometimes appeared as early as twenty-four hours after delivery, and sometimes not till five weeks afterward. The accompanying fever, which is of a hectic form, usually declines about the fourteenth or twenty-first day, but in some cases runs on for six or eight weeks, and the patient becomes greatly emaciated. The first appearance of improvement takes place about the groin, where the disease commenced, the pain and tumour gradually subsiding in this quarter, and the amendment spreading in a continuous line.* Sometimes, though rarely, both sides are affected simultaneously, and, in a few instances, the sound leg has exhibited something, though a less degree, of the same complaint, as the diseased leg has improved. The improvement is very slow; and, in many cases, the affected limb continues weak, and with morbid enlargement through life.

[Velpeau's opinion, that the origin of the disease is connected with an alteration of the sacro-iliac symphysis, has been already noticed.] Dr. Whyte, M. Caspar, and Mr. Trye, concur in deriving the disease from some affection of

sex, the disease may commence either in the hemorrhoidal, vesical, or other branches of the internal iliac veins, in consequence of inflammation, or organic changes of structure in one or more of the pelvic viscera. It arises, however, much more frequently from inflammation, excited in the superficial veins of the leg, and extending upwards to the great venous trunks of the thigh and pelvis, as exemplified in several examples collected by Dr. R. Lee, from the practice of Sir Astley Cooper and others. Phlegmasia dolens seems to the editor, then, not to be precisely synonymous with crural phlebitis but an occasional effect of it.—Ed.

* Dr. Mann, of Boston, states the following curious fact in regard to bucnemia. He was called in consultation to a case of this disorder, where the attending physician, supposing the swelling contained some fluid which required to be evacuated, had made an incision through the skin and adipose substance of the enlarged limb, in order to discharge its contents: "herein," adds Dr. M., "he was not only disappointed, but, to his mortification, the incised part became gangrenous: a sphacelus of the whole limb soon followed, which terminated fatally in about ten days after the operation."—*Conn. Mass. Med. Soc.*, vol. ii.—D.

the lymphatics of the distended side. Dr. Whyte refers it to an extravasation from the lymphatic vessels ruptured by the pressure of the child's head: Professor Caspar, to a mixed inflammation of the absorbents and cellular membrane (*Comm. de Phlegmasia dolens*, 8vo., Halle, 1819); and Mr. Trye, to inflammation of the lymphatic glands. Dr. Ferriar ascribes it to inflammation of the side affected generally; and Dr. Hull to a joint inflammation of the muscles, cellular membrane, and inferior surface of the cutis seated in the affected part, and an effusion of coagulable lymph, the large blood-vessels, nerves, lymphatic glands, and glands imbedded in them at times participating in the inflammatory action. The last, if not the real cause, would be sufficiently plausible if the inflammation be supposed to commence in the lymphatics, instead of being merely extended to them. As it is, Dr. Hull's hypothesis has been adopted and enlarged by Dr. Hosack, who regards the complaint as an inflammatory disease, "not merely affecting the limb, but the whole system," commencing, not in the groin or pelvis, but about the calf of the leg; not limited to the lymphatics or even to females, but common to both sexes, and to every part of the affected limb; sometimes appearing in both limbs at the same time; and where depletion is not actively employed, occasionally, like gout and rheumatism, transferred from one limb to another: produced usually by a suppression of the natural excretions, exposure to cold, stimulating drinks, and other means of excitement. To the disease thus described Dr. Hosack has given the name of *CRURITIS* (*Obs. on Cruritis, or Phlegmasia Dolens*, 8vo., New-York, 1822), not quite classically formed; as partaking of two distinct tongues, and not quite applicable to an affection so variable as to seats, and so migratory even when it once shows itself. The disease is ably described, and followed up with the hand of a master, but it is not, as it appears to me, the disease before us, and belongs rather to our next genus.

Mr. Davis has probably thought the same; for he has entirely stripped the tumid leg of the unrestrained license of attack allowed it by Dr. Hosack, and of its migratory spirit afterward: has restrained it to the female sex, and to the immediate neighbourhood of the pelvis. "The proximate cause," says he, "of the disease called phlegmasia dolens, is a violent inflammation of one or more of the principal veins within, and in the neighbourhood of the pelvis, producing an increased thickness of their coats, the formation of false membranes in their internal surface, a gradual coagulation of their contents; and occasionally a destructive supuration of their whole texture: in consequence of which, the diameters of the cavities of these important vessels become so gradually diminished, sometimes so totally obstructed, as to be rendered mechanically incompetent to carry forward into their corresponding trunks the venous blood brought to them by their inferior contributing branches."—(*Med. Chir. Trans.*, vol. xii., part ii., p. 3.)

Here again we have a very accurate description of a disease by no means uncommon, which, moreover, is supported by a variety of cases, most of which have unfortunately a history of their dissections appended to them, containing a clear manifestation of the nature of this very fatal inflammation, and for the most part of the formation of a false membrane within the affected vessel. But if the present author have succeeded in truly delineating the disease before us, either in his specific definition or his diagnostic description, it must be obvious to every reader who will compare them with the appearances laid down by Dr. Davis, that two different inflammations are referred to in the respective statements, the symptoms of which cannot possibly co-exist; that the very fatality of that described by Dr. Davis is of itself a sufficient proof of a clear and very striking distinction;* and that, though both occasionally take place soon after childbirth, the enlargement he has treated of is far less a phlegmasia dolens than a particular variety of venous inflammation, the *PHLEBITIS* of several authors: for a striking example of which, proceeding from an obscure cause, and extending over the arm instead of over the leg, I may refer to Dr. Duncan's interesting case, in the Transactions of the Edinburgh Medico-Chirurgical Society.† It gives us the same general swelling over the entire limb; rather phlegmonous than erythematous; but, to adopt the author's own simile, still more resembling an anasarous affection, yet without pitting. It gives, moreover, the same fatal result; and, on examination after death, develops the same thickening of the coats of the vein, and the same obstruction from morbid secretions. And to show still further how little foundation there is for this doctrine, we have in the very next article in the same volume, composed by the same indefatigable author, various cases of diffuse inflammation of the cellular membrane without any affection of the neighbouring veins, so closely approaching the general character of the sparganosis before us, that he finds a difficulty in calling them by any other name, and appears greatly inclined to adopt Dr. Hull's hypothesis of the disease.—(*Trans. Medico-Chir. Soc. Edin.*, vol. i., p. 582.)

There is apparently as little reason for the hypothesis of Dr. Denman, who, while regarding it as an inflammation of the lymphatics, refers the inflammation to an absorption of some acrimonious matter secreted by the uterus; for the

* As Dr. Davis's main object was to record the appearances on dissection, the circumstance of his having brought forward only fatal cases must not be received as a proof of the general or common fatality of the disease.—Ed.

† Case of Inflammation of the Cephalic Vein, which terminated fatally, vol. i., p. 439. The swelling, named by Dr Good *bucnemia sparganosis*, and more commonly by other writers *phlegmasia dolens*, is to be regarded as an occasional effect of the obstruction and disorganization of the femoral and iliac veins by phlebitis. On this ground the editor cannot regard the proposed name of *crural phlebitis*, as a substitute for *phlegmasia dolens*, as correct.—Ed.

disease has occurred where there has been no more morbid action of the uterus than of the mamma; and all the secretions have proceeded healthily and in their proper quantity.*

The cure is to be attempted first by a free application of leeches all along the course of the limb, poppyhead fomentations, or, what is better, a swathe of flannel wrung out in hot water applied over the whole extent of the limb, surrounded by a loose bandage of sheeting. To this plan should be added purgatives of considerable activity, and where the irritation is considerable, free doses of Dover's powder. General bleeding is rarely, though sometimes necessary. As soon as the inflammatory symptoms have a little subsided, local stimulants may be had recourse to, so as to excite the torpid absorbents to increased action: of which the most useful in the author's hands has been the liniment of ammonia with laudanum.

The laudanum, on a cursory view, may seem to add to the vascular torpor; but it tends to take off the pain and soreness that still remain, and thus enables the tranquillized vessels the more easily to recover their tone. Yet whatever application of this kind is employed, it should be accompanied with gentle friction, continued for half an hour or more, if the limb is able to bear it; for the friction itself is of essential service, and tends, perhaps, even more than any other local stimulant, to restore the limb to a healthy action.

Mr. Trye advises, for the same purpose, the use of mercurial ointment; and others that of small doses of calomel. But neither have proved decidedly useful; while in some instances of great debility, they have evidently produced mischief. The chronic weakness is to be removed by a continuance of the friction, bathing with sea-water, or, which is much better, bathing in the sea itself, an elastic flannel bandage, horse-exercise, pure air, and, if necessary, general tonics and astringents. [Dr. Lee has not seen any benefit produced by mercurial and iodine applications; and, at the commencement, he relies chiefly on the free abstraction of blood by leeches applied above and below Poupart's liga-

ment, in the direction of the femoral and iliac veins. In a case recorded by Dr. Sims, great relief was derived from puncturing the swelling in different places with a needle.—(Dr. R. Lee's art. PHLEGMASIA DOLENS, in *Cyclop. of Pract. Med.*)]

SPECIES II.

BUCNEMIA TROPICA.

TUMID LEG OF HOT CLIMATES.

THE TUMID LIMB HARD, LIVID, AND ENORMOUSLY MISSHAPEN; SKIN AT FIRST GLABROUS, AFTERWARD THICK, SCALY, AND WARTY; SUCCESSIVELY BULGING AND INDENTED: OCCURRING CHIEFLY IN TROPICAL CLIMATES.

This species is intended to comprise that singular disease, known in the West Indies, and generally over Europe, by the name of *Barbadoes leg*, from its being indigenous to the Island of Barbadoes. Yet it is not in Barbadoes alone that it makes its appearance; for it is of high antiquity, as well as of very wide range, in hot, and especially in tropical climates; and

constitutes the genuine *دَاءُ الْفِيلِ* *dal-fil* or elephant-leg of the Arabians, being so denominated from its livid, tumefied, scaly, misshapen appearance. As the Arabic *dal* or *دال* *دَاءُ الْفِيلِ* is literally elephantiasis or elephant-leg, and as the Greeks distinguished another and very different disease by the name of elephantiasis, the Greek translators of the Arabian writers were very generally betrayed, from the unity of the name, into a confusion of the two disorders, as we shall have occasion still further to observe when treating of proper ELEPHANTIASIS under the fourth order of the present class: and the confusion has, in a considerable degree, descended to our own times, inasmuch that many writers of the present day continue to jumble the elephantiasis, or elephant-leg, of the Arabians, with the elephantiasis, or elephant-skin, of the Greeks, and to describe them as a common affection, though

* The views of American writers on the nature of bucnemia sparganosis differ as much as those of European authors. In a paper of some extent (N. A. Med. and Surg. Journal, vol. iv.), Dr. Huston considers the disease "as consisting in a complete engorgement of the whole lymphatic system of the affected limb, produced by an inflamed condition of the different conglobate glands, through which the chief lymphatic vessels have to pass, on their way from the affected part to the thoracic duct." Eberle (Practice of Med.) entertains the same belief. Dewees doubts the accuracy of the views of Davis in assuming the disease to be analogous to phlebitis (Practice of Physic). Dr. Jameson, of Baltimore, considers it "as but a variety of an extensive group of inflammations, the peculiar characteristic of which is, a tendency to the effusion of serum or watery fluid."—(Amer. Med. Recorder, vol. xv., p. 66.) Dr. Francis's paper (New-York Med. and Phys. Journal, vol. i.) mentions several instances of bucnemia, attended with peculiar circumstances; among others, an example of the disorder affecting a male subject;

an instance of the transfer of the complaint from one limb to the other in the same lying-in female; another case also, in which the same female became affected with it in four successive labours; at each recurrence it attacked the same limb, the right; in another case, where bucnemia appeared in the arms. According to Dr. Beck, Ferriar was the first author who remarked that this disease might appear in the upper extremities, and Carus has mentioned instances of its occurrence there. Callister takes the same view of its seat, as existing sometimes in the upper limbs: the opinion of Dr. F., therefore, that other parts than the lower extremities may become its seat, has the concurrent testimony of several eminent men in its behalf; and very recently, Otto, in his *Handbuch der Pathol. Anat.*, vol. i., has sanctioned the same belief.

American practitioners generally treat this disease with great activity, by bloodletting and other depletory means. Dr. Dewees has found it necessary to bleed six or seven times before the complaint yielded.—D.

no two complaints can be more unlike: the former being a mere local malady, produced accidentally, and confined to the individual who labours under it; and the latter a constitutional disease, in every quarter hereditary, and in most quarters contagious.

The Arabians, however, had the disease called elephant-skin, the elephantiasis of the Greeks, by themselves called *juzam* جزام, as well as the *dal-fil*, or elephant-leg, the disease before us. And, as the malady called leprosy, and by the Arabians *beras* برص, was supposed by many physicians, as well Arabian as Greek, to terminate frequently in *juzam*, or proper elephantiasis, the disease before us has occasionally also been confounded with leprosy as well as with elephant-skin, and all the three affections have been huddled together by many writers into one common disease. Even Dr. Schilling, a late practitioner of considerable merit at Surinam, has not escaped this last error; for he describes the tumid leg under the name of leprosy; confuses its earliest symptoms and appearance with those of the leprosy of the Greeks, and especially with those of the *lepra* or *lepræ candida*, and then distinguishes elephantiasis, the disorder he professes to be the immediate subject of his pen, as a peculiar branch of leprosy, merely varied by its commencing in the feet, instead of in any other part of the body; and, carrying on the confusion, he next interprets the tumid leg, or disease before us, as a mere variety of elephantiasis.—(*G. G. Schillingii de Lepræ Commentationes*, 8vo., Lugd. Bat., 1776.)

For a distinct and more correct account of this species, we must turn to the writings of Dr. Hillary (*Works*, vol. i., p. 549, 4to. edit., 1799) and Dr. Hendy, who have judiciously separated it from both the leprosy and the elephantiasis of the Greek writers, and treated of it as an individual malady: the former under the name of "Barbadoes leg," and the latter under that of the "Glandular Disease of Barbadoes." It is singular, however, that Dr. Hendy should have adopted the erroneous idea, that the disease before us is not only endemic to Barbadoes, but that it is to be found nowhere else; and that patients who migrate from this island for a cure are almost sure to obtain one, unless in a chronic or inveterate stage of the disease, to whatever quarter they direct their course. It has been known immemorially in India, and is by the oriental writers, and even by Sir William Jones, justly distinguished from the *juzam*, which he tells us must not be confounded with the *dal-fil*, or swelled legs described by the Arabian physicians, and very common in that country. It is also indigenous to the Polynesian Isles, where it takes the name of *yava-skin*, as being supposed to originate from drinking the heating beverage called *yava*; and, like the gout among ourselves, is regarded in a sort of honourable light.*

The tropical bucnemia, like the puerperal, is occasioned by an effusion of coagulable lymph into the cellular membrane under the skin of the part affected, in consequence of inflammation of the lymphatics of the lower limb, and especially of the inguinal glands; the cause of which is at present quite unknown.

[The doctrine, that the disease essentially consists in an inflammation of the lymphatic vessels and glands, may be said now to be on the decline. In fact, we commonly see these organs inflamed, both in warm and cold climates, without any consequences resembling bucnemia tropica. Dr. Graves (*Trans. of the King's and Queen's College of Physicians*, vol. v., p. 65) notices various circumstances amounting very nearly to a complete refutation of the opinion. Thus, he particularly adverts to a passage in Dr. Hillary's work, from which it appears that the disease sometimes attacks the arm, scalp, ears, back part of the neck, the loins, &c. Enormous chronic growths of the integuments and cellular membrane sometimes affect the arm, penis, and scrotum, even in this country; the disease closely resembling the Barbadoes leg, and examples of which had been seen by Mr. Chevalier.—(*See Med. Chir. Trans.*, vol. ii., p. 71.) It is obvious, as Dr. Graves has remarked, that, in such parts, the swelling could not have arisen merely from glandular inflammation; and as, from various facts which he has brought forward, it is proved that inflammation of the skin and subjacent cellular tissue is in itself capable of producing a swelling, in all other respects similar to that of Barbadoes leg, he is inclined to think that a more accurate investigation of the subject would have induced Dr. Good to modify the opinion he has delivered on the subject.

As far as the point can be decided by a reference to cases very similar to the Barbadoes leg, which have occasionally taken place in Great Britain or Ireland, the editor certainly joins Dr. Graves in the belief, that the disease does not arise from, or essentially consist in, disease of the lymphatic glands or vessels. In the highly interesting example of an extraordinary enlargement of the right lower extremity, recorded by Mr. Chevalier, and which occurred in an English woman in this metropolis, no change in the absorbent glands could be detected after death, either at the groin or within the pelvis.—(*Op. cit.*, vol. ii., p. 67.) In a very similar case, related by Dr. Graves, and which happened in a young man, twenty-five years of age, admitted into the Meath Hospital, "the swelling had commenced many years before his admission into the hospital, and had attained its enormous size gradually, and without the least pain or inflammation of the skin, the subjacent adipose tissue, or *inguinal glands*." Dr. Graves has no doubt, that, as in Chevalier's case, the tumefaction arose from an extraordinary growth of the skin and subjacent adipose

in natives of the United States who have never visited a tropical climate.—See Hosack's *Med. Essays*, vol. iii., p. 99.—D.

* Cases of bucnemia tropica have occurred also

membrane, quite independently of inflammation.*

The diseases described by Mr. Chevalier and Dr. Graves, seem to the editor to correspond to the enormous growth of the scrotum, so common in Egypt and other warm countries, yet sometimes met with in France, this country, and other parts of Europe.† Dr. Graves is of opinion, that the example which he has published is entirely different both from phlegmasia dolens and the Barbadoes leg, which affections, he says, arise from inflammation. It certainly appears, that some extraordinary enlargements of the lower extremity have depended upon a chronic growth and thickening of the integuments and cellular tissue, no inflammation having occurred, at all events, until the disease was far advanced. Yet, in other instances, a similar alteration of the skin and cellular membrane has been preceded either by an attack like that of phlegmasia dolens, as happened in Mr. Chevalier's example, or by fever, and heat and redness of the skin, as illustrated in one curious modification of the disease, described by Dr. Graves, and, as it seems, by no means uncommon in Ireland, where it affects the arms, perhaps, more frequently than the legs.]

In the tumid leg of hot climates, the skin, instead of maintaining the paleness of the first species, very soon becomes suffused with a deep red or purple hue; while the saburral fluid that exudes from the cutaneous exhalants, concretes, as its finer parts fly off, into rough and sordid scales, and the skin itself becomes enormously thickened and coriaceous.

The effusion is usually preceded by a febrile paroxysm, induced by the glandular inflammation just noticed; and which, from the first, discovers a tendency to recur, though often at irregular periods, so as to resemble an erratic intermittent. Every fresh attack adds considerably to the effusion, and consequently to the morbid size of the limb, and exacerbates every symptom; and hence the greater severity of this species than of the former, and the monstrous disfigurement of the leg and foot by which it is

distinguished. In many instances, also, the inflammation extends to the surrounding as well as to the descending parts; and hence the scrotum, like the pubes in puerperal bucnemia, is often peculiarly affected and distended to an enormous magnitude; while, occasionally, the glands of the axilla participate with those of the groin, and the forearm becomes also enlarged. In a few instances, the disease is said to have commenced in the axilla; but such cases are very rare, and not well established.

In this manner the disease at length assumes a chronic character: the monstrous size and bloated wrinkles of the leg are rendered permanent; the pain, felt acutely at first, subsides gradually, and the brawny skin is altogether insensible. Yet, even from the first, except during the recurrence of the febrile paroxysms, the patient's constitution and general functions are little disturbed; and he sometimes lives to an advanced age, incommenced only by carrying about such a troublesome load of leg; which, however, as we have noticed already, is regarded in the Polynesian Isles as a badge of honour.

In our own country, the disease is rarely met with but in its confirmed and inveterate state, after repeated attacks of fever and effusion have completely altered the organization of the integuments, and rendered the limb altogether incurable. In this state, the distended skin is hard, firm, and peculiarly thickened, and even horny; while the muscles, tendons, ligaments, and bones are, for the most part, little affected. [Most of the cases noticed in London are in Africans. The editor has seen one or two such examples in St. Bartholomew's Hospital. The most remarkable of these was published in one of the early volumes of the Medical and Physical Journal.]

In this advanced stage, the disease seems to be altogether hopeless: nor in any stage has the practice hitherto pursued been productive of striking success. This has consisted chiefly in endeavours to alleviate the febrile paroxysms by laxatives and diaphoretics, and subsequently to strengthen the system by the bark. It would be better, perhaps, by active and repeated bleedings, as well general as local, and powerful purgatives, to endeavour to carry off the whole of the first effusion as quickly as possible; and then to direct our attention to a prevention of the paroxysms to which the constitution appears to be peculiarly subject, after a single one has taken place, by prohibiting exposure to the damp air of the evening, and by the use of tonics.

An original and chronic affection of this kind, in which the integuments of the legs were much thickened, the limbs swelled to such an extent as to prevent the patient from walking, and incrustated with such a vast quantity of brawny scurf and scales, that handfuls of them might be taken out of his bed every morning, was successfully attacked many years ago by a mistake of one plant for another. The case is related by Dr. Pulteney; and the patient, who had been recommended to swallow a table-spoonful of the juice of the water-parsnip, with two

* Trans. of the King's and Queen's College of Physicians, vol. v., p. 56. A woman died in La Charité in 1820, with what Andral calls elephantiasis of one of her lower extremities, but which, probably, corresponded to the cases arranged by Dr. Good under the present title. The muscles were found, after death, reduced to a few pale, slender fasciculi; but the cellular substance was converted into an enormous mass, very hard, and including in some places cells filled with a serous fluid. At certain points it had all the physical qualities of cartilage.—(Anat. Pathol., tom. i., p. 277.) The same author has also seen an extraordinary ossification of the layers of the intermuscular cellular tissue, in the leg of a subject that died with bucnemia. The muscles were in the state of atrophy. The osseous matter, which was deposited in the spaces between the layers of muscles, was blended, in the deeper part of the limb, with bony vegetations arising from the periosteum.—Vol. cit., p. 297.

† See the editor's Dict. of Practical Surgery, art. SCROTUM, published by Harper & Brothers, New-York, 1834.

spoonfuls of wine, every morning fasting, was erroneously supplied with half a pint of what afterward appeared to be the juice of the roots of the hemlock-dropwort (*anemone crocata*, Lin.): the first dose produced such a degree of vertigo, sickness, vomiting, cold sweats, and long-continued rigour, that it almost proved fatal. So strong, however, was the patient's desire of relief, that, with the intermission of one day, he repeated the dose with a slight diminution in the quantity. The effects were still violent, though somewhat less alarming; and he persisted in using half the quantity for several weeks. At the end of a month he was very greatly improved, and, shortly afterward, the whole of his symptoms had nearly left him.—(*Phil. Trans.*, vol. lxiii.)

Amputation of the affected leg has sometimes been made trial of, but apparently without any success. Dr. Schilling informs us, that in some, a locked jaw takes place about the seventh day from the operation, which is soon followed by tetanus, and ends in death; that, in others, fatal convulsions ensue immediately; and that those who survive the operation, have wounds hereby produced that will not heal; while the disorder, still connected with constitutional causes, often seizes on the other foot.—(*G. G. Schillingii de Leprâ Commentationes*, 8vo., Lugd. Batav., 1776.) And, in this last assertion, he is corroborated by one or two cases related by Dr. Hendy.—(*On the Glandular Disease of Barbadoes*, 8vo., 1784.)

[In the modification of the disease represented by Dr. Graves as common in Ireland, and as following fever and repeated attacks of a kind of inflammation, more like erysipelas than any thing else, he suggests the following treatment. When the case is not of very long standing he recommends, during the febrile paroxysms, antiphlogistic treatment, purgatives, leeches repeatedly to the inflamed parts, and cold lotions. During the intermissions, rest, moderately tight bandages, bark, and, if it fails, arsenic. The moment the inflammatory paroxysms recur, the antiphlogistic plan is to be resumed.]—(*Dr. Graves, in Trans. of the King's and Queen's College of Physicians*, vol. v., p. 46.)

GENUS XII.

ARTHROSIA.

ARTICULAR INFLAMMATION.

INFLAMMATION MOSTLY CONFINED TO THE JOINTS;
SEVERELY PAINFUL; OCCASIONALLY EXTENDING
TO THE SURROUNDING MUSCLES.

ARTHROSIA is a term derived from ἀρθρώω, "to articulate," whence arthrosis, arthritis, and many other medical derivations. The usual term for the present genus of diseases, among the Greek physicians, was *arthritis*, which would have been continued without any change, but that for the sake of simplicity and regularity, the author has been anxious to restrain the termination *itis* to the different species of the genus ENPRESMA.

Arthritis, then, among the Greeks, was used in a generic sense, so as to include articular inflammations generally. But as almost every sort of articular inflammation has, in recent times, been advanced to the rank of a distinct genus in itself, it has frequently become a question, to which of them the old generic term should be peculiarly restrained. And hence some writers have applied and limited it to gout; others have made it embrace both gout and rheumatism; others again have appropriated it to white swelling; while a fourth class of writers, in order to avoid all obscurity and dispute, have banished the term altogether.

Now gout, rheumatism, whether acute or chronic, and white swelling, however they may differ in various points, as well of symptoms as of treatment, have striking characters that seem naturally to unite them into one common group. Gout and rheumatism are so nearly allied in their more perfect forms, as to be distinguished with considerable difficulty; and in many instances, rather by the collateral circumstances of temperament, period of life, obvious or unobvious cause, antecedent affection or health of the digestive function, than from the actual symptoms themselves. Stoll maintains that they are only varieties (*Rat. Med.*, part iii., p. 122–137; v., p. 420) of the same disease: Bergius, that they are convertible affections. White swelling, in one of its varieties, is now uniformly regarded as a sequel of rheumatism, or the result of a rheumatic diathesis; while the other varieties cannot be separated from the species.

From the close connexion between gout and rheumatism, Sauvages, and various other nosologists, distinguish some of the cases of disguised gout by the name of *rheumatic gout*. Mr. Hunter warmly opposed this compound appellation; for his doctrine was, that no distinct diseases, or even diseased diathesis, can co-exist in the same constitution. And, as a common law of nature, the observation is, I believe, strictly correct; one of the most frequent examples of which is the suspension of phthisis during the irritation of pregnancy. But it is a law subject to many exceptions; for we shall have occasion, as we proceed, to notice the co-existence of measles and smallpox; and I had not long since under my care, a lady in her forty-ninth year, of delicate health and gouty diathesis, who was labouring under a severe and decisive fit of gout in the foot, which was prodigiously tumefied and inflamed, and had been so for several days, brought on by a violent attack of lumbago,* to which she was then a victim, and which rendered her nights more especially sleepless and highly painful. The constitutional disease had in this case been roused into action by the superadded irritation of the accidental disease; and the two were running their course conjointly. It is also

* Lumbago is so common in gouty subjects, that the editor is inclined to believe it is as frequently met with in them as in rheumatic patients. He cannot, therefore, regard the above case as decidedly proving the co-existence of gout and rheumatism in the same individual.

a striking fact, that one of the severest illnesses that attacked Mr. Hunter's own person, and which ultimately proved to be disguised gout, *podagra lata*, he suspected, in its onset, to be a rheumatic ailment. The case, as given by Sir Everard Home, in his life of Mr. Hunter, is highly interesting and curious, as showing the singular forms which this morbid Proteus sometimes affects, and the various seats it occupies; as also, that a life of abstemiousness and activity is no certain security against its attack; for Mr. Hunter had at this time drunk no wine for four or five years, and allowed himself but little sleep at night.

Arthrosia, therefore, as a genus, may, I think, be fairly allowed to embrace the following species:

1. Arthrosia Acuta. Acute Rheumatism.
2. ——— Chronica. Chronic Rheumatism.
3. ——— Podagra. Gout.
4. ——— Hydarthrus. White Swelling.

SPECIES I.

ARTHROSIA ACUTA.

ACUTE RHEUMATISM.

PAIN, INFLAMMATION, AND FULNESS, USUALLY ABOUT THE LARGER JOINTS AND SURROUNDING MUSCLES; OFTEN WANDERING; URINE DEPOSITING A LATERITIOUS SEDIMENT; FEVER A CAUSA.

THE disease varies in respect to violence of the fever, and seat of the pain. The varieties, determined mostly from the last feature, are as follow:—

- | | |
|-----------------------|---|
| α Artuum. | Pain felt chiefly in the joints and muscles of the extremities. |
| Articular rheumatism. | |
| β Lumborum. | Pain felt chiefly in the loins; and mostly shooting upwards. |
| Lumbago. | |
| γ Coxendicis. | Pain felt chiefly in the hip-joint, producing emaciation of the nates on the side affected, or an elongation of the limb. |
| Sciatica. | |
| δ Thoracis. | Pain felt chiefly in the muscles of the diaphragm, often producing pleurisy of the diaphragm. |
| Spurious pleurisy. | |

The common remote cause of ARTICULAR RHEUMATISM, as of all the other varieties, is cold or damp applied when the body is heated: though it may possibly be produced by any other cause of inflammatory fever, where the constitution has a peculiar tendency to a rheumatic action. This tendency or diathesis seems to exist chiefly in the strong, the young, and the active; for, though it may attack persons of every age and habit, these are principally its victims. We may hence, as well as from its symptoms, prove rheumatism to be an inflammatory disease. "Even in the weak and emaciated," observes Dr. Parr, "the pulse is hard, the blood coriaceous, and bleeding often indispensable." [Rheumatism is seldom met with

in very young children, and, out of one hundred rheumatic patients, ninety are above the age of sixteen. The following is the result of what was noticed in relation to this point by M. Chomel, in La Charité. Out of seventy-three patients attacked by rheumatism, thirty-five were between the ages of fifteen and thirty; twenty-two between thirty and forty-five; seven between forty-five and sixty; seven were turned sixty; and only two were under fifteen.

Daily experience proves that both sexes are subject to rheumatism. If women more frequently escape from it, owing perhaps to their less robust constitutions, and their being generally less exposed to cold and damp than the other sex, they are still known to be particularly liable to it when, after being tenderly brought up, they are exposed to the exciting causes; and their tendency to be attacked by it is known to be increased by interruption of the menstrual discharge. Hence, also, women between the ages of forty and fifty frequently suffer from it. Rheumatism is not so prevalent in certain families as gout; in other terms, it is less hereditary. Yet, though the disease can hardly be called hereditary, an individual born of rheumatic parents will certainly be in greater risk of suffering from the complaint than another person whose parents were quite healthy. According to a table kept by M. Chomel, out of seventy-two rheumatic patients, thirty-six had rheumatic parents, twenty-four had healthy parents, and twelve could furnish no information on the subject.] How far the observation of Sir C. Wintringham is true, that those who have suffered amputation are susceptible of this disease more than others (*Comment. de Morbis quibusdam*, art. 79), the author cannot say from his own practice; but it is the remark of a physician who was not accustomed to form a hasty judgment.

[The generality of writers, down to the beginning of the present century, admit that the seat of rheumatism may be either in the muscles or the fibrous tissues, so called by Bichat, consisting of the capsules of the joints, fibrous sheaths, the periosteum, and other fibrous membranes, the aponeuroses, tendons, and ligaments. This is the doctrine of Rivière, F. Hoffman, A. Leroy, and Pinel; to whom is to be added M. Chomel. Among those who believe that rheumatism may be seated indifferently, either in the muscular system or the fibrous, some conceive that the disease never extends to the muscles but secondarily, and that it always first attacks the fibrous or ligamentous structures. Dr. Clutterbuck, in his lectures, even defines rheumatism to be an inflammation of the ligamentous structure, connected with the different joints, and covering the muscles attached to them; which is in fact the theory of Bichat. Dr. Scudamore, who regards the tendinous portions of the muscles as the seat of rheumatism, believes that, if the muscular fibres were inflamed, they would be affected with swelling, which is not the case, while an increase of volume is always observable in the fibrous structures attacked. In opposition to the

hypothesis of Dr. C. Smyth, that the essential seat of rheumatism is in the muscles, Dr. Scudamore does not consider the permanent weakness of these organs, the diminution in their size, the imperfection of their action, and the pain following their contraction, as proofs of the inflammation having its seat in the muscular fibres; but only as the consequences of the impairment of the synovial and tendinous structures, and of the extension or disturbance of these textures in a state of inflammation, whenever the muscles are put in action.

Acute rheumatism chiefly attacks the fibrous parts of the large joints of the shoulder, hip, knee, elbow, &c., and the muscular aponeuroses.* This inflammation is not in reality attended with much swelling of the texture essentially affected, the density of which prevents any considerable effusion of lymph into its interstices. It is true, however, as Dr. Clutterbuck has remarked, that a good deal of swelling often attends acute rheumatism; but this is owing to the extension of the inflammation into the surrounding cellular texture.]

A few years ago, the proximate cause of rheumatism was imputed to inflammation of the arteries themselves of the muscles and tendons; in short, to an immediate *arteritis*. Some cases and dissections, in support of this doctrine, were brought forward in France by M. Barde (*Obs. communiquées à la Société de Méd.*), and MM. Dalbanc and Vaidy (*Dict. des Sciences Méd. Journ. Compl.*, vi., Août, 1819); but the anomalous diseases to which they refer have not been generally received as examples of rheumatism.

In the case related by Mr. Barde, the heart, all the larger arteries, and even the *venæ cavae*, gave evident proofs of inflammatory action. Their coats were thickened, hardened, of a dark-red colour, in some parts covered with a whitish purulent matter, and in some the interior tunica was destroyed: the heart itself being considerably enlarged and inflamed.

[The foregoing hypothesis of *arteritis* being the proximate cause of acute rheumatism, is sufficiently refuted by the consideration, that, if it were true, rheumatism would always accompany arterial inflammation, which is not the fact. If another argument were required to subvert the opinion, it might be readily found in the flying and very wandering nature of rheumatic pains, which pass, as Bichat (*Anat. Gén.*, tom. ii., p. 263) expresses himself, with astonishing quickness, from one situation to another. Broussais, in his *Leçons Pathologiques*, thus accounts for rheumatism: "When," says he, "the action of the skin is diminished, it is determined to another part; and here it is to the capsules or articular ligaments, the textures around the joints, that the irritation is determined."]

In the general course of acute rheumatism,

* The parts are generally hot and red, and frequently the pain is situated in the theca of the tendons: Dr. Elliotson has noticed red streaks in the direction of the latter parts.—Lect. at Lond. Univ., as published in *Med. Gaz.* for 1833, p. 652.—ED.

its peculiar inflammation does not continue long enough in any one organ to injure the structure of the arterial tunics; often, in effect, as in gout, we witness its disappearance in a moment, and find it migrating to some other part of the body.

As a general rule, it may be asserted, that rheumatic inflammation does not tend to suppuration. [It is one of the characters of the fibrous system hardly ever to suppurate. Bichat believed that rheumatic inflammation never ended in the formation of an abscess, though coagulable lymph might be sometimes effused round the tendons affected.] In a few rare instances, the contrary has been known to take place (*Morgagni, De Sed. et Caus. Morb.*, ep. lvii., art. 20; *Med. Comment. Edin.*, vol. iv., p. 198); and, in one or two cases, I have myself been a witness to an extensive abscess. But the general rule is not disturbed by such rare exceptions. The inflammation, therefore, is of a peculiar kind. There will often, indeed, be effusion, and the limb will swell considerably; but the effused fluid is gradually absorbed, and the swelling not unfrequently, though not always, is accompanied with an alleviation of the pain.

Sometimes the pains take the precedence of the fever; but, in other cases, the fever appears first, and the local affection does not discover itself till a few days afterward.* There is no joint, except perhaps the extreme and minute joints of the fingers and toes, but is susceptible of its attack, although it usually commences in, and even confines itself to, the larger. Among these, however, it frequently wanders most capriciously, passing rapidly from the shoulders to the elbows, wrists, loins, hips, knees, or ankles, without observing any order, or enabling us in any way to prognosticate its course; always enlarging the part on which it alights, and rendering it peculiarly tender to the touch. The urine is often at first pale, but soon becomes high-coloured, and deposits a red sediment. It may be distinguished from gout by being little connected with dyspepsy, commencing less suddenly, evincing more regularly-marked exacerbations at night, but less clear remissions at any time: to which we may add, its attachment to the larger, rather than the smaller joints; and its connexion with exposure to cold and damp. It runs on from a fortnight to three weeks; and the average of the pulse is rarely under a hundred.

The fever is generally accompanied with copious and clammy sweats [often of an exceedingly sour smell]; but the skin still feels tense and harsh; nor does the sweat issue freely from

* Acute rheumatism presents a state of active fever, accompanied with inflammation of the fibrous tissues about the joints. One point not entirely decided is, whether the fever is the cause or the effect of the inflammation? Sydenham adopted the first of these views, which has found an able advocate in Dr. Barlow (*Cyclop. of Pract. Med.*, art. RHEUMATISM), who endeavours to prove (a fact generally acknowledged) that the state of the constitution is what principally claims regard in the treatment of acute rheumatism.—ED.

the immediate seat of pain. It seems to be an ineffectual effort of the remedial power of nature to carry off the complaint : for it is by this evacuation alone that we can at length succeed in effecting a cure. But the perspiration will be always found unavailing, so long as it continues clammy, and the skin feels harsh, and there is a sense of chilliness creeping over the body, or any part of it, during the perspirable stage. The exacerbation, which regularly returns in the evening, increases during the night, at which time the pains become most severe ; and are then chiefly disposed to shift from one joint to another.*

[Acute rheumatism is not, generally speaking, attended with danger. Sometimes, however, it induces inflammation in parts of great importance to life ; seemingly, in consequence of their partaking more or less of the ligamentous or fibrous tissue. The periosteum is a structure that is frequently attacked ; and hence those aching pains in the bones by which patients are severely tortured. The pericardium is another organ to which rheumatic inflammation is frequently directed : the case being indicated by great pain in the region of the heart, and great disorder in the action of this viscus. Sometimes the dura mater, another fibrous membrane, suffers ; the patient being afflicted with severe headache and delirium, and often falling a victim to the disease. There is also no doubt, that the pleura and diaphragm are very liable to acute rheumatic inflammation ; and surgeons most experienced in diseases of the eye, recognise a species of rheumatic inflammation to which that organ is subject, and which has its seat in the sclerotic coat, whose fibrous texture is well known. Frequently it affects the loins, producing *lumbago* ; the muscles at the back of the neck, the face, or any other part, where fibrous membranes, aponeuroses, ligaments, tendons, or perhaps muscles, are situated.]

Where fever is violent, and especially where the frame is robust, our only effectual remedies are copious bleeding and the use of diaphoretics : by the former, which will often demand repetition, we take off the inflammatory diathesis ; and by the latter, we follow up the indication which nature herself seems to point out, and endeavour, by still farther relaxing the extremities of the capillaries, to render that effectual, which, without such collateral assistance, is, as already observed, for the most part exerted in vain, and with an unprofitable expenditure of strength. The most useful diaphoretic is Dover's powder ; and its benefit will often be increased if employed in union with the acetated ammonia, and sometimes if combined with

camphire. Aperients are useful to a certain extent ; but they have not been found so serviceable as in various other inflammations. Small doses of calomel have occasionally, however, seemed to shorten the term of the disease, though they have not much influence in diminishing the pain. To obtain this, Dr. Hamilton has combined calomel with opium ; and, in his hands, it appears to have been successful. Opium alone is rather injurious ; nor has any decided benefit resulted from other narcotics, as hyoscyamus, hemlock, and aconite.

No constitution is invulnerable to the attack of rheumatism, although the young and the vigorous fall most frequently a prey to its torture. Hence not unfrequently we meet with it in persons of weak and irritable habits, who will not bear the lancet with that freedom which gives any chance of its being useful. Local bleeding is here to be preferred, but it cannot be depended upon ; since, though the pain may diminish, or even totally subside, it is in many cases only to make its appearance in some other quarter.* Here also, if in any case, we have reason to expect benefit from uniting stimulants with diaphoretics, as ammonia, camphire, and the resinous gums and balsams.

In such habits, and particularly if opium should disagree with the system, it may be worth while to try the rhododendron (*r. Chrysanthum*, Lin.). This plant is a native of the snowy summits of the Alps and mountains of Siberia ; and in Russia, as we learn from Dr. Guthrie, is employed very generally, both in gout and rheumatism, with a full assurance of success, a cure seldom failing to be effected after three or four doses (*Med. Comment.*, vol. v., p. 434) : in consequence of which, it has formed an article in the *Materia Medica* of the Russian Pharmacopœia for nearly a century. Dr. Home tried it upon a pretty extensive scale in the Edinburgh Infirmary, and found that it acts both as a powerful diaphoretic and narcotic ; and is at the same time one of the most effective sedatives in the vegetable kingdom. In most of the cases it retarded the pulse very considerably, and, in one instance, reduced it to thirty-eight strokes in a minute. It has also the advantage of occasionally proving aperient. But it sometimes produces vertigo and nausea ; and, as a general medicine, is not to be preferred to Dover's powder (*Clinical Experiments, Histories of Dissections*, 8vo., Edin., 1780), or even the antimonial powder with opium, where the latter can be borne without inconvenience.

It is possible also in habits of this irritable kind, if in any, that we are to look for that extraordinary and decisive benefit from a free use of the bark at an early period of the disease, which we are told has been obtained. Contem-

* When the disease subsides, the parts do not desquamate and itch, as they do after gout ; but they merely cease to be hot, swollen, and inflamed. (Dr. Elliotson's Lectures.) Rheumatism does not begin, like gout, particularly in the night-time ; and it arises from an evident exciting cause, exposure to cold, or cold and wet, which is not the usual occasion of gout. In the latter disease, you have not, in the early stage, the same tendency to profuse and often sour perspirations.—Ed.

* Dr. Elliotson finds that free local bleeding generally answers better than venesection ; and he observes, that whether leeches or cupping be employed, great benefit will result from applying cold lotions as long as the temperature of the part is higher than it ought to be.—See his Lectures at the Lond. Univ., as published in the *Med. Gaz.* for 1833, p. 853.—Ed.

plated as a highly acute inflammatory affection, nothing could at first sight appear to be more inconsistent with all rational practice than the use of such a medicine, and every one must feel predisposed to coincide with Dr. Cullen, when he tells us, in reference to acute rheumatism, "I hold the bark to be absolutely improper, and have found it to be manifestly hurtful, especially in its beginning, and in its truly inflammatory state."—(*Mat. Med.*, part ii., ch. ii., p. 100.) Yet, in direct opposition to such feelings and such assertion, we find the bark freely prescribed from the onset of acute rheumatism, apparently with success, by Dr. Morton, who seems first to have recommended it for this purpose, Sir Edward Hulse, Dr. Hugh Smith, Dr. Fothergill, Dr. George Fordyce, and Dr. Haygarth of Chester.* Dr. Fordyce affirms distinctly, that, at the time of writing, he had for fifteen years relinquished bleeding in favour of the bark; and that, during this period of time, he had not above two or three patients out of several hundreds for whom he had prescribed it; and had rarely met with any instance of a metastasis, a very common occurrence when he was in the habit of employing copious bleeding.—(*On Fever*, dissert. iii.)

I have also tried the bark in various instances from an early period of the disease, and when the bowels were free from confinement: but I have rarely met with success, and have often, like Dr. Cullen, had reason to think it injurious. [When a trial of bark is judged proper, the sulphate of quinine is a convenient preparation that should not be forgotten. Indeed, it has already been recommended by Dr. Whiting (see *Lond. Med. Phys. Journ.*, Feb., 1826) and others.]

The above remarks will apply to the other

* Clinical Hist. of Diseases, 1805. On this point Dr. Elliotson has the following remarks:—"You will not find in Haygarth's work any authority for such practice. You will find in his book accounts of the successful treatment of rheumatism by bark; but then, it was not till he had evacuated the patient upwards and downwards, and employed the antiphlogistic plan. After that, it is said that it prevented the disease from recurring. I have not had occasion to use bark, for I have found the disease give way 'to antiphlogistic means, colchicum, and mercury.' The two best internal medicines are, without doubt, colchicum and mercury. Colchicum here, as in the case of gout, generally does no good till it purges; and when once it purges the patient thoroughly, the disease usually gives way. It should be given as in gout, with magnesia. As soon as it purges, it is right to desist, and also as soon as its effect ceases. If you give a dose of one, two, or three minims of hydrocyanic acid with the colchicum, it sits better on the stomach." In obstinate cases, instead of going on with colchicum, Dr. Elliotson exhibits mercury, and makes the mouth tender. "If you do this in the first instance, instead of giving colchicum, the success is about the same. Colchicum may gripe, and mercury may make the mouth sore, so that you may not be able to continue them, and you may then leave off the one, whichever it may be, and exhibit the other; or, if you begin with one, and find it does no good, you may exhibit the other."—Ed.

varieties of acute rheumatism as well as to the first, that which affects the joints generally, and is the most common form under which the disease shows itself: yet the few following observations, more immediately directed to the other varieties, may not be altogether unprofitable.

LUMBAGO has sometimes been confounded with nephritis, or a calculus in the kidneys or ureters; but the proper nephritic affections are distinguished by some irregularity in the secretion of urine, and, as we have already had occasion to observe, with a numbness shooting down the thigh, and a retraction of either testicle.

RHEUMATISM OF THE HIP-JOINT was called among the Latins *ischias*, from *ischios*, the Greek term for hip; which was afterward corrupted into *ischiatica* or *sciatica*; a word that has occasionally found its way into the dramatic poetry of our own country, as in Shakspeare's *Timon*,

"—The cold *SCIATICA*

Cripple our senators, that their limbs may halt
As lamely as their manners."

This variety, at its onset, has sometimes been mistaken for a phlegmonous inflammation of the psoas muscle. But in the latter there is, from the first, less tenderness to the touch, but much more enlargement, and the pain shoots higher into the loins. In *sciatica*, indeed, the whole limb, instead of continuing to swell, soon wastes away, and the emaciation extends to the nates of the affected side, so that the muscles have neither strength nor substance; while the thigh seems elongated.

When ACUTE RHEUMATISM attacks the PLEURA,* or any of its duplicatures or appendages, it exhibits many of the symptoms of pleurisy or peripneumony. But here, also, as in every other case of rheumatism, we have much greater tenderness upon pressure than in phlogotic inflammation, while the pyretic symptoms are considerably less, and often highly disproportionate to the pain that is endured, so that the degree of pain and that of fever become no measure for each other.

There is this peculiar character belonging to the three last varieties, that though they are less disposed to wander generally than the first, they are peculiarly apt to run into each other's proper field, and to affect the stomach, which, in consequence, becomes sometimes enormously flatulent and expanded, with a sense of heat like that of a burning coal. If the back or loins be pressed hard to obtain ease, the pain is transferred to the side or stomach; and if the pressure be followed up into the side, it returns with violence to the back or hips; or the breathing is impeded, and can only be carried on in an erect position.—(*Cartheuser, Diss. de Lumbagine rheumatica*, Fr., 1755; *Scheid, Diss. de Lumbag. rheumat.*, Arg., 1794.)

Generally speaking, however, in these three varieties the disease is less erratic than in the first, and particularly in lumbago and *sciatica*. And it is owing to this fact that the loins and

* This case is most commonly believed not to affect the pleura at all, but merely the muscles or fibrous tissues of the parietes of the chest.—Ed.

the hip, from having been more uniformly affected, are often so long, even after the complaint has subsided, before they recover any degree of tone, so that the patient is frequently a cripple for many months; and still suffers from chronic rheumatism.

Local applications, which are rarely of service in the first or articulate variety, as the pain is so apt to wander from every joint to every joint, may in all these be frequently employed with more advantage; and where general and copious bleeding may be contra-indicated, leeches or cupping have often afforded considerable relief. The compound camphire liniment, as an elegant rubefacient, is perhaps more frequently employed than any other medicine of the same tribe, but it dries too soon upon the skin, and heats and stimulates without exciting moisture; and hence it is less useful than camphire dissolved in oil, or oil united with ammonia. In all these applications, however, the friction with a warm hand is of itself highly serviceable, and should be long persevered in and frequently repeated. And on this account, essential advantage has often been derived in cases of lumbago, or where the rheumatism has fixed itself between the shoulders, from a waistcoat of the coarsest brown paper, worn close to the skin, which excites a gentle moisture, both by its perpetual friction and the stimulus of the tar with which it is so largely impregnated. [After the acute stage of lumbago, great benefit may often be derived from the Burgundy pitch plaster, or emplastrum picis comp. Dr. Clutterbuck has sometimes succeeded in relieving lumbago by half a grain of elaterium, followed by a grain or two of opium: it generally excites both vomiting and purging. Of course, one would only have recourse to such treatment in a case attended with great severity and obstinacy.*]

Blisters seem rarely to be of all the advantage we should expect; but the vesication from sinapisms succeeds better than that from cantharides. The burning of moxa is a favourite remedy on the continent, but has been little tried in our own country, and is more suited for the chronic form of the disease. The tartar emetic ointment has been also frequently made use of, and sometimes with success: it gives a permanent irritation, but the exulcerations it produces frequently prove foul and troublesome. Dr. Perceval of Dublin, in a manuscript note to the volume of Nosology, tells me that, in sciatica, he has known the pain removed by a sweating course of James's powder, after a considerable emaciation of the nates.

Bark and gentle stimulants, as guaiacum, bardana, and seneka, may be used with advantage, with a liberal regimen and chalybeate waters. Sulphureous fumigation has also of late

been very extensively employed on the continent, and partially in our own country, in the cure of both the present and ensuing species, and, according to the testimony of those who have employed it, with great success. M. Galés, of Paris, who seems first to have tried it, affirms, that of sixty-five patients who were submitted to it, twenty-five were cured, thirty-two much relieved, while only eight received no benefit. Mr. Wallace, who has also tried it at Dublin on a large scale, does not speak so decisively of its benefit in these complaints as in cutaneous eruptions.—(*Obs. on Sulphureous Fumigation, as a Remedy in Rheumatism and Diseases of the Skin*, Dublin, 1820.)

SPECIES II.

ARTHROSIA CHRONICA.

CHRONIC RHEUMATISM.

PAIN, WEAKNESS, AND RIGIDITY OF THE LARGER JOINTS AND SURROUNDING MUSCLES; INCREASED BY MOTION; RELIEVED BY WARMTH; LIMBS SPONTANEOUSLY OR EASILY GROWING COLD; FEVER AND SWELLING SLIGHT, OFTEN IMPERCEPTIBLE.

CONCERNING the proper position, and, in some sort, the nature of this disease, Dr. Cullen confesses himself at a great loss. In his Synopsis, he arranges it as a sequel of acute rheumatism, and so explains it in his definition: yet he gives it a distinct name, that of Arthrodynia, for the express purpose, as he tells us, of having a distinct name at hand for any one who may choose to regard it as a separate *genus*; and whoever is so disposed is at full liberty, he adds, as to any objection of his own. Yet, in his First Lines, he takes a different view, and perhaps a more correct one, than either of the above. Chronic rheumatism, instead of being a mere *sequel* of acute rheumatism, or a distinct *genus*, is here made a separate *species* of a common genus. "Of this disease," says Dr Cullen, "there are two species, the one named the acute, and the other the chronic rheumatism." And in his subsequent description of the latter, instead of the universal assertion in his earlier work, "pro sequela rheumatismi acuti rheumatismum chronicum dictum *semper* habeo," he modifies it by the word *commonly*. "The chronic," says he, "is *commonly* a sequel of the acute rheumatism."—(*Aph. ccccl.*)

There can be no doubt, indeed, that it is so; but as in many instances it is a distinct disease, characterized by symptoms of its own, and demanding a very different treatment, it ought certainly to be arranged as a distinct species.

Chronic rheumatism has as many, and nearly the same varieties, as the acute. It becomes fixed in the loins, in the hip, in the knee, but seldom in the thorax. Its symptoms are in most respects like those of acute rheumatism, only that there is little or no fever; so that, while the general heat is very considerable, and the pulse usually upwards of a hundred strokes in a minute in the acute species, the skin in the chronic species seldom exceeds its natural temperature, and the pulse is rarely quicker than

* In severe lumbago, Dr. Elliotson has recourse to cupping on the loins, and gives a large dose of opium (three grains), which is followed by half a drachm of vinum colchici every eight hours.—(See Clinical Lect., *Lancet*, 1830-31, p. 492.) I have always found an active purgative one of the best incipient measures, whatever may be the rest of the treatment.—Ed.

eighty strokes; the joints are less swollen, and of a pale, instead of a reddish hue, cold and stiff, and roused with difficulty to a perspiration, and always comforted by the application of warmth.*

The disease continues for an indefinite period, and sometimes only terminates with life itself. The affected joint is occasionally debilitated in the utmost degree, so that when the acute pain is not present, the weakness resembles that of a stroke of palsy.

Cold, the common cause of the acute rheumatism, is also a common cause of chronic, even where the acute species has not preceded: and violent strains and spasms may be enumerated as other causes. But, in these cases, the constitution must be peculiarly disposed to rheumatic action.

Every symptom proves most distinctly that the present is a disease of debility; and the mode of treatment must be founded upon this idea. Hence, stimulants of almost all kinds are found serviceable. Warm active balsams and resins, as those of copayva, cubebs (See *Dr. Cranc's Obs. in Edin. Med. Journ.*, No. lxxix., p. 305), and guaiacum,* essential oils of all kinds, from resinous substances, as turpentine and amber; from aromatic or pungent plants, as camphire and mustard, and especially cajeput, the green distilled oil from the leaves of the *melaleuca leucodendron*, are all employed in their turn; sometimes alone, where they combine a sedative with a stimulant power, as camphire and cajeput, and sometimes in union with opium, which often proves a very valuable addition.

Most of these are also powerful diuretics; and, as acute rheumatism is best and soonest removed by warm sudorifics, so chronic rheumatism seems to be chiefly relieved, and, indeed, radically cured, by diuretics of a like stimulus. Hence, horseradish and garlic are often found serviceable, and turpentine still more so, which, in truth, forms the basis of the greater number of the medicines just enumerated. How far the arum, or dulcamara, may be specifically entitled to this character, I cannot determine from my own practice. They are both introduced into the table of diuretics by Dr. Cullen, and are highly commended by many physicians

* Occasionally the symptoms will be like those of acute rheumatism, only less violent. In general, however, the sweating does not continue, and the parts are not above their natural temperature, as they are in acute rheumatism. "It is sometimes rather difficult," says Dr. Elliotson, "to make an accurate diagnosis. If the disease has been acute rheumatism at first, you will find there has been sweating."—Lectures at Lond. Univ., in *Med. Gaz.* for 1833, p. 852.—ED.

† One of the best stimulants in cases of chronic rheumatism is the ammoniated tincture of guaiacum. This is a medicine given in various doses, from thirty drops to a drachm at a time; and Dr. Elliotson has known patients who took 3vj. three or four times a day. Sometimes, says he, it purges, and sometimes it produces the nettle-rash; but, "when internal stimulants are necessary in rheumatism, I think this is one of the best."—Lectures at Lond. Univ., &c.—ED.

of great celebrity for their arthritic virtues. But it is possible that, whatever virtues of this kind they possess, are rather derived from their stimulating the excretories generally, and rousing the entire system, than from their acting specifically upon the kidneys. The *colchicum autumnale*, which has sometimes [the author might have said, very frequently] proved serviceable, has more decided pretensions to a diuretic character.*

Local stimulants are here of more service than in the preceding species. The moxa has been more generally used on the continent for chronic than for acute rheumatism, and is certainly more entitled to a trial. It is peculiarly recommended by Larrey.—(*Recueil de Mémoires de Chirurgie*, &c., 8vo., Paris, 1821.) In our own country, however, practitioners have far more generally had recourse to cataplasms of ammonia, cummin, and mustard-seeds, occasionally intermixed with euphorbium or cantharides; or, in their stead, have made use of friction, and, which is far preferable, the vapour-bath, brine, warm-bathing, and have afterward kept the joint well-clothed with flannel, and sent through the organ small shocks of electricity, or roused it by the stimulus of the voltaic trough. Sulphureous fumigations, or the application of sulphur in a gaseous form, as first employed by Dr. Galés of Paris, are in common use on the continent, and have occasionally been employed with success in our own country. And, when every thing else has failed, the patient is usually advised to try, what, perhaps, it would be better that he should try at first, the mysterious agency of the Bath waters.

The arsenic solution I have never tried in this complaint.† It is strongly recommended by Dr.

* Dr. Good, among the numerous medicines specified by him as having been recommended for chronic rheumatism, makes no mention of mercury. Whether the parts are hotter than they should be or not, Dr. Elliotson finds obstinate cases, especially such as are attended with exacerbation of the pain in the night, give way to mercury when they will not yield to any other medicine. All men of experience know how frequently pains in the bones, from syphilis, are supposed at first to be merely chronic rheumatism, and how quickly mercury sometimes relieves them.—ED.

† Generally speaking, the arsenical solution is used with reluctance by Americans: its action on the stomach, and its peculiar influence in causing pain in the limbs, &c., have been repeatedly observed; in some extremely obstinate cases, however, it may be found serviceable, but we should begin with half the dose prescribed by our author. Among external applications, few remedies can compare with the oil of cajeput, which may be rubbed on the affected part in combination with olive-oil or camphorated liniment: carded cotton is often far more soothing to the painful limb than flannel; strips of oiled silk and of caoutchouc have also been highly recommended.

The late work on Neuralgic Affections by Mr. Teal, has enlarged our views of the mysterious nature of rheumatism: he contends that rheumatic affections, and even neuralgia itself, frequently depend on an irritation, or a partial degree of inflammation, at the origin of the spinal nerves: and hence, he observes, we may sometimes trace the

Bardsley (*Medical Reports*), and, in his hands, it seems often to have succeeded. It may be commenced in doses of ten drops, and gradually increased to double this quantity, and should be united with a few drops of laudanum if it sit uneasy on the stomach by itself. The colchicum wine and vinegar have certainly been employed with great and decided benefit in chronic rheumatism, to which they are more adapted than to the acute form of the disease.*

In many of the eastern parts of the world, and particularly in China and Japan, a mode of treatment for various acute muscular and nervous pains has been in immemorial use, under the name of zin-king, or needle-pricking, and consists in pushing from two to five or six finely-pointed gold or silver needles, at a small distance from each other, into the seat of pain, to the depth of from half an inch to an inch, or something more. This has of late been tried, under the name of acupuncture, in France, by M. Berlioz (*Mémoire sur les Maladies Chroniques, les Evacuations Sanguines, et l'Acupuncture*, Paris, 1816), and other practitioners,

chronic sufferings of rheumatism to spinal disorder. Acting on this belief, Dr. J. K. Mitchell, of Philadelphia, has applied cupping-glasses over the spinal region, and soon removed pains of rheumatic nature. The same practice has been successfully followed by Dr. R. H. Thomas, of Baltimore.—(N. A. Archives of Med. and Surg., &c., vol. i., p. 189.) Dr. Eberle remarks, "it would appear, that in many cases of fixed pain simulating rheumatism, one or more of the vertebrae of the spine are very tender to pressure, and that if in such cases leeches or cups be applied over the diseased portion of the spinal marrow, almost immediate removal of the rheumatic pains will be effected."—(*Practice of Medicine*, vol. i.) As a dernier resort, the waters of the White and Salt Sulphur Springs, and the Warm Springs of Virginia, which are highly recommended by Dr. M. Page, of Richmond, the Bluelick and Harrodsburgh Springs in Kentucky (Yandell, in *Transylvania Journal of Medicine*, vol. v., p. 375), or the Avon mineral waters in the state of New-York, may often be used with advantage.—D.

* Dr. Elliotson adds his testimony in support of the excellent effect of arsenic on chronic rheumatism. The stomach will bear it better, if hydrocyanic acid be given with it or just before it. Dr. Good's first doses of the arsenical solution are greater than what practitioners usually venture upon. It is best to begin with two or three minims, and increase the quantity gradually: few patients can bear above seven or eight minims. Although there may be no danger in the cedema sometimes caused by this mineral, Dr. Elliotson regards the circumstance, when it occurs, as a sufficient reason for discontinuing it. Were any gastritic affection to be produced by arsenic, perseverance with the medicine would, of course, be dangerous. When the disease assumes an intermittent form, Dr. Elliotson gives either arsenic or a large dose of bark or quinine, either just before a paroxysm is expected or afterward, or smaller doses in the intervals. He also speaks very favourably of the effects of a narcotic, given in a full dose just before the pain is about to begin; as, for instance, one grain of stramonium, repeated in two or three hours if necessary, and the head remain unaffected. Were the medicine to excite drowsiness, giddiness, or delirium, an emetic would be proper.—Ed.

and in our own country by Mr. Churchill (*A Treatise on Acupuncture*, &c., Lond., 1828), for various affections of the above character, but particularly in severe chronic rheumatism, and, according to the accounts published, with considerable and almost instantaneous relief. The puncture produces little or no pain, and should be followed by no hemorrhage. A single puncture is often found sufficient to remove the ache, though it shoots occasionally to some neighbouring part; in which case, the same process is to be followed up to the seat of metastasis, when it is usually found to vanish altogether. The needle, when introduced, is suffered to remain in each puncture for about five minutes before it is withdrawn, and, in this part of the world, is commonly made of fine steel. [Dr. Elliotson has employed acupuncture very extensively: his experience confirms the observation of Mr. Churchill, that it is chiefly useful in the rheumatism of fleshy parts, and in chronic cases. Like the same writer, he also finds one needle, left an hour or two in a part, more efficient than several applied but a few minutes. Of forty-two cases thus treated, thirty were cured: and the other twelve, being more or less acute, were not adapted for it, and yielded to antiphlogistic treatment.—(*See Med. Chir. Trans.*, vol. xiii., p. 467.) Some writers would attempt to explain the modus operandi of acupuncture on the principle of counter-irritation; but M. Pouillet has endeavoured to show by experiments that electro-magnetic phenomena take place in the operation.—(*See Journ. de Physiologie Expér.*, par F. Magendie, tom. v., art. i.)]

When the disease is limited to the extremities, whether of the arms or legs, flannel bandages have often been found highly serviceable; and they should be applied with as much tightness as the patient can bear without inconvenience.—(*Trans. of King's and Queen's College, Dublin*; *Dr. Gratton*, vol. i., p. 169, 1817.)

SPECIES III. ARTHROSIA PODAGRA GOUT.

PAIN, INFLAMMATION, AND FULNESS, CHIEFLY ABOUT THE SMALLER JOINTS; RETURNING AFTER INTERVALS, OFTEN PRECEDED BY, OR ALTERNATING WITH, UNUSUAL AFFECTIONS OF THE STOMACH, OR OTHER INTERNAL PARTS; UNSUPPURATIVE.

THE origin of the term gout, or *goutte*, in French, is little known, or rather is almost forgotten. Among the ancients, most diseases accompanied with tumefaction were ascribed to a flow of some morbid fluid or humour to the part affected, which was called a rheum or defluxion; and the rheum or defluxion was denominated cold, hot, acrid, saline, or viscid, according to the nature of the symptoms. The Arabian writers ascribed even this cause to various diseases of the eyes, which were hence called gutta serena, and gutta obscura, "clear or cloudy drops, or defluxions," according to the external appear-

ance. Rheumatism and gout were alike attributed to the same origin: and, as the terms *rheuma* and *gutta* were used in medicine synonymously, both importing defluxion, the old opinion is still verbally preserved, and has descended to us in the names of rheumatism and gout, though the old pathology has been abandoned. "We have still," says Dr. Parr, "the treatise of Carpinati, published at Padua in 1609, De *Gutta*, seu *Juncturarum dolore*; but the term may be traced to Valescus de Tarenta, who wrote his Commentary early in the fifteenth century; and Schneider, in his *Liber Catarhorum Specialissimus*, published at Wittenburg in 1664, usually denominated the sixth volume, and peculiarly scarce, describes the gout as a catarrh."—(*Med. Dict.*, App.) [The term, however, is still more ancient, and was used by Radulphus, a Dominican of the thirteenth century, who writes, "*cum guttâ, quam podagram, vel arthriticam vocant, frequenter vexareter.*"]

The resemblance between gout and rheumatism is so close, that the one is often mistaken for the other; and both by Bergius were regarded as convertible; yet, while the former chiefly fixes on the small joints, the latter attacks the large; and the first is often hereditary, while the second is rarely or never so. Gout is far more connected with a dyspeptic state of the stomach than rheumatism: its incursions are, for the most part, more sudden, its nocturnal exacerbations less striking, but its remissions much clearer. While rheumatism mostly begins in the shoulder or elbow, gout always begins in the foot or ankle.

Gout, moreover, is a far more complicated complaint than rheumatism; and hence there is no disease to which the human frame is subject, that has led to such a variety of opinions, both in theory and practice, many of them directly contradictory to each other, as the gout; and I may add, there is no disease, concerning the nature and treatment of which physicians are so little agreed; so that, to this moment, it constitutes perhaps the widest field for empiricism, and the hottest for warfare, of any that lie within the domain of medical science.

Shutting the door to disputation and unfounded theory as far as we are able, let us, in as few words as possible, attend to the clear and established history of this disease as we would to that of any other, and draw our pathology and our mode of practice from the principles which it will be fairly found to inculcate.

In the first place, it is admitted on all hands, or at least with exceptions so few as scarcely to disturb the general consent, that gout, in whatever way it shows itself, is a disease of the system; or, in other words, is dependant upon a peculiar diathesis or state of the constitution. And next, it is as commonly admitted, that this diathesis is in some instances original, and in others hereditary or derived. There are many persons in whom this complaint makes its appearance, who can trace no such affection in their ancestors;* and as such persons are specially

distinguished by a habit of indolence, luxury, and indulgence, and particularly in the pleasures of the table, it is from this habit that the gouty diathesis is supposed to originate. There are others who, though exhibiting a life of great regularity and abstemiousness, afford proofs of the same diathesis in occasional paroxysms to which it gives rise; and such persons are almost always capable of tracing it hereditarily. For the diathesis, having once established itself, keeps its hold on the system, and is propagated from race to race, whatever be the manner of life of the individual, or the general state of his constitution; though there can be no question, that those descendants are most subject to its paroxysms who indulge in the excesses that laid its first foundation.

A gouty diathesis, thus produced, may remain quiescent, and not discover itself for many years, till it meets with some occasional cause of excitement, when it shows itself by a sudden and painful disturbance of some part of the system;* but a disturbance of a very different kind, as well as affecting very different organs, according to the temperature, constitution, manner of life, or some incidental circumstance of the individual: where the general health is sound, fixing on one or more of the extremities, in the form of a peculiar but very acute inflammation, that runs through a regular paroxysm and gradually subsides; and, where the health is infirm, and the general form debilitated, exciting great derangement in some internal organ or set of organs, and particularly those of digestion; or shifting from one form to another, and thus proving itself, under every form, to be the same disease, and laying a foundation for the three following varieties:—

- | | |
|--|---|
| <p>a Regularis.
Regular fit of
gout.</p> | <p>Pain, swelling, and inflammation of the affected joint considerable and acute; continuing for several days, often with remissions and exacerbations; then gradually resolving, and leaving the constitution in its usual or improved health.</p> |
|--|---|

Scudamore, it appears that in a given number of gouty individuals, the majority acknowledged no hereditary claim to the disease. Yet we are not to imagine, from the result of this estimate, that, in a large proportion of cases, the predisposition is not received by children from their parents: the fact is familiarly known and universally acknowledged.—Ed.

* "A state of plethora, absolute or relative," as Dr. Barlow observes, "precedes every accession of gout, and is the principal, if not the immediate cause of it. The intensity and duration of the paroxysm, too, are dependant on the degree of plethora prevailing, although other circumstances may contribute to prolong the attack. But, notwithstanding this, gout is not simply plethora leading to or ending in local inflammation. There is something more from which gout derives its distinctive character, and this ideal, at least unexplained existence it is, which constitutes the essence of gout."—Cyclop. of Pract. Med., art. GOUT.—Ed.

* From some tables published by Sir Charles

- β Larvata. Disguised and lurking in the constitution, and producing derangement in the digestive or other functions, with only slight or fugitive affection of the joints.
- γ Complicata. The disease fixing on some internal organ instead of on the joints; or suddenly transferred from the joints after having fixed there; producing in the internal organ affected debility or inflammation, according to the state of the constitution.

The predisposing cause of a gouty diathesis, when it first forms itself in an individual, is plethora, or the state of the system produced by full living and indolence.

An entonic state of the vessels, joined with plethora, may be set down as the predisposing cause to acquired gout; and this hypothesis seems consistent with the fact of the common occurrence of gout in strong robust individuals. When it has been transmitted hereditarily, it is more disposed to show itself in men of robust and large bodies, of large heads, of full and corpulent, and especially gluttonous habits, or whose skin exhibits a coarser surface, in consequence of being covered with a thicker rete mucosum.

[The middle and advanced periods of life are more disposed to gout than the early periods. Thus, it does not commonly attack men until after the age of thirty-five, and generally not till a still later period.* When the gout does appear in more early life, it seems to be in individuals in whom the hereditary disposition is exemplified, and to whom the exciting causes have been strongly applied. According to Hippocrates, eunuchs are not liable to gout, nor boys previously to venery; but these opinions are probably not very correct; since, with respect to the latter, the disease is well known to be almost peculiar to an advanced period of life; and the eunuchs, who, in the time of Hippocrates, were chiefly Persian slaves, were, in all likelihood, confined to the strict discipline and the frugal and temperate lives enjoined to all, and therefore not exposed to the most active causes of gout. For Galen, in his Commentary upon this observation of Hippocrates, tells us, that, in his time, the remark was no longer true, "owing to too much indulgence on their part in an indolent, as well as intemperate mode of life;" and the remark is confirmed by modern experience. There is a Greek epigram, literally signifying, "Of limb-relaxing Bacchus, and limb-relaxing Venus, is born a daughter, the limb-relaxing Gout." And a similar doctrine is contained in the adage, "Bacchus pater, Venus mater, et Ira obstetrix Arthritidis." While,

* When the predisposition is strong, however, it may commence much earlier. The editor has seen several instances of it in persons not more than twenty years of age.—ED.

says Dr. Bateman, this fact is confirmed on the one hand, by the testimony of ages, in the affirmative, it is corroborated also, on the other hand, by observation, in the negative. Dr. Cullen remarks, that gout seldom attacks those who are employed in bodily labour, or who live much upon vegetable aliment, or take no wine or fermented liquors. Indeed, the gout is said to be altogether unknown where these liquors are not used, as among the common people of Turkey. According to Van Swieten, some people, who, after being in comfortable circumstances, have been reduced to labour for their sustenance, and to exchange a luxurious table and indolence for a spare diet and activity, have never suffered from gout again. He mentions particularly the instance of a certain priest, who enjoyed a rich living, and had been an old and constant sufferer from gout, but, happening to be taken by the pirates of Barbary, he was kept constantly at work in the galleys for two years; "which had this good effect, that afterward, when he was ransomed from captivity, having lost all his troublesome and monstrous fatness, he never once had a fit, though he lived several years after the event." Various similar examples are related by Schenckius.—(*Obs. Med. Rarior.*, lib. v., p. 659, ed. 1644.) In a word, as Dr. Bateman remarks, much exercise, which will often counteract the influence of intemperance, will, when combined with temperance, counteract even the hereditary disposition to the disease.

Women are not very liable to gout, probably from their more regular and abstemious mode of living; but those females whom it attacks are generally of robust and full habits. It is said to be very rare before the cessation of menstruation, which, as Dr. Bateman thinks, only implies, that it is generally a disease of advanced life. For Dr. Cullen (*First Lines*, &c., §494) has observed, that robust females are often attacked before the menses have ceased; and he knew of cases where it occurred in females whose courses were more abundant than usual.*]

The podagric diathesis must be distinguished from the paroxysms to which it gives rise, and which constitute the only manifest indications of its existence.

The paroxysms of gout are excited by certain occasional causes, some of which are obvious, and some doubtful, or altogether unknown; but, without the co-operation of these, the gouty diathesis may remain unnoticed, or quiescent in the body for years, or, perhaps, through the whole term of a man's life. And hence we often see an individual, whose ancestors have been notorious for this complaint, pass the whole of his days without betraying any marks of it, while it

* Bateman, in Rees's Cyclopaedia, art. GOUT. For this relative immunity of females from gout, they seem indebted to their greater temperance, and also to the facilities which the female constitution possesses of throwing off redundances by natural outlets. Dr. Gregory observed in his practice, that such women as suffered from gout had antecedently been subject to profuse hemorrhages, and were generally plethoric through indolence and high feeding.—ED.

appears in one or more of his children, perhaps in their very boyhood.

The occasional causes are numerous; for, where the diathesis exists strongly, almost any thing that is capable of producing a general disturbance in the system, or of throwing it off the balance of ordinary health, is sufficient to become a cause; and this, whether the incitement be of an entonic or an atonic character. And hence, paroxysms in different individuals are often produced by intoxication, or excess of eating; violent emotions of the mind, particularly the depressing passions, as grief and terror; sudden exposure to cold when the skin is in a state of perspiration; wet applied to the feet; great labour of the body; severe application of the mind, especially when protracted, so as to break in upon a due allowance of sleep; cold, flatulent fruits, and often acidulous liquors; a sudden change from a spare to a full, or from a full to a spare diet; excessive evacuations of any kind; and, occasionally, a sudden cessation of such as are habitual.*

The more violent the attack of a paroxysm, and the longer its continuance, the more the diathesis is confirmed, and the oftener the attack is renewed. On which account, it is of great importance to alleviate and abridge the paroxysms as much as possible, and especially when they are as yet new to the system.

Whether particular climates or countries are more disposed to favour the existence of gout than others, separate from the occasional causes just adverted to, may be doubted.† Such an opinion, however, has prevailed among the vulgar, as well as among many of the more learned in most ages. Thus, among the Greeks, it was a popular belief, that Attica was the hotbed of gout, as Achaia was of ophthalmia: whence Lucretius,

“Attithe tentantur gressus, oeuleique in Achæis finibus.”‡

Gout clogs the feet in Attica, the sight
Fails in Achaia.

And thus, too, in more recent times, we are told that China (*Le Conte, Nouvelles Mémoires sur l'Etat présent de la Chine*, Paris, 1696), and even some of the German provinces, are exempt from the attack of gout, while, in our own country, it exercises an almost irresistible sway. The last assertion is true enough; but we are not driven to the variable nature of our climate to account for the fact.

Thus far we can proceed safely, respecting

* The doctrine that lowering the diet, or that a change from a full to a spare diet, will excite gout, is one that the editor has never seen a confirmation of; and if it were true, he thinks that the well-fed gouty priest, taken by the Barbary pirates, and made to work in the galleys, as mentioned by Van Swieten, ought, at all events, not to have been cured by low living and hard labour. In Scotland there is an old saying, that any man may free himself from gout by working for, and living on, sixpence a day.—Ed.

† Gout is by no means common in very hot climates; and the summer in this country materially diminishes the number of cases.—Ed.

‡ De Rer. Nat., vi., 1117.

VOL. I.—O o

the general pathology of this Proteus disease. But the moment we enter upon the field of its PROXIMATE CAUSE, we are bewildered in a hopeless labyrinth, without a thread to guide our entangled footsteps amid the growing darkness. There has, indeed, been no want of attempts to explain the subject; but thus far, they have been attempts alone; ingenious conjectures, rather than enucleated facts. Thus some, among whom was the learned Boerhaave, resolved the proximate cause of gout into a morbid texture of the nerves and capillaries; and others, into a peculiar acrimony of the fluids; respecting the nature of which, however, those who adopted this view were never able to agree; several of them, like Hoffmann, affirming it to be a tartaric salt, several a bilious salt, several again an acid and several again an alkali.

This morbid material, in whatever it consists, was supposed to be separated from the system, and thrown off during the continuance of the paroxysm, which, consequently, it became the duty of the physician to encourage. And by some pathologists it was held, that the morbid matter thus despumated has, in various instances, proved contagious, and this not to man only, but to other animals as well: thus M. Pietsch informs us, that he has known dogs affected with the same disease by licking the ulcers that have followed upon a fit of gout, accompanied with what he erroneously calls chalk-stones.

Dr. Cullen has taken great pains, in a series of nine consecutive arguments, to prove the error or absurdity of most of these opinions; and then he proceeds to establish his own; which consists in regarding the proximate cause of a gouty diathesis as dependant upon a certain vigorous and plethoric state of the system; and the proximate cause of a gouty paroxysm as produced by an occasional loss of tone in the extremities, often communicated to the whole system, but especially to the stomach, succeeded by a powerful reaction in the same quarter, which constitutes the pain and inflammation, and is an effort of the vis medicatrix naturæ to restore the tone thus injured.—(*Pract. of Phys.*, part i., b. ii., chap. xiv., DXXXIII.) But, by this hypothesis, we gain as little as by any of the preceding. It is obviously a mere extension of the Cullenian doctrine of fever to the disease before us, and is chargeable with the same incongruity: for here, as in fever, the stage of strength or increased energy is made to depend upon the stage of weakness; as the weakness or loss of tone is made dependant upon a peculiar vigour and plethoric state of the system. There is, indeed, no great difficulty in conceiving how loss of tone may follow excess of energy; but by what means recovered energy is to be a result of loss of tone, is a problem of more laborious solution.

One of the marks by which a REGULAR PAROXYSM of GOUT is said to be distinguished from that of rheumatism, is the suddenness of its onset. This is true, as Sydenham has correctly observed, with regard to the general course of regular gout, in which the constitution is in other respects perfectly sound. But in other cases

the fit is often preceded by certain prodromi, which those who have suffered from it before very sufficiently understand, and uniformly take as a warning; such as a coldness or numbness of the lower limbs, alternating with a sense of pricking or formication along their entire length; frequent cramps of the muscles of the legs; a crassament in the urine (*Butler, Naderc out dekkinge der menschelyke Waters, Harlem, 1697*); slight shiverings over the surface; languor and flatulence of the stomach; and sometimes a pain over the eyelids, or in some other organ.—(*Eph. Nat. Cur. Dec., i., ann. iii., obs. 252.*)

The paroxysm is said by Dr. Sydenham, who has drawn its picture to the life, to show itself most commonly in January or February; but I have known it occur so often towards the close of the summer, and in the autumn, and have attended so many patients who have never had it except in the latter seasons, that the rule does not seem to be in any way very well established. The first attack is usually in one of the feet, most commonly about the ball or first joint of the great toe; it commences at night, or during the night, and there is sometimes, though not always, a slight horror, succeeded by a hot stage. The local pain and swelling increase in violence, the joint assumes a fiery redness, and the whole body is in a state of great restlessness. The symptoms remit sometimes towards the next morning, yet occasionally not till the morning after; but they still return during the night, though in a more tolerable degree, for three or four days, or even a week: when the inflammation subsides, as by resolution; the foot almost instantly recovers its vigour, as though nothing had been the matter with it; and if the patient have been antecedently indisposed, he enjoys, as on recovering from an ague, an alacrity of body and mind beyond what he has experienced for a long time before; the constitutional indisposition disappearing with the paroxysm.

At the commencement of the disease the return of it may be annual, or not oftener than once in three or four years; but it is perpetually encroaching on the constitution, so that the intervals gradually become shorter, and the attacks more frequent and of longer continuance: whence, as Dr. Cullen has justly observed, "in an advanced state of the disease, the patient is hardly ever tolerably free from it, except perhaps for two or three months in the summer."

Nothing can be more specific, more true to itself, or more distinct from every other kind of inflammation, than that of the disease before us, when thus exhibited in a regular fit; the inflammation of erythema does not differ more from that of phlegmon than both these, and, indeed, every other, from that of gout: it never suppurates, never ulcerates when simple and genuine, however violent may be the attack, and though, to the eye of inexperience, the skin may seem to be on the point of bursting; while, in the midst of the severest pain, there is a sense of numbness, weight, and want of energy;

inasmuch that, if the pain could for a moment be forgotten, the limb would feel paralytic; and, though the muscles which move the limb be not affected, they raise it or drag it along like a dead load. If the inflammation run through its course where it first fixes, it subsides by a resolution that leaves no external discoloration, or internal weakness or disability; and if it make a transfer from one extremity to another, it passes with inconceivable rapidity; the limb now affected being loaded with all the vehemence of the inflammatory action, and that lately the seat of pain being all of a sudden restored to perfect soundness.

It is rarely, however, that any metastasis takes place on its first appearance in a healthy constitution; nor indeed till after various organs, or the entire habit, have been weakened by repeated assaults. We have already observed, that it is the nature of the disease to weaken the habit in this manner till the system is completely broken down. In this case, the paroxysms, though much longer and more frequent, are less violent and painful than at first; but there is no joint exempt from its incursion, nor perhaps an internal organ that does not suffer from induced weakness: so that, in the language of Sydenham, "the patient exists only to be wretched and miserable, and not at all to taste of the happiness of life."

[In the inveterate and protracted form of the disease, the joints remain not only weak and stiff after the termination of the fit, but they become at length so contracted and disabled, that, although the patient can stand, and perhaps walk a little, yet it is very slowly, and with great lameness and difficulty. In many persons, though not in all, this immobility of the joints is further increased by the formation of concretions of a chalky appearance on the outside of them, and for the most part immediately under the skin. The secretion or deposition of this matter is characteristic of the disease, being the consequence of gouty inflammation alone. It seems to be deposited at first in a fluid form, but afterward becomes dry and firm; in which state the concretions have the appearance of a friable earthy substance, and have been erroneously called *chalk-stones*. By the investigations of Dr. Wollaston, however, it has been ascertained, that they contain no calcareous or earthy matter; but consist of lithic or uric acid combined with soda, forming what the chymists term the lithate or urate of soda. These concretions occur principally about the joints of the toes and fingers, in little nodules, which Sydenham compares to crabs' eyes; but sometimes they appear about the larger joints, where they occasion a whitish swelling almost as large as an egg, which becomes gradually inflamed and red. There is an instance of a very large concretion of this nature, recorded in the surgical works of Sir E. Home. But perhaps the most curious case is that related by Mr. Watson: the patient, who was a martyr to gout, had so extensive a deposition of urate of soda, that the concretions not only enveloped the joints of his great toes, formed tumours on his legs, and

rendered the synovia of the large joints as thick as cream, but "the joints of the fingers were swelled and knotty, every knot being a lump of chalk; and I was told (says Mr. Watson) that, when he played at cards, he used frequently to score up the game with his knuckles."* It is singular that our author, with his very extensive information on all subjects connected with medical science, should have fallen into the error of describing gout-concretions as really composed of lime.]

It seems probable, that urate of soda has sometimes been thrown off by the skin. I have seen, says Swediaur, an inveterate case, in which the patient, labouring under a paroxysm of several months' duration, had the entire surface of the body covered every morning with a white powder, as though he had been dusted with flour.—(*Nov. Nosol. Meth. Syst.*, i., p. 218.)

Thus far we have followed up the progress of a regular attack of gout in a constitution otherwise healthy and vigorous. But the same diathesis exists in systems of delicate and infirm health, and where there is a want of sufficient energy to work up a fit of inflammation, and throw it off at its appropriate outlets. And in such case, as soon as it becomes roused into action by any of the causes of excitement already enumerated, it constitutes the SECOND VARIETY, assumes the guise of various other diseases, as dyspepsy, hysteria, hypochondrias, palpitations of the heart, vertigo, hemiplegia, with several modifications of palsy or apoplexy. The stomach and bowels, however, form the chief seat of affection; the appetite is fastidious or destroyed; a spasmodic stricture or painful oppression is felt in the epigastric region, or the stomach is distended almost to bursting with flatulence; nausea, eructations, vomiting, and all the symptoms of indigestion follow, and are alternated with severe colic or costiveness. In the meanwhile, the disease shows itself, at times, in one or more of the joints, in slight and fugitive pains, as though making an ineffectual effort to kindle up a paroxysm of proper inflammation, but which there is not energy enough in the system to accomplish; whence the articular pains cease almost as soon as they appear, and the visceral derangement is renewed; sometimes slowly subsiding after a continuance of several weeks, and sometimes wearing out the entire frame, and terminating in abdominal or cellular dropsy.

It sometimes happens, however, that while the general constitution of a podagric patient is

tolerably sound, one or more of the internal organs form an exception to the general rule, and are less healthy than the rest. And as, upon an excitement of gouty inflammation in a gouty habit, the inflammation seizes ordinarily upon the weakest part of the body, it makes its assault upon such organ rather than upon the hands or the feet; or, if it commence in the latter, is readily transferred to it; constituting the THIRD OF THE VARIETIES before us, and which has usually been called RETROGRADE OR MISPLACED GOUT. And if the general system should at the same time be below the ordinary tone of health, when the paroxysm is thus excited by the force of some occasional cause, the organ affected may evince great languor and painful inertness, as in the second variety, rather than acute inflammation, as in the first. The sensation in the stomach, instead of being that of a fiery coal, is that of a cold lump of lead; in the head, it changes from maddening pain to oppressive horror, in which the patient suddenly starts from sleep almost as soon as he has begun to doze, from the hideousness of the ideas that rush across the mind and form the distracting dreams.

The fit is sometimes transferred to the bladder; in which case, there is acute pain at the neck of the organ, strangury, and a discharge of thin acid mucus from the urethra.* The rectum has also been occasionally the seat of metastasis, and has evinced various species of affection, as simple vehement pain, spastic constriction, or hemorrhoidal tumours. When thrown upon the lungs, it mimics the symptoms of a peripneumony.

[The following observations by Dr. Bateman appear valuable. Many errors have probably been committed, in considering almost every species of indisposition that occurs in gouty habits as arising from the gouty diathesis. We remember to have heard this point strenuously insisted upon by the able Professor of Physic in the University of Edinburgh, Dr. Gregory. Many of the symptoms above enumerated are obviously connected with the impaired functions of the stomach, and occur in dyspepsy or indigestion. Such are various hypochondriac sensations; the palpitations of the heart, often proceeding from over-distention of the stomach with flatus, by which the heart is mechanically pressed upwards; cramps in different parts of the body, which are often relieved by a discharge of wind of the stomach; difficulty of breathing, often arising from the distention of the stomach, which impedes the descent of the diaphragm; and the headache, giddiness, &c., which are daily observed to be connected with

* See Medical Communications, vol. i., art. 3. Two or three years ago, the editor saw a lady in the Fleet Prison, not more than thirty years of age, and the mother of several children, who was in such a state from deposits of urate of soda around almost all her joints, that her limbs were of little or no use to her. She had resided a considerable time in France; but had always been abstemious in her mode of living. When her knees were bent and extended, a rattling noise was produced, like what would arise from shaking a bag of marbles.—Ed.

* "Not unfrequently there is a nephritic attack; an attack of inflammation of the kidneys, and a deposition of lithic acid, or some compound of it. Occasionally these things take place with the gout; occasionally they take place only during the intervals; but a deposition in the urine, and a fit of gout, where there is deposit in the joints, are frequently very closely connected."—Professor Elliotson's Lectures, see Med. Gaz. for 1833, p. 832.—Ed.

impaired digestion. On the other hand, inflammatory disorders of the lungs and other viscera, congestions in the head, inducing headache, somnolency, vertigo, &c., and ultimately various degrees of paralytic and apoplectic disease, not essentially different, in any respect, from the same affections in habits free from a gouty diathesis, have probably been suffered to go on, and to prove fatal, under the notion that they were gouty, and the proper remedies have been therefore neglected.*]

In applying the art of medicine to the cure or alleviation of gout, our attention must be directed to the state of the patient during the paroxysms, and during their intervals; and particularly to the state of his constitution or previous habits, which, according to their character, may demand a different and even an opposite mode of management.

Let us commence with the PAROXYSMAL TREATMENT; and, first of all, with that of the inflammatory attack, as it shows itself in a regular fit of the disease.

It was formerly the belief, as we have already seen, that a gouty paroxysm was an effort of nature to throw off from the constitution, and thereby restore it to a state of perfect health, some peccant matter forming the proximate cause of the distemper; and it was hence also conceived in addition, to adopt the language of Sydenham, that the more vehement the fit, the sooner it would be over, and the longer and more perfect the intermission. And, in this view of the subject, there can be no question, that the wisest plan must have been that of leaving the paroxysm to run through its regular course without interruption. Yet, as this hypothesis has long fallen into discredit, we are not in the present day prevented, on such ground, from endeavouring to subdue the inflammation of a gouty paroxysm by the ordinary means resorted to in inflammations of any other kind, as bleeding, purgatives, sudorifics, local astringents, and even refrigerants. But a very general objection has since been taken to this plan on another ground; and that is, the great danger of repelling the disease to some internal organ of more importance, and thus of converting a regular paroxysm into a case of retrograde or atonic gout. And, in consequence of this apprehension, the practice, even in the hands of many of our most celebrated physicians, has,

for a long period, been in the highest degree vague and vacillating. Sydenham prohibited equally purging and sweating of every kind, whether gentle or copious, and only allowed bleeding where the patient was young and vigorous, and on the first or second paroxysm: while of cold applications he takes no notice whatever. He admits, however, the use of laudanum where the pain is very acute: trusting chiefly for the cure of the disease to an alterant regimen and apozems to be resorted to in the intervals. Dr. Cullen allows bleeding with the same restriction as Sydenham, though he recommends the application of leeches to the inflamed part, as at all times a safer practice than the use of the lancet. Of cathartics and sudorifics he takes no notice, otherwise than as these may enter into the general course of antiphlogistic regimen; he is decidedly adverse to the use of cold; and thinks that warm bathing and emollient poultices, blistering, burning with moxa, camphorated and aromatic oils, induce the inflammation to shift from one part to another, and consequently tend to repel the inflammation from the extremities to some more important organ: while opium, though it affords relief in present paroxysms, occasions them to return with greater violence; and therefore he observes, by way of conclusion, "The common practice of committing the person to patience and flannel alone, is established on the best foundation."—(*First Lines of the Practice of Physic*, aph. DLXIX.)

Now, as we have already seen that the gout, after it has shown itself in paroxysms, is never idle; that one paroxysm, in the opinion of Sydenham, Cullen, and every other physician, hastens on another, renders its intervals shorter, and its durations longer; and progressively saps all the energies both of mind and body, and renders life itself a burden; it is of serious importance to inquire, whether this fear of a repulsion, however well founded in some instances, be not allowed too generally? whether it be not possible to draw a definite line between the form of the disease in which it ought to operate, and that in which it ought not? and whether in the latter case we may not derive all the benefit from a full use of a reducing process, which is obtained in other inflammations accompanied with a like degree of constitutional vigour?

From the history of this disease, as it has already passed before us, we may draw this general corollary; that the specific inflammation of gout, or whatever other morbid character it may evince, when once excited by some occasional cause into action, has a peculiar tendency to fix and expand itself upon the weakest parts of the system, and, where several parts are equally weak, to pass in sudden transitions from one part to another, though transitions are rare where the system is sound.

In healthy constitutions, the weakest parts are the extremities; and hence, in such constitutions, these are the parts, as we have already seen, in which the gout uniformly opens its assault. Here it commences, and here it runs through its course, seldom migrating, or, when

* See Bateman in Rees's Cyclopædia, art. GOUT. In this view Dr. Barlow also concurs. "A paroxysm of gout," says he, "can be regarded only as a constitutional disturbance of an inflammatory character, attended with local inflammation of a peculiar kind, in one or more joints, running a determinate course, and, in the earlier accessions, terminating in health for the most part, within a very few days. Such being the character of simple gout, there is no reason why the complications so much dwelt on should be considered as specially belonging to it, or regarded otherwise than as accidents arising from peculiarity of constitution, contingent derangements of health, or the lesions or morbid tendencies entailed by preceding accessions."—See Cyclop. of Pract. Med., art. GOUT.—ED.

it does migrate, only passing from one extremity to another: as from foot to foot, or one of the feet to one of the hands; and limiting itself to these quarters, because they are the weakest parts of the system.

In unhealthy habits, however, the extremities are not the weakest parts of the system, but perhaps the stomach, or the heart, or the head, or the lungs, or some other organ; while several of these organs may, moreover, be equally debilitated, according to the idiosyncrasy, or to accidental circumstances. And, true to the general rule, we see the gouty principle, when roused into action in habits of this kind, fixing itself from the first on one of those important viscera, rather than on the extremities; or roaming from one to another, on its alternating its course from these organs to the extremities, or from the extremities to these organs. And as metastases are rare where the system is sound, they become frequent in proportion as it loses this character, and especially in proportion to its debility in particular parts.

These are rules which we cannot too closely study and commit to memory, and they seem to point out to us the line of distinction between that form of the disease in which we ought to entertain a prudent fear of revulsion, and that in which we may safely act without any such fear whatever. They directly lead us to two states of constitution that require a very different, and in many instances a very opposite mode of treatment; and seem to settle the important question before us, under what circumstances it may be expedient to employ a palliative plan, and under what a cooling and reductive?

Let us commence with the first of these two states, forming a regular but violent fit of gout, as it shows itself in a sound constitution, and inflicts its torture on the hand or the foot. Guiding ourselves by the laws just laid down, there seems no reason why, instead of "committing the person to patience and flannel alone," we should not pursue the evacuating and refrigerant means employed in tonic inflammations of any other kind, and have cause to expect a like success; such as bleeding, so strongly recommended by Dr. Heberden, and allowed occasionally by Sydenham, and emptying the bowels, relaxing the skin generally, and cooling the fiery heat of the affected limb by cold water or any other frigorific application.* With a transfer of morbid matter we have now no longer to contend. Yet, even where such a cause is admitted, as in most exanthems, the plan thus proposed is, in many instances, pursued without hesitation. Thus, in measles, cathartics and

venesection are not only in general use, but often indispensable; in the height of malignant scarlet fever, we sponge or wash the entire surface of the body with cold water; and in small-pox, not only purge freely, but expose the patient to the coldest atmosphere of the winter season.

In weakly habits or idiosyncrasies, or incidental debilities of particular organs, we have admitted that a metastasis, as we have already seen, is a frequent result, and peculiarly marks the character of gouty inflammation; and here, indeed, refrigerants, violent purgatives, and venesection ought to be most sedulously abstained from; and not unfrequently, the best practice we can adopt is that of "committing the person to patience and flannel alone." But what I am anxious to establish is, that, agreeably to the laws which regulate the progress of gout, a metastasis in sound and vigorous constitutions is rarely to be expected, and perhaps never takes place except from one extremity to another. In order that some internal organ may become the seat of transferred gout, it is necessary that it should possess a weaker action than the part from which the inflammation is to be transferred: but the parts of weakest action in a sound and vigorous constitution are the extremities themselves; and it is probably because the living energy is, in all the extremities, upon a balance, that in a sound frame a metastasis, even from one extremity to another, is a rare occurrence.

[In the foregoing argument, the doctrine that the weakness or weak action of any part is what disposes it to be affected by a metastasis of gout, is only asserted, and by no means proved. The abundance of fibrous and ligamentous structures about the foot and hand may seem to many pathologists a better reason for these parts being so disposed to gouty inflammation, than the hypothesis of weakness.]

As far as I have seen, the inflammation of a regular fit of gout subsides gradually, though rapidly, under the treatment now proposed, without any repulsion whatever. In a few instances, during the use of a cold pediluvium, or shortly afterward, I have known patients speak of a peculiar kind of *aura* creeping over them and through them, and exciting an undefinable sense of glowing, which has lasted for a few minutes, without any inconvenience at the time, or even any change in the pulse; and certainly without any ill effect afterward.

But, it may be replied, there is no resisting facts. The cases are innumerable in which great mischief has resulted from the depleting and the refrigerant plan; and, as we cannot

* "In simple gout, we know of no good reason why the treatment applicable to the same degree of general fever and local inflammation, occurring from other causes, should not be employed: its general safety and efficacy we can faithfully attest, nor are we aware of any peculiar caution being required beyond what the accompanying state of the constitution and the attending symptoms must necessarily suggest. In all diseases, however inflammatory, the state of the constitution requires to be taken into account in judging of the activity

of practice that may be safely ventured on; and the same consideration is needed in gout; but, assuredly, none is due in this respect to the imputed essence of gout, nor to the apprehension of interfering with it, which has been too long suffered to paralyze the efforts of the practitioner."—Dr. Barlow in Cyclop. of Pract. Med., art. GOUT. These sentiments should never be forgotten with reference to the treatment of gout; and they seem to the editor to be supported both by reason and experience.—Ed.

always tell that all the internal organs are or are not in a state of sound health, it is most prudent to abstain from a practice which may prove highly injurious in case of a mistake.

The answer to this remark is, that here, as well as in every other disease, professional judgment is to be called into exercise, and the practitioner is to draw largely upon that skill and discrimination which it was the object of his education to bestow upon him: and thus bestirring himself, he will rarely fall into an error. That mischief has resulted, and frequently, from the use of the plan before us, cannot be denied by any one; but that great and essential good, and an easy and rapid cure, have been also in hundreds of instances effected, must be admitted as readily. No clear distinctive line, however, has hitherto, so far as I am acquainted with, been acted upon, or even laid down; and hence it is rather to be ascribed to a want of discrimination upon this subject that the evils adverted to are chargeable, than to any mischief in the plan itself. Yet it may be doubted whether the injury produced, even by an injudicious use of evacuants and refrigerants, amounts to a thousandth part of that entailed on the constitution by allowing the gout to make its inroads tacitly and unresisted; till by degrees it triumphs equally over all the powers, as well of the body as of the mind, and, in the forcible language of Sydenham, "The miserable wretch is at length so happy as to die."*

Of the benefit produced by the external use of cold water, the author can speak from a trial of several years formerly upon his own person, and is only anxious that others should participate in what has proved so decisive a comfort to himself. It is his duty to state, however, that, apparently owing to too much exertion of mind in the composition of this work, the gout has since appeared, accompanied with a more irritable state of the general frame than had hitherto been manifested. On this last occa-

* "If the character of gout, in its simplest form and highest intensity," as Dr. Barlow remarks, "be unequivocally inflammatory, it is difficult to conceive why its various shades and modifications should be otherwise regarded. The differences are not greater than are continually met with in several other diseases; nor, when they do occur, is there any difficulty in referring the peculiarities to the particular constitution, the effects of previous disease, and other contingent circumstances, amply sufficient to account for them. These circumstances may, and in numberless instances do, require that the appropriate remedies of inflammation should be applied with caution, but they can by no means warrant the principles of treatment founded on the inflammatory nature of gout being wholly reversed, as is too often witnessed. There has been too much disposition, arising from timidity, ignorance, and false theory, to transfer to simple active gout the cautions and the apprehension of interference, which the contemplation of the complex and less active modifications has given rise to." In the correctness of these observations the editor fully concurs: the principles here inculcated ought to have their proper weight in the practice of every man who wishes to treat this disease with success.—Ed.

sion, therefore, he did not venture upon the cold bath, but confined himself chiefly to the wine of colchicum, with very frequently a full dose of magnesia; and, by this simple plan alone, he has again been able to obtain a restoration of health, and the full enjoyment of foot-exercise.

Yet the bolder practice before us is by no means of modern invention, however it may have become a subject of warm controversy in the present day. An active evacuant plan, both by venesection and purging, has never ceased to be in use among many practitioners, and is particularly alluded to by Sydenham, though with a view of entering his protest against it, as injurious to a free discharge of the peccant matter, which, in his opinion, required to be carried off; while, with respect to the external use of cold water, not to mention that it seems to be alluded to by several of the Greek writers, and especially by Hippocrates (*Aphor.*, sect. v., p. 25), it has descended in a stream of recommendations from Zacutus Lusitanus (*De Medicorum Princip. Historiâ*, lib. iii., Amsterd., 1641), in 1641, to Kolhaas (*Baldinger, Neuer. Mag.*, band. v. p. 521, 1788), and Keck (*Abhandlungen und Beobachtungen*, Berl., 1789), in 1788 and 1789. Bartholin speaks of the use of snow as a common application in 1661 (*De Usu Nivis medico*, 1661, 8vo.), and Pechlin both of snow and cold sea-water towards the close of the same century.—(*Observ. Physico-Med.*, Hamb., 1691, 4to.)

But this treatment, I am ready to admit, has often been employed rashly, and sometimes with great and even fatal mischief. It ought never to be ventured upon except, as already stated, where the constitution is decidedly sound and vigorous; for, though I subscribe to much of Dr. Kinglake's therapeutic plan, I cannot agree with him that a gouty paroxysm is a merely local affection. The treatment before us should be limited to those who are in full vigour, and perhaps entony of health; and is especially to be avoided where the stomach is dyspeptic, the lungs asthmatic, the heart subject to palpitation, the head to nervous pains or drowsiness; or where there is any known disability in any other important organ.*

Yet even here we need not, I think, condemn the sufferer to the torture till cured by patience and flannel; for it will often be in our power at least to palliate his pain, and not unfrequently to expedite his cure, without any risk whatever of affecting his general state of health. Leeches may, in many instances, be applied where venesection would be of doubtful expediency; a liniment of oil of almonds, impregnated with opium, rubbed on the tumefaction with a protracted and very gentle friction, I have often found highly serviceable in mitigating the pain; and epithems of tepid water,

* Though Dr. Elliotson approves of the use of a spirituous tepid lotion, he thinks that no medical practitioner is justified in recommending cold applications, as they may bring on apoplexy, violent gastrodynia, or an affection of the heart, and the speedy death of the patient.—See *Lectures in Med. Gaz.* for 1833, p. 851.

as recommended by Dr. Scudamore, alone or mixed with a portion of ether or alcohol, formed by cloths wetted with the fluid, and applied to the inflamed part, renewable as they become dry, in many cases prove a grateful substitute for cold water; and are preferable to poultices, warm water, or even vapour-baths, which too generally relax and weaken the joint, and prevent it from recovering its elasticity, after the paroxysm is over, so soon as it otherwise would do.

At the same time, the body should be cooled with gentle aperients or injections; and, while drenching sweats are avoided, which never fail to be injurious, the breathing moisture or diaphoræ should be imitated, which often breaks forth naturally in an early part of the morning, and is sure to afford relief after a night of distraction. Nor should opium be omitted where the pain is very acute; for, while it affords temporary ease, it diminishes the duration as well as the violence of the paroxysm. Dr. Cullen, in his *Practice of Physic*, seems disposed to postpone the use of this medicine till the paroxysms have abated in their violence; for, when given in the beginning of gouty paroxysms, he asserts that it occludes the fits to return with additional fury. Yet, it should never be forgotten, that it is a law in the history of gout, and one to which we have already adverted, that the frequency and vehemence of the ensuing paroxysms are measured by the violence of those that have preceded.

In the meantime, the regimen should be light and unirritant, and the diet below the standard to which the patient has been accustomed; though, to guard against a metastasis to the stomach, we must be cautious that we do not reduce it too much. His beverage should be cool and unstimulant; Sydenham allows him sound table beer, and, if he have been accustomed to stronger malt liquors, such a drink may be conceded to him. His chamber should be well ventilated, and his dress light and easy.

In the two ensuing varieties, constituting atonic and retrocedent gout, we have a podagric diathesis grafted upon an unsound frame; the unsoundness being general or local: and, however fearless we may be of the disease fixing on any internal organ in the preceding variety, we have here a constant apprehension that it may do so, and, in many cases, see it commence in such organs.

In atonic gout, our uniform attempt should be to produce a transfer from the part on which it has seized, and fix it in the extremities: in retrocedent gout, on the contrary, to render the vacillating attack on the extremities more permanent, and prevent it from shifting to any other quarter.

To obtain the first intention, we have to strengthen, and even stimulate the system generally, by warm tonics and a generous diet, and, above all things, to take off the severe sufferings, in whatever it may consist, from the affected organ; for the longer the fit continues there, the weaker the organ will become, and the less capable of any instinctive remedial ex-

ertion. At the same time, we may solicit the paroxysm to the extremities by putting the feet into warm water.

In atonic gout, the sufferings, though widely different, according to the seat of the disease, are almost insupportable. In the head the pain is maddening, or the disorder is accompanied with great horror, or mimics the stupor of an apoplexy: in the stomach there is a faintness like that of death, with the sense of a cold lump of lead lodged within it; or there is a gnawing or a burning agony, or a spasmodic stricture which cuts the body in two, and renders breathing almost impossible; often also accompanied with a rapid and sinking palpitation of the heart.

It is of importance, before we proceed, to determine accurately that these anomalous symptoms are really those of gout; of which we have chiefly to judge from the general character of the patient's constitution, his hereditary predisposition, habits of life, and the ailments to which he has been previously subject. In most cases during the paroxysm, and especially where the stomach is affected, the warmest cordials are necessary, as brandy, the aromatic spirit of ammonia, the tincture of ginger or of capsicum, or, what is still better, usquebaugh. And it is always advantageous, and especially where the bowels are confined, to add to it some warm aperient, as aloes or rhubarb. Most of our family gout-cordials are made upon this principle, and judiciously consist of some active aperient, and the hottest aromatics dissolved in ardent spirits. And the patient who is subject to these attacks, should never be without having something of this kind at hand, since the paroxysm often makes its onset without any warning. Yet he should resolutely forbear having any recourse to any such medicine, except in the time of necessity; for a habitual indulgence in any of them will still farther debilitate the affected organ, and indeed the entire system; and hence quicken the returns of the paroxysm, and render the stimulant antidote less availing. The best aperient, and at the same time stimulant medicine that I know of for this purpose, is the essential oil of turpentine; which, as uniting the powers of an active cathartic and a camphorate cordial, gives us all the qualities we are looking for. I do not know that this valuable medicine has ever yet been brought into general practice in any form of gout; but I may venture to predict, that those who try it, in the modification before us, will seldom have to repent of their experiment. The dose should be about six drachms, swallowed unmixed.

Most of the preparations of ether contained in the current *Pharmacopœia* of the London College, may be employed with benefit in the variety before us, and particularly in that icy coldness of the stomach, accompanied with a numbness of the limbs and a rapid palpitation of the heart, under which it occasionally exhibits itself. Phosphorus itself has sometimes been ventured upon in this case, in the proportion of two or three grains to a dose, dissolved in double

the proportion of ether; but I have never employed it, and cannot speak of its good effects. Musk seems, in many instances, to have been of decided advantage, if given in sufficient doses, as well in gouty affections of the head as of the stomach. The case related by Mr. James Pringle is strikingly in its favour (*Phys. and Lit. Essays*, vol. ii., art. xii.), and seems to have induced Dr. Cullen to make trial of it in similar instances, who found it produce sudden relief, by free doses repeated after short intervals; and this where the lungs, as well as the head and stomach, were the seat of transferred disease.—(*Mat. Med.*, part ii., ch. viii.)

External irritants may also be beneficially employed at the same time, and particularly those of rapid action, as the compound camphire liniment, sinapisms, and the burning of moxa, or coarse flax, as recommended by Hippocrates: at the same time the extremities, as already advised, should be plunged in the warm bath.

But our sheet-anchor is opium; and it should be given freely, and in union with some preparation of antimony, so as to act towards the surface generally, and thus restore to the living power its interrupted equilibrium. Small doses of opium will here be of no avail; and we may generally repeat or increase the quantity to a large amount with perfect safety. "In a case of the gout in the stomach," says Dr. Cullen, "I have by degrees gone on to the dose of ten grains twice a day; and, when the disease was overcome, the dose of opium was gradually diminished, till, in the course of two or three weeks, it was none at all: and in all this no harm appeared to be done to the system. We frequently find that when a strong irritation is to be overcome, very large doses may be given without procuring sleep, or showing any of those deleterious effects that, in other cases, appear from much smaller quantities. All this appears from the practice now well known in tetanus, mania, smallpox, gout, and syphilis."—(*Id.*, part ii., ch. vi.)

In retrocedent gout, the same plan is to be pursued where the attack has actually shifted from the feet or hands to some internal organ. But where it still lingers in the extremities, though with slight pain and inflammation, and frequent cessations, as though it were on the point of removal, we should increase the morbid action by local irritants applied to the joint, as camphire, ammonia, blisters, sinapisms, or the moxa; and at the same time prescribe a light, but generous diet, with rather more wine than the patient is in the usual habit of taking; carefully avoiding all violent cathartics, and keeping the bowels moderately open with rhubarb, aloes, or the compound colocynch pill.

In gout, however, the INTERVALS OF THE DISEASE are of as much importance to be attended to as its paroxysms: and here, also, the mode of management under the first form should differ essentially from that under the second: for, though the occasional causes may in many cases be the same, they have in the former to operate upon a vigorous, perhaps upon an entonic scale

of power, and in the latter upon a scale decidedly reduced and atonic.

In every variety, all known occasional causes must be equally avoided. Where the diet has been too rich it must be lowered, and where too spare and abstemious, made more liberal. Indolence and a sedentary life must give way to regular exercise; and over-exertion of body or mind, to repose and quiet. In the young, robust, and corpulent, whether the disease result from too great indulgence at the table, or an habitual taint, it may be requisite to abstain from animal food, wines, and fermented liquors, altogether; but where the sufferer has passed considerably beyond the zenith of life, and the luxuries of the table have become habitual, his ordinary fare should be reduced or diminished, rather than entirely commuted. And, in every change, it is better to proceed slowly, than to rush rapidly from one extreme to another: since nothing has so great a tendency to prepare the internal organs for gouty paroxysms, as such sudden and violent transitions. The bowels should be kept in regular order, and the hour of rest be early.

A due and unsparing attention to these general rules of the hygiene will often be sufficient to keep those free from all disturbance of the gout for many years, and perhaps for the whole of their subsequent life, who have only known it in the form of a few regular paroxysms. But where the system, and especially the digestive function, are weak, and the patient has had anticipations of atonic or recedent gout, or has actually suffered from its assaults, it will be necessary to superadd a course of INVIGORATING MEDICINES.

There are three classes of remedies that generally pass under this name; stimulants, bitters, and astringents. The first increase the action, the two last augment the tone. Stimulants can rarely be employed alone, except in cases of emergency; for a lax state of fibres will bear little increase of action, without, at the same time, suffering an equal increase of debility. But they may often, and in the case of gout perhaps always, be combined with astringents and bitters with great and decisive benefit. Upon this subject, however, I have already treated so largely under LIMOSIS DYSPEPSIA, or INDIGESTION, that it is only necessary to refer the reader to that part of the work for the present purpose.

Most of the celebrated specifics for preventing a return of gout have been formed of these classes of medicines in combination, and especially of bitters and aromatics; and it is singular that, although the variety of them which nature offers to us is almost infinite, they have been employed with little change from the time of Galen and Cælius Aurelianus in the second century, to that of Sydenham in the seventeenth. The famous powder purchased by the second Duke of Portland, who distributed its receipt for general use, from the service it appeared to have rendered him, is formed for the most part of the very same ingredients, modified either from the Greek writers, Cælius Aurelianus and Ætius, or from Dr. Sydenham's

prescription; though it is a simplification of the latter, by omitting several of the articles that enter into his composition, one or two of which had better be retained. In this reduced form, it consists of equal parts of the five following materials, finely powdered and intimately commixed: birth-wort, gentian, germander, ground-pine, and the tops and leaves of the lesser centaury. The dose is a drachm taken fasting every morning for three months; after which it is to be reduced to three quarters of a drachm for three months longer; then to half a drachm for the remainder of the year; and, after this, the same dose is to be continued every other morning only, through the next twelve months: by which time it is presumed that a cure will be accomplished.

The real effect of this and similar medicines is very doubtful, and the doubt arises from the gradual mischief which a gouty diathesis has a tendency to produce in the corporeal system; and the benefit which the exact and abstemious regimen that is prescribed during the use of the Portland or any other course of bitter tonics, is calculated to afford of its own accord. In some instances, such medicines seem to have produced little or no effect of any kind: in others, the joint result of remedy and regimen seems to have been highly salutary; while, in others again, the patients, though free from open and decided fits of the gout, appear to have sunk gradually under complaints more distressing and fatal than the gout itself, as dyspepsy, lowness of spirits, and dropsies of almost every part, especially hydrothorax, ascites, and anasarca.

Now, it is possible that the regimen alone may have produced the good where good has been experienced, and the gouty diathesis the evil, where evil has followed; or that the bitter tonics themselves may have done both, according as the individual to whom they have been administered has been in a proper or improper state of body for a trial of them. They are not to be used indiscriminately; for, while the relaxed and debilitated, those who are subject to atonic and retrocedent gout, may have recourse to them with great advantage, they will be sure to prove injurious to those of high tonic health, and who are distinguished by attacks of gout in regular but vehement paroxysms.

Some bitters, even among those in common use, may possess more of the sedative and narcotic principle than others; and, where this is the case, though such may be fittest for employment in the first instance, they ought to be dropped for others of a different kind, as orange-peel, bark, columbo, and serpentaria, as soon as all local irritation has ceased. The strongest bitter we are acquainted with is the *nux vomica*, and the narcotic quality of this is known to every one. Opium possesses it in a still higher degree. It has of late been suspected to exist in wormwood, and been distinctly traced in the hop and some of the lettuce tribe.

Dr. Cullen, however, has taken a different view of this subject. He supposes all bitters to possess a deleterious quality of some kind or other, and that, in all gouty persons, they have

a power of warding off fits of this disease; but that, from this deleterious property, when long persevered in, they weaken the stomach and other organs of digestion to which they at first gave tone, and thus ultimately induce the diseases we have just noticed, and which are too apt to follow upon a debility of these viscera. And, in proof of this opinion, he tells us of the fate of nine or ten persons who had been liable for some years before to have "*a fit of a regular or very painful inflammatory gout*, once, at least, and frequently twice, in the course of a year; but who, after they had taken the Portland powder for some time, were quite free from any fit of inflammatory gout," and, having completed the course prescribed, "had never a regular fit, nor any inflammation of the extremities, for the rest of their life. In no instance, however," continues Dr. Cullen, "that I have known, was the health of these persons tolerably entire. Soon after finishing the course of their medicine, they became valetudinary in different shapes, and particularly were much affected with dyspeptic, and what are called nervous complaints, with lowness of spirits. In every one of them, before a year had passed, after finishing the course of the powders, some hydroptic symptoms appeared, which, gradually increasing in the form of an ascites or hydrothorax, especially the latter joined with anasarca, in less than two, or at most three years, proved fatal."—(*Mat. Med.*, part ii., ch. ii.)

As Dr. Cullen gives us no account of any mischief that has followed the use of bitter tonics in constitutions marked by general debility and atonic gout, the evils he has described seem, on his own evidence, to be limited to those whom we have already cautioned against the employment of such a course. No proper classification or line of distinction seems to have been drawn or adhered to; which would probably have presented us with very different results if it had been, and have superseded the clashing and unsatisfactory explanation of atonic effects uniformly produced by a continuance of tonic medicines.

The subject, however, requires to be further examined by a more accurate classification of gouty patients who may be put under the influence of medicines of this kind; and I throw out the hint for this purpose. Yet, that a persevering course in bitter tonics does not uniformly prove in any way injurious to those who engage in it, is, I think, demonstrable from the daily use of table beer in almost every family throughout the country, and its appearing to be one of the wholesomest beverages we can adopt. Dr. Darwin, indeed, ventures to ascribe part of the mischief produced by highly-spirited malt liquors to some noxious quality in the hops they contain; but the stronger and headier malt liquors are uniformly prepared with a much smaller proportion of hops than the weaker, and especially than those which go under the name of table beer. For the only point aimed at by the employment of hops is to prevent an acetous fermentation, which is effectually guarded against by the larger proportion of spirit con-

tamed in ale and strong beer, but which every one knows would soon take place in table beer if it were not powerfully impregnated with this grateful bitter. And hence the remark of Dr. Darwin seems to have no foundation whatever, since the stronger bitter affords a beverage proverbially wholesome, while the weak bitter is that which proves injurious.

There have also, in all ages, been offered to the public specifics for the sudden cure or removal of the paroxysm when present, as well as for preventing its return hereafter. Lucian, in his *Tragopodagra*, gives us, with great humour, a list that occupies a page, of such as were chiefly in vogue in his day; and the catalogue is certainly not diminished in our own. Those that have acquired the highest reputation appear to have been composed of some species of hellebore, or of meadow-saffron; the first of which is among the remedies quoted by Lucian; though it is probable that the *ῥιζὴν ἑλαειβορῶν* of the Greeks was a different plant from either the white or black hellebore of modern dispensaries.

The favourite specifics of the present day are M. Husson's *Eau médicinale*, and the *vinum colchici*, or wine of meadow-saffron. The exact components of the former are kept a secret; though its basis is well known to be either the one or the other of the above plants, most probably the meadow-saffron. The effects of the *Eau médicinale* and of the colchicum wine do not essentially differ; for, after taking about sixty drops of either, the pulse becomes slower, and at length sinks, in about twelve hours, from ten to twenty strokes in a minute below its natural number, at which time the inflammation subsides. The action of both medicines is accompanied with great languor and a deadly nausea or sickness, which terminates in vomiting, or a discharge from the bowels, or both. If the dose be in a small degree in excess, the symptoms are syncope, cold sweat, extreme prostration of strength, violent vomiting and purging, a wiry and almost imperceptible pulse, or a state of utter and very alarming insensibility. And, in some constitutions, these effects have followed from the use of even a common dose.

Sir Everard Home made several trials of the colchicum wine on a dog, both by the stomach and by infusing it into his jugular vein. From thirty drops he recovered in about seven hours; from sixty drops, in eleven; but a hundred and sixty drops, thrown into the jugular vein, killed him, after having suffered great agony, in five hours. On opening him, the stomach, smaller intestines, and colon, were highly inflamed.—(*Phil. Trans.*, 1816, art. xii., xiii.) And it is hence obvious that this medicine, like many other emetics and cathartics, acts rather upon the stomach through the medium of the circulation, than on the system through the medium of the stomach. It is possible that the colchicum may act by a specific power on the peculiar inflammation of a regular fit; yet, as other intestinal irritants have occasionally produced a like effect, and particularly the *gratiola officinalis* (hedge-hyssop), and *ranunculus flammula*,

the disappearance of the paroxysm may also be ascribed to a transfer of action to the stomach and intestines. Generally speaking, specifics operate by a secret and inexplicable power, as the bark in intermittents, the vaccine virus in shielding the constitution against smallpox, and mercury in syphilis: for, though a pytalism gives proof that the system is impregnated with the last, there are few practitioners so attached to the Cullenian doctrine in the present day, as to contend that the venereal virus is carried off by the salivation, since we are perpetually beholding it carried off under the influence of mercury without any salivation whatever.

Yet, admitting that the colchicum has a specific power over a regular inflammatory paroxysm of gout, it is clear that it has no such power over the gouty diathesis, since the paroxysm has never been so removed as not to return again. And it hence becomes a serious question, whether the mischief produced in the constitution by the employment of so active a medicine, in the large doses recommended by some practitioners, be not greater than the temporary good obtained by the suppression of the inflammation?

From the rapidity and force of the operation, it is clear that they ought never to be tried, or never without the utmost caution, except in the first variety of gout, or where the system is firm and healthy, and the disorder shows itself in a regular fit. And as it is highly desirable, for reasons already stated, to restrain the violence of the paroxysm, shorten its duration, and carry it off as soon as possible, the use of the one or the other of these medicines may be judicious, so long as the system is able to recover itself with speed from their influence, and provided the patient limit himself to the smallest dose that will answer the purpose.

Yet these medicines, from too little attention to their real effects, and from a mistaken idea that they are equally a specific for gout under every form, have not often been confined to the entonic variety, nor employed with sufficient discrimination in the second and third varieties of the disorder, in which the system, and particularly the digestive organs, are in a state of chronic debility; and the inflammatory fit, when it shows itself in the hands or feet, is incomplete and evanescent. In all such cases, such medicines, without the superintendence of much practical caution and judgment, cannot fail to do serious injury to the constitution. They have a tendency to increase the ventricular weakness, and hereby to leave the system more open to all the miseries which gout is so perpetually entailing. And hence the reason of the very general complaint among those who have tried these remedies, that, although they remove the fit at the time, they shorten the intervals, and render their frames more obnoxious to relapses. In my own person, I have never exceeded forty drops of the colchicum wine, prepared after the form of the Royal College; and I have seldom failed to find this serviceable, though I cannot affirm that it has been uniformly so.

The remarks of Dr. Lucas upon this subject are well worthy of attention, and, as being offered since the first edition of the present work, may be quoted as confirming the author's views. Having contended for a specific principle in gout, which he thinks obvious from the peculiar acid smell of the perspiration, and the deposit of urate of soda concretions, he proceeds as follows:—"I am much strengthened in this opinion by the effects of the Eau médicinale and other gout medicines of the day in procuring summary relief in the first instance, at the expense of more frequent visits of the disorder, till at length it is constantly present, and in some form or other proves fatal. The inflammation here is probably cured before the morbid matter can be thrown off, which, therefore, shortly renews its attack, while the powers of the constitution generally give way under this unsuccessful conflict: for it does not appear how the cure of inflammation, abstractly considered, can be too rapid, if effected with safety to the organization."—(*On the Principles of Inflammation and Fever*, 8vo., 1822.) It hence follows, as already observed, that our great object in the employment of these medicines should be to moderate the inflammation, without trenching on the strength of the constitution.*

Where the inflammation has subsided, and weakness alone remains, and an inability to use the limb without pain, I have at times found the support of a compressing bandage produce considerable comfort.†

* Colchicum rarely proves beneficial, unless it produce either nausea, copious perspiration, or purging, or all these effects together. Hence, the common practice is to give the vinum colchici in half-drachm doses, every four or six hours, joined either with magnesia or the sulphate of magnesia, so as to determine its action to the bowels. Modern practitioners seem to be acquiring every day greater and greater partiality to colchicum as a means of relieving gout; and, while the apprehension of various evils from its free employment is not universally allowed to be well founded, its action in shortening the paroxysm of the disease, as soon as nausea or purging is brought on by it, is very generally acknowledged. In cases of active gout, occurring in a full habit, it is best always to let bleed and a purgative of calomel and antimony precede the exhibition of colchicum. Dr. Spillan, of Dublin, prefers a tincture of the seeds, of which ʒi., ʒiiss, or ʒij., may be given at night, and repeated, if necessary, the next morning. This quantity, he says, will generally purge briskly; but if it fail, a third dose the following night will be sure to succeed.—(See his Supplement to *Pharmacopœia*.) The editor, instead of encountering this risk of losing so much time, prefers giving the wine of colchicum in a mixture, containing magnesia, or the sulphate of it. Colchicum purges, allays pain, and lowers the pulse, and, when we know these facts, we need not trouble ourselves with an inquiry, whether it has a specific power over gout or not.—F.D.

† The American profession is much indebted to Dr. Rush for his enlightened views on the cause and treatment of gout, published many years ago, which induced practitioners to adopt a depletory plan of treatment, by bloodletting, purgatives, blisters, &c., even long before the nature of gout

SPECIES IV. ARTHRISIA HYDARTHROS. WHITE SWELLING.

COLOURLESS SWELLING, CHIEFLY OF THE LARGER JOINTS: INFLAMMATION SLOW, AND DEEP-SEATED: PAIN FIXED AND SEVERE: IMPERFECTLY SUPPURATIVE: FEVER A HECTIC.

This inflammation, like that of rheumatism, attacks the larger, rather than the smaller articulations. Yet, as the joints are uniformly the seat of its assault, and it frequently runs through its course without the production of genuine pus, however severe its symptoms and fatal its termination, it has a manifest relation to the two preceding species, and ought to be arranged under the same genus.

The ordinary occasional cause is a strain, or some other injury to the joint affected; but this cause does not equally operate in all persons to the production of such a result; and it is hence obvious, that there is, as in the case of gout and rheumatism, a predisposition or peculiar diathesis favouring the origin of hydarthrus, existing in some individuals, to which others are strangers. And we find this predisposition showing itself also, as we have already seen, in the podagric diathesis, both in persons of a strong, robust, and tonic state of health, and in persons of relaxed and inelastic fibres, particularly in those who inherit a scrofulous taint. And hence the disease exhibits itself under distinct forms, seats itself in different parts of the joint, and demands different modes of treatment.

[In the foregoing editions of this work the author took his description of white swellings chiefly from the writings of Mr. B. Bell, and adopted the very hypothetical division of the disease into *tonic* and *atonic*, meaning by the former case the rheumatic white swelling of several other writers, that most frequently takes place in young plethoric people, "possessing that firm elasticity of health and fibre, which, upon the application of accidental causes, gives rise to rheumatism, as well as this variety of hydarthrus." The *atonic* white swelling was, in our author's opinion, a name suited for that

was as well understood as it is now. The practice of applying cold air or cold affusions to the gouty surface or extremities, has fewer advocates in this country than abroad; and too many instances might be cited, where their employment has not only aggravated pain, but induced a fatal metastasis. American physicians sometimes give the colchicum in combination with a solution of tartarized antimony. In this way a more advantageous action of the medicine on the skin is often secured. Opium must be administered with caution, particularly if plethoric or local determination to important organs exists; in such cases, it were better to repeat venesection; after which, the well-known Dover's powder is to be preferred. The Eau médicinale has sometimes partially mitigated an attack of gout with us as elsewhere; but it has also been detrimental. Carded cotton to the part affected is much more grateful and soothing than flannel, and the cajuput-oil, blended with some stimulating liniment, is among the best embrocations.—D.

variety which commences in the cancelli of the bones. It is rather extraordinary that Dr. Good should have preferred this principle of division, and selected the epithets *entonic* and *atonic*, which involve us at once in conjecture and hypothesis, instead of a division of the subject founded upon facts demonstrated by dissection, and a choice of names, calculated to express, as correctly as possible, the particular texture chiefly and primarily concerned in each variety of white swelling, and the nature of the morbid changes. When it is considered that our author was not unacquainted with the valuable researches of Mr. Brodie, the course adopted seems the more singular. The editor, not feeling that it would be right, in the present state of surgical knowledge, to repeat the author's description of white swelling, has been obliged to introduce a short sketch of the subject arranged on other principles.

Hydrarthrus is divisible into the following varieties:—

- | | |
|------------------------|---|
| a Membranæ synovialis. | White swelling commencing in the synovial membrane. |
| β Cartilaginum. | — commencing in the cartilages. |
| γ Ossium. | — commencing in the bones. |

The term *white swelling* has been commonly applied to enlargements of the joints, in consequence of the colour of the skin being often not at all changed, even in very advanced periods of the disease. As it expresses what is generally true, the name can hardly be found fault with on the ground of its conveying any erroneous notion; yet, it is objectionable on another principle, which is, that it is applied to several diseases of the joints, which are of very different characters in every other respect, thus tending to keep up a want of scientific discrimination, which conduces to a great deal of confusion and obscurity in practice. The texture of the joint, principally and primarily concerned in the disease, and the nature of such disease, form, as we have already remarked, a better and more useful basis of nomenclature.

The synovial membranes of the joints constitute bags, without any external opening; in this respect resembling the peritoneum, the pleura, and the pericardium, to which Mr. Brodie conceives it also bears some analogy, both in its functions and diseases. At all events, experience proves, that it is frequently the seat of inflammation; it is in fact one of the fibrous textures, particularly pointed out by Bichat and other writers, as a common situation of rheumatic inflammation. The consequences of its inflammation, as enumerated by Mr. Brodie, are, first, a preternatural secretion of synovia; 2dly, effusion of coagulable lymph into the joint; 3dly, in other cases, a thickening of the membrane; a conversion of it into a gristly substance; and an effusion of coagulable lymph and serum into the cellular texture, by which it is connected to the external parts. In

the museum of the London University are several specimens of adhesions of the folds of the membrane to each other, the result of previous inflammation. Unless the disorder arise from mechanical injury, inflammation of the synovial membrane rarely terminates in supuration. When the disease is unchecked, it may lead to ulceration of the cartilages; but he thinks that where this change is combined with inflammation of the synovial membrane, the affection of the cartilages is mostly the primary one, and that of the membrane the consequence of the formation of an abscess in the joint.*

The symptoms are pain in the joint, frequently very severe at one particular spot, and followed in a day or two by swelling. At first, the swelling arises entirely from fluid in the cavity of the joint; but afterward the synovial membrane becomes thickened, or lymph is effused on its outer or inner surface; the fluid in the joint is, therefore, less easily felt, and the mobility of the joint itself diminished. As the swelling is chiefly produced by the distended state of the synovial membrane, its shape is not that of the heads of the bones, and is modified by the resistance it meets with in certain directions from ligaments and tendons. The disease is less frequent in the hip and shoulder than in the more superficial joints. After inflammation of the synovial membrane has subsided, the fluid is absorbed; and in some instances the joint regains its natural figure and mobility; but in other cases swelling and stiffness remain, and the patient is very liable to a recurrence of the disease, whenever he is exposed to cold, or takes much exercise. Sometimes the inflammation not only lingers in the part, but extends to other textures, and at length the cartilages ulcerate, supuration is established, and the articular surfaces are destroyed.

Inflammation of the synovial membrane seldom attacks young children, but is very frequent in adults: a feature in which it exhibits a resemblance or relationship to the rheumatic inflammation of fibrous textures in general. Indeed, it is this species of white swelling that is particularly implied in the descriptions given by many writers of the form of the disease to which they apply the epithet *rheumatic*. Mr. Brodie further remarks, it may occur as a symptom of gout or rheumatism; or of derangement of the health by syphilis, or the unskilful use of mercury. In other examples the affection of the joint is quite local, being produced by a sprain or contusion, an extraneous cartilaginous body in the joint, or, what is still more usual, by exposure to cold.

When the case has arisen from the ill effects of mercury, Mr. Brodie recommends sarsaparilla; when from rheumatism, opium conjoined with diaphoretics, and the colchicum, which is also particularly useful where the complaint is connected with gout. But when several joints

* See Brodie's *Pathological and Surgical Obs. on the Diseases of the Joints*, pp. 16 and 19, 2d edit., Lond., 1822. A different view of this point is adopted by Mr. Key.—See *Med. Chir. Trans.*, vol. xix.—Ed.

are simultaneously attacked, he deems the moderate use of mercury the most successful practice.

In all cases, however, Mr. Brodie has found topical treatment the most important. In the acute stage of the inflammation, he has recourse to leeches and even venesection; aperient medicines; saline draughts and diaphoretics; and, when the swelling and tension are very great, he prefers fomentations and poultices, but, under other circumstances, cold lotions. In the chronic stage, perfect quietude of the joint, leeches or cupping, repeated several times, and a cold lotion, are the means advised. When the inflammation has somewhat yielded he applies large blisters, and, if necessary, repeats them from time to time; a plan which he finds more effectual than that of keeping a single blister open with the savin cerate. In a further stage, when the inflammation has yielded still more, he employs strong liniments, containing a proportion either of lin. ammonia, tinctura cantharidum, or sulphuric acid. The remaining stiffness will be removed by friction with the hand alone, or camphorated mercurial ointment; free exercise of the limb; or by allowing a column of water to be pumped on the joint from a height, as is practised at the watering-places.

Another form of disease affecting the synovial membrane, and commonly classed as a white swelling, is that in which the membrane is converted into a thick pulpy substance, of a light brown colour, intersected by white membranous lines. As the disease advances, it leads to ulceration of the cartilages, caries of the bones, wasting of the ligaments, and the formation of abscesses. According to Mr. Brodie's investigation, the disease is slow, but, in the end, the joint is invariably destroyed. The case is rarely seen in any other joint than the knee.

The disease commences with a slight stiffness and tumefaction, without pain. At last, the motion of the joint is generally seriously impaired; though, in some cases, a certain degree of it remains. The swelling is less regular than that produced by inflammation of the synovial membrane, and is soft and elastic, as if arising from fluid. The patient suffers no pain until abscesses form, and the cartilages ulcerate, at which period hectic fever usually comes on, and the patient gradually sinks, unless the limb be amputated.

Mr. Brodie deems this form of the disease incurable. All that can be done is to check its progress by rest and cold lotions; and to alleviate the pain attending ulceration of the cartilages by fomentations and poultices. In the end, the limb must be sacrificed for the preservation of life; at least, until some new treatment, capable of restoring the natural texture of the synovial membrane, be discovered. From certain accounts published of the effects of iodine, employed internally and externally, it would seem to deserve a fair trial. Mr. Buchanan, of Hull, applies the tincture to many white swellings, both in the acute and chronic stages, with surprising success, according to the statements contained in his late publication.—(*Es-*

say on Diseased Joints and the Non-union of Fracture, 8vo., Lond., 1828.)

One species of the disease, vulgarly denominated white swelling, appears, from the researches of Mr. Brodie, to commence in the articular cartilages; and this change is found to be the primary one in a large proportion of the cases in which the hip-joint is concerned.* Ulceration of the cartilages of the knee is attended with one remarkable difference from inflammation of the synovial membrane, viz., in the former, the pain is at first slight, and gradually becomes very intense, which is exactly the reverse of what happens in the latter. Neither is there, for a considerable time after the disease has begun, any evident swelling, and when this does show itself, it arises from a slight degree of inflammation in the cellular membrane on the outside of the joint, and seems greater than it really is, owing to the wasting of the muscles. No fluctuation is perceptible, as where the synovial membrane is inflamed; nor is there the peculiar elasticity which accompanies the conversion of that membrane into a thick pulpy substance. However, in a few cases, the synovial membrane is secondarily affected, and the synovia or pus may collect within the joint. If the disease proceed, abscesses generally form, the ligaments are destroyed, and the joint becomes dislocated. The editor has seen several cases, in which the head of the tibia has been drawn into the ham; and melancholy examples of the luxation of the thigh-bone from the acetabulum, in consequence of this disease in the hip, may be seen daily in the streets of every city and town in Europe.

In the treatment of primary ulceration of the cartilages of the joints, Mr. Brodie attaches considerable importance to keeping the part motionless. It is this disease, for which he finds caustic issues particularly useful. In the early stage, local bleeding, venesection, and the warm bath, are sometimes serviceable; but stimulating plasters are inefficacious, and friction always hurtful.

Another form of white swelling takes place so often in persons with decided marks of scrofula about them, that it is generally regarded as a scrofulous disease. It originates in the cancellous structure of the bones, and ulceration consequently takes place in the cartilages of the joint, and the disease then follows nearly the same course as when it has commenced with ulceration of the cartilages. The heads of the bones of the affected joint at first become unusually vascular, and deprived of their due proportion of lime, while, at first, a transparent fluid, and afterward a yellow cheesy substance, is deposited in their cancelli. As the caries of the bones advances, inflammation takes place in the cellular membrane on the outside of the

* From some researches undertaken by Mr. Aston Key, it would appear that ulceration of cartilages is preceded by the formation of a vascular substance by the synovial membrane, which substance is the organ by which the cartilaginous tissue is removed.—See *Med. Chir. Trans.*, vol. xix.—Ed.

joint. Hence, a puffy and elastic swelling in the early, and an œdematous one in the advanced stage of the disease. At length an abscess is formed in the joint, and, making its way by ulceration through the synovial membrane, bursts externally, after causing numerous sinuses in the soft parts. In the last stage of the disease, the bones, instead of being preternaturally vascular, become less so than in the healthy state; a circumstance to which Mr. Lloyd has imputed the exfoliations which sometimes occur.—(*On Scrofula*, p. 123.)

According to Mr. Brodie's observations, the disease is often met with in children; and is rarely seen in individuals past the age of thirty. The hip and shoulder are less liable to it than many other joints. As it is connected with a particular diathesis, it sometimes affects several joints at the same time, or recurs in others after the one originally attacked has been cured or removed. In this form of white swelling, a degree of pain in the joint, generally not a very distressing one, precedes for some time the occurrence of swelling in the soft parts. When the cartilages ulcerate, the pain increases; but it is not severe until an abscess has formed, and the parts over the abscess become distended and inflamed. When the abscess bursts, a thin pus, with portions of substance resembling curd, is discharged. "I conceive all such collections of matter," says Mr. Hunter, "to be of a scrofulous nature: they are most common in the young subject, and seldom found in the full grown, or old. The suppuration is not proper pus, nor the swelling proper inflammation."—(*On the Blood*, &c., p. 391.) Sinuses then generally remain, at the bottom of which diseased bone may be felt with a probe. In the worst cases, the patient either dies hectic, or is obliged to submit to amputation. In others, a curative process ensues; and the disease terminates either with or without ankylosis, according to the extent of the destruction of the articular surfaces. In the complicated joints of the foot and hand, the chances of recovery are found by Mr. Brodie to be even less than in larger joints.

With respect to the treatment, the plain connexion of the disease with scrofula implies that such general remedies as are calculated to improve the state of the constitution, cannot fail to be proper. Loss of blood seems to Mr. Brodie less useful in this form of white swelling than in some others. He has also seldom known any benefit derived from blisters and liniments; issues and setons, though serviceable, he has only found so in an inferior degree. Cold lotions check the extension of the disease to the soft parts, and retard the formation of abscesses. He lays much stress on the advantages of keeping the joint perfectly quiet, or as far as it can be done with due regard to health. Hence, he is an advocate for mechanical contrivances for

this purpose; and as far as the editor can judge, this seems to be the principle chiefly aimed at by Mr. Scott in the mass of plasters, bandages, pasteboard, &c. with which he surrounds the diseased joint and limb.* When abscesses are forming, fomentations and poultices are to be employed. When suppuration ceases, and a tendency to ankylosis begins, Mr. Brodie applies round the limb strips of linen, spread with soap cerate.

As for the means of improving the health, the pure air of the seacoast; nourishing plain diet; steel medicines; mineral acids; and, in children, occasional mercurial purgatives; with the benefit arising from being a good deal in the open air in summer, are those principally recommended.—(*Brodie's Pathological and Surgical Obs. on the Joints*, 8vo., Lond., 1822.)

Some practitioners are partial to the counter-irritation arising from the application of tartar-emetic ointment to the integuments of the diseased joint; some prefer setons; some caustic issues; and others the moxa. But, in numerous examples, all plans seem to fail. Whether the high praises now bestowed on the iodine, as a remedy for white swellings, will be justified by general and impartial experience, time will soon determine. As our author remarked in his last edition [no medicine acts so directly on the absorbent system as iodine; and we are informed by Dr. Gairdner, that M. Mannoir, of Geneva, has in one case of a very decided character, and in which even amputation had been advised, after a failure of every other means, found the use of the ointment of iodine, together with the tincture, completely succeed; so as not only to remove the tumour, but to restore as free a motion to the affected joint as was possessed by the sound knee. The dose of the tincture contained one twelfth of a grain of iodine at its utmost. The patient was eight years of age.—(*Essay on the Effects of Iodine*, &c., pp. 49, 64, 8vo., 1821.) [The most encouraging accounts of the effects of iodine in the cure of white swellings hitherto published, are those of Mr. Buchanan of Hull, who applies the tincture† with a camel-hair brush to the integuments, by which it appears to be rapidly absorbed.‡]

* See *Surgical Obs. on the Treatment of Chronic Inflammation*, 8vo., Lond., 1823. The merit of first suggesting this principle of treatment the editor believes due to the late Mr. Crutwell, of Bath.

† R Iodinæ ʒj., Spir. Vinos. Rect. ʒij fl. Tinctura.

‡ See an Essay on a New Mode of Treatment for Diseased Joints; and the Non-union of Fracture, 8vo., Lond., 1823. Although iodine applications are frequently useful in the treatment of chronic diseases of joints, the editor does not find their power so great as some writers represent.

ORDER III.

EXANTHEMATICA.

ERUPTIVE FEVERS.

CUTANEOUS ERUPTIONS ESSENTIALLY ACCOMPANIED WITH FEVER

THE term Exanthemata among the Greeks, from *ἐκβαίνω*, "effloresco," "per summa erumpo," "to effloresce, or break forth on the surface," imported cutaneous efflorescences or eruptions *generally*. It has since been limited to express cutaneous eruptions *accompanied with fever*, a boundary assigned to it by Sauvages, Linnæus, Vogel, Sager, Macbride, Cullen, and various others, and this, in effect, is its general meaning in the present day. Dr. Cullen, however, in his note on Exanthemata, thinks it worth considering whether the word should not be restrained to eruptions (he does not say *febrile* eruptions) produced alone by specific contagion; "eruptiones a contagione specificâ ortæ;" while Dr. Willan has still more lately narrowed it, so as to include those eruptions only which fall within the meaning of the English term *RASH*, whether *febrile* or not *febrile*.

The two last senses of EXANTHEMATICA, or EXANTHEMATICA, are new and singular. Dr. Cullen, however, has not followed up his own suggestion into his own classification; while Dr. Willan has not always continued strictly true to his own views and definition, as I have observed in the running comment introductory to the present order in the volume of Nosology, to which the reader may turn, for a fuller examination of this subject, at his leisure.

The term, therefore, in the present work, is employed in its common and current sense, so as to include all cutaneous eruptions in which fever exists as an essential symptom; whether accompanied with or destitute of contagion; which last is a doubtful, and perhaps an inappropriate ordinal character: doubtful, because we cannot very precisely tell where to draw the line; and inappropriate, because it is a character that applies to diseases of very different kinds, and scattered over the entire classification, as dysentery and influenza, in which there is fever without cutaneous eruption; itch, and many varieties of tetter, in which there is cutaneous eruption without fever; and blennorrhœa or clap, in which there is neither fever nor cutaneous eruption. The genera included in the order are distinguished by the nature of the eruption, as consisting of red, level, or nearly level patches or pimples filled with a thin ichorous fluid; of pimples filled with a purulent fluid; and of foul, imperfectly sloughing tumours; and hence consist of the four following:—

- | | |
|-----------------|-----------------------|
| I. Enanthésis. | Rash Exanthem. |
| II. Emphylisis. | Ichorous Exanthem. |
| III. Empyesis. | Pustulous Exanthem. |
| IV. Anthracia. | Carbuncular Exanthem. |

Each of these, with the exception of the third, comprises several species; and all concur in evincing the existence of morbid and specific poisons in the blood, acting the part of animal

ferments,* converting the different fluids into their own nature, exciting the commotion of fever, and being eliminated on the surface, as the best and most salutary outlet to which they can be carried, by the very fever which they thus excite.

The whole is a wonderful circle of morbid and restorative action, evincing the most striking proofs of that instinctive or remedial power of nature, whose presence in every part of every living frame, whether animal or vegetable, is continually discovering itself; and which, under the general control of an infinite and omniscient Providence, is perpetually endeavouring to perfect, preserve, and repair the individual, and to multiply its species.

We have many times had occasion to observe, that wherever any diseased action is taking place internally, there is a constant effort exhibited in the part, or in the system generally, to lead it to the surface, where it can do least mischief, rather than let it spread itself on the deep-seated or vital organs, where its effects might be fatal. Mr. John Hunter was peculiarly fond of dwelling on this admirable economy of nature, and of illustrating it from the course pursued in inflammations of every kind (*On Blood, Inflammation, &c.*, pp. 236, 450, 467), which, to obtain this beneficial end, often wind their way outwardly through a multiplicity of superincumbent organization, instead of opening into some momentous cavity in the interior, from which it is perhaps only separated by a thin membrane. But there is no part of pathology in which this display of a final cause, of an operative intention admirably adapted to the end, is more striking, than in the order of eruptive fevers.

It is by means of the fever that the disease works its own cure; for it is hereby that a general determination is made to the surface, and the morbid poison is thrown off from the system.

But the fever may be too violent; and, from accidental circumstances, it may also be of the wrong kind; both which facts occasionally occur in inflammations, and require the art of medicine for their correction.

When a febrile poison, producing a cutaneous eruption, is generated or has been conveyed into the blood, a small degree of fever is sufficient to throw it upon the skin; and if it exceed the proper extent, the specific virus will be multiplied, and the fever itself may become a source of real danger. It was formerly the practice to encourage the fever by cardiacs, a heated atmosphere, and a load of bedclothes, from an idea that we hereby solicit a larger flow of morbid matter from the interior to the surface. The fact is unquestionable; for be the exanthem what it may, the skin will hence, in almost every instance, be covered with eruption. But it did not occur to the pathologists of those times, that the morbid virus was an animal ferment capable of multiplying itself by accessories: and that heat and febrile action, beyond

* This language must be understood only in a figurative sense.—Ed.

a very low medium, are among the most powerful accessories we can communicate. And hence the advantage of the modern practice of applying cold water in scarlet fever, and cold air in smallpox, with a view of mitigating the fever that often accompanies these diseases: for, by diminishing the febrile violence, we do not, as was formerly imagined, lock up the contagion in the interior of the system, but prevent it from forming afresh and augmenting there.

But the fever, though the natural mode of cure, may not only be too violent, but it may be also of the wrong kind. And here, again, the whole scope of professional skill is often demanded.

Some of the morbid poisons we are now advertising to have a natural tendency to excite a fever of one description, and others of another. Thus the fever of smallpox and measles is ordinarily inflammatory; that of scarlet fever may commence with an inflammatory type, but it has a strong tendency to run into a typhous form: while that of pemphigus and plague is typhous from the beginning.

Much also, in this respect, will depend upon accidental circumstances, as the constitution of the year, and the prevailing epidemic; the constitution of the patient, his habit of life, or hereditary predisposition. For under the control of these, we sometimes see an eruptive fever, having naturally a typhous turn, restrained in its tendency; and, on the contrary, a fever with an inflammatory turn, as in smallpox or measles, converted into a malignant or a typhous. Yet the general intention pursued by the instinctive or remedial power of nature, is one and the same: and it is the duty of the medical practitioner to watch over that intention, and co-operate with it; to moderate the natural means when in excess; to quicken them when deficient; and to correct them when deflected by accidental circumstances.*

* In the very beginning of acute exanthematica, congestions of different mucous membranes exist almost constantly, and, as Andral observes, it is a remarkable fact in the history of these diseases, that in each of them the congestion has a determinate situation; in scarlet fever, the mucous membrane of the pharynx; in measles, that of the air-passages; and in variola, that of the stomach. —(Anat. Pathol., tom. ii., p. 224.) Exanthematica are not to be regarded merely as cutaneous diseases; they are rather affections of the whole system, extending their effects to internal organs as well as the surface. In measles, as Dr. Elliotson remarks (Lancet for 1830-31, p. 393), the mucous membrane of the nostrils, the conjunctiva, the mucous membrane of the air-passages, often down to the very air-cells, nay, occasionally the substance of the lungs and the pleura, and even the intestines, are much affected. In smallpox there is great affection of the larynx, such as frequently destroys life; a great affection also of the epigastrium; the stomach is particularly tender, and is really inflamed from the first. In scarlet fever the eyes and nose are not much affected, but the inside of the mouth, the soft palate, the pharynx, and the tongue, suffer intensely, and sometimes in such a degree, that their condition is mainly concerned

GENUS I.

ENANTHESIS.

RASH EXANTHEM.

ERUPTION OF RED, LEVEL, OR NEARLY LEVEL PATCHES; VARIOUSLY FIGURED; IRREGULARLY DIFFUSED; OFTEN CONFLUENT; TERMINATING IN CUTICULAR EXFOLIATIONS.

THE term *enanthesis* is derived from the Greek *ἐν*, "in, intra," and *ἀνθίω*, "floreo,"—"efflorescence from within or from internal affection." Whence the term stands opposed to *exanthesis*, which, in the present system, constitutes a genus under the sixth class, and comprises such efflorescences as are merely superficial or cutaneous, and not necessarily connected with internal or constitutional affection. *Enanthesis* is here, therefore, used to express fever accompanied with rash, the latter word being employed in the broader of the two senses assigned it by Dr. Willan, as importing red, irregular, confluent patches; whether simple, as in the case of scarlet fever; or compounded of papulæ, small, acuminating elevations of the cuticle, not containing a fluid, as in the case of measles; or existing in the form of wheals, as in that of nettle-rash.

And hence *enanthesis*, as a genus, furnishes us with three species:—

- | | |
|-------------------------------|----------------|
| 1. <i>Enanthesis Rosalia.</i> | Scarlet fever. |
| 2. ————— <i>Rubeola.</i> | Measles. |
| 3. ————— <i>Urticaria.</i> | Nettle-Rash. |

SPECIES I.

ENANTHESIS ROSALIA.

SCARLET FEVER.

RASH, A SCARLET FLUSH, APPEARING ABOUT THE SECOND DAY ON THE FACE, NECK, OR FAUCES; SPREADING PROGRESSIVELY OVER THE BODY; AND TERMINATING ABOUT THE SEVENTH DAY: FEVER A TYPHUS.

THIS is the *scarlatina* of most modern writers, a barbarous and unclassical term that has unaccountably crept into the nomenclature of medicine upon the proscription of the original and more classical name of *ROSALIA*, which it is the author's endeavour to restore.

Upon this subject I must refer the reader to the running comment in the volume of *Nosology*, where he will find it explained at full length. At present it is sufficient to observe that although, since the introduction of *scarlatina*, its use has been generally tolerated, no classical scholar has been satisfied with the term, while several have peremptorily refused to adopt it.

Dr. Morton had so mortal an aversion to the term, that he preferred the error of blending

in producing death. There is sometimes sickness in this disease; an inflammation of the stomach and intestines; the mucous membrane of the alimentary canal is affected below the pharynx, so that there is tenderness in the epigastrium; and sometimes there is inflammation within the head and within the chest, as well as within the abdomen.—Ed.

scarlet fever with measles, and of arranging the varieties of the two diseases under the common generic name of MORBILLI, to employing *scarlatina*. De Haen appears to have had nearly as great a dislike to it.—(*Med. Contin.*, tom. i., cap. vii.) Dr. Huxham for a long time eluded the term by using FEBRIS MILIARIS RUBRA, or MALIGNA, for some of the varieties of scarlatina, and FEBRIS ANGINOSA MILIARIS for others: Dr. Heberden has still more lately exchanged it for FEBRIS RUBRA; and Thieri, in direct allusion to the original name, calls it expressly *mal de la rosa* (*Recueil Periodique*, vol. ii., p. 337); Ploucquet employs PORPHYRISMA, as Borsiero or Bursierius had made use of *purpura* before him; Dr. Willan continues *scarlatina*, but thinks it necessary to apologize for its continuance. "The denomination *scarlatina*," says he, "was first applied to this disease by British writers: however offensive the term may be to a classical ear, it cannot well be displaced, having obtained admission into all the systems of nosology. Another age will correct and refine the language now used in subjects untouched by the masters of physic."—(*Cutaneous Diseases*, p. 253.) It is singular that Swediaur, with all his love for Greek terms, and the determination with which he set out to give every genus a Greek name, should, while ranking this disease as a genus, still retain the objectionable term.—(*Nov. Nosol. Meth.*, syst. i., 164.)

It will not be the present author's fault if the correction so generally called for in the case before us should be postponed to another age, or the error complained of be chargeable on future nosologists.

In saying that "the denomination *scarlatina* was first applied to this disease by British writers," Dr. Willan can only mean that it was by British writers first applied *technically*, and introduced as a professional term into the Medical Vocabulary: for the term itself is Italian, and was long as a vernacular name in use on the shores of the Levant before it was imported into our own country.

Scarlet fever, measles, and smallpox seem, indeed, equally to have reached us from the east, and to be diseases of comparatively modern origin. [It has been suspected that the first of these contagions came originally from Africa. In Europe, it first broke out in a severe form in Spain in 1610, and it raged at Naples in 1618. In 1689 it appeared in London, and in 1735 it spread gradually, but slowly, over the American continent.]* Some writers fancy that they can distinguish a few traces of one or two of the foregoing disorders in the works of Paulus Ægina, and other Greek physicians; but the passages referred to are too general and unprecise to establish any such conclusion. No such diseases are described; and had they existed at the time, a few determinate and scattered

hints, which may apply to other diseases as well, could not have been the whole to which they would have given rise. The names, indeed, by which they were at first known, as VARIOLA, RUBEOLA, or rather RUBIOLA, ROSALIA, and even MORBILLI, evidently point to the school of Cordova, and lead us to the Arabian or Saracenic physicians for our first account of them. And it is not to be wondered at that in such accounts we should meet with some degree of confusion and many inaccuracies, and should perceive that as measles were for a long time confounded with smallpox, so scarlet fever was with measles; whence it is difficult in one or two instances to determine what is the precise species of disease referred to by Avicenna, Ali Abbas, and Rhazes; for, while they seem to allude to the scarlet fever, we are not sure that they mean it.

On this account it is that *rosalia*, *rossalia*, and *rubeola*, alike derived from the colour of the efflorescence, are, among the earliest writers who used these terms, applied equally to scarlet fever and measles; and when some distinction was at length attempted by the introduction of the word *morbillio*, or *morbilli*, in like manner a Spanish or Cordovan diminutive, the line of distinction not being accurately drawn or adhered to, this term was also erroneously applied to both; and the confusion became more intricate. So *rougeole*, which among the French writers is the common name for measles, imported also at one time scarlet fever: and this so generally, that when in process of time physicians became sensible of the difference between the two maladies, and it was necessary to establish distinct terms, we learn from Chevenau, that among the Marsellois, *rougeole* was at first appropriated to the scarlet fever, while the measles were denominated *senapion*.* And in this manner both diseases continued in every country, till within the last half century, to be regarded and even treated of with but little discrimination; sometimes as different species, sometimes as a common species, and sometimes as varieties of a common species. And hence, even in our own country, we find them united in several of their varieties, not only in the writings of Dr. Morton, but still more lately in those of Sir William Watson.

Since, however, they have been considered, and most correctly, as different diseases, another extreme has been run into; for *rosalia* itself has been broken into subdivisions that are in no respect worth contemplating separately; one or two of which, as we shall perceive presently, have themselves been elevated by some pathologists into the rank of distinct maladies. For all the purposes of perspicuity, it will be sufficient to study it under the two following varieties:—

* See Gregory's Elements of Physic, p. 126, edit. 2. Prosper Martianus, an Italian physician, who gave a description of the disease as it prevailed in Rome about the middle of the seventeenth century, is said to be, if not the first, among the earliest writers on *scarlatina*.—Ed.

* Observ. Med., p. 454. In 1778, Dr. Withering published an Essay on Scarlet Fever, a second edition of which appeared in 1793; to this author Dr. Bateman assigns the merit of having first accurately described *scarlatina* as a distinct disease. But Withering seems to have been anticipated by Plenciz, who published in 1776.—Ed.

- a Simplex. Fever moderate, and terminating with the rash; little prostration of strength; slightly contagious.
- β Parithmitica. Fever severe; throat ulcerated; rash later in its appearance, and less extensive; often changing to a livid hue: highly contagious.
- Scarlet fever with sore throat.

Children are by far the most frequent subjects of both these varieties, and communicate the disease readily to each other. They are both occasionally epidemic, and in this form occur most usually at the close of the summer. "The scarlet fever," observes Sir Gilbert Blane, "very rarely affects adults. The great majority are under puberty; some between twenty and thirty; a few between thirty and forty. Only one case above forty has occurred to my own observation."* Public schools may be one cause of the greater frequency of the disease in our own day. The anticipating symptoms are those of fever [restlessness, anxiety, depression of spirits, chilliness, pain in the head, soon followed by heat, thirst, and sickness]. About the second day from the beginning of these complaints in the FIRST VARIETY, numerous specks or minute

* Select Dissertations, &c., p. 213, 8vo., Lond., 1822. The late Earl of Exmouth died of scarlet fever at the age of forty-nine; and Mr. Squib, the auctioneer, in Saville Row, has also very recently fallen a victim to the same disease at the age of forty-five. Both these cases happened in the autumn of 1833. In order to determine the relative frequency of scarlet fever in the sexes at different ages, Dr. Tweedie selected from the register of patients admitted into the London Fever Hospital 200 cases, in the order of their admission. The following table gives the general results:—

Age.	Males.	Females.	Total.
From 6 to 10	7	8	15
10 to 15	8	15	23
15 to 20	17	40	57
20 to 25	14	39	53
25 to 30	8	21	29
30 to 35	6	10	16
35 to 40	1	2	3
40	1	0	1
42	0	1	1
48	0	1	1
57	0	1	1
	62	138	200

As Dr. Tweedie explains, however, the table is not complete, the number of children under six years of age who take the disease not being ascertained, in consequence of no children under that age being received into the above institution. The list shows, however, the great majority of females at every age, and (putting out of consideration cases in children under six years of age) proves, in opposition to Sir Gilbert Blane's statement, that the majority of those who are seized with scarlatina are not under puberty. For if the young children under six years of age be taken into the calculation, no doubt Sir Gilbert Blane's representation would be found to be correct. Dr. Tweedie's list, however, is exceedingly instructive, and certainly exhibits a much larger proportion of cases in individuals past puberty than would have been expected.—Ed.

patches of a vivid red colour appear about the face and neck; and within twenty-four hours, a like efflorescence is diffused over the surface of the body, and occasionally even tinges the inside of the lips, cheeks, palate, and fauces. Sometimes the efflorescence is continuous and universal; but more generally on the trunk of the body there are intervals of a natural hue between the patches, with papulous dots scattered over them.* There is an exacerbation in the evening, at which time the rash is most florid, as it is least so in the morning. In some cases that have occurred to me, it has only shown itself in the daytime in the form of scattered patches, or even specks, though the skin has been very generally roughened and rendered anserine from a more than usual determination of blood to the cutaneous papillæ. Yet even in these cases, the pathognomonic efflorescence has appeared in a later or less degree in the evening. On the fourth day, the disease is at its height. On the fifth the eruption begins to decline; the interstices widen, and the florid hue fades. On the sixth the rash is very indistinct, and is wholly gone on the seventh. On the eighth and ninth the cuticle is seen peeling off.

The pulse during the eruptive stage is usually very quick and feeble; the tongue is covered with a whitish fur in the middle, often interspersed with scarlet points from an elongation of the turgid papillæ; while the sides of the tongue are of a dark red. The face is considerably tumefied; and there is great anxiety and restlessness, with a sense of tingling or itching in the skin, and sometimes at night a slight delirium. Though the fever is in most cases moderate, it sometimes runs high, but in the present variety is rarely alarming. In many cases, indeed, the eruption appears and passes through its course with little inconvenience of any kind from fever, itching, or restlessness.

Sauvages, and Cullen, who has copied Sauvages' definition, represent the efflorescence as not taking place till the fourth day after the attack. Dr. Heberden, on the contrary, fixes it on the first or second day (*Med. Trans.*, vol. iii., p. 397); Dr. Willan "usually on the second day." This last is the ordinary period, and as such I have entered it in the definition. It is obvious, however, that the interval observes some variety; though not a little of the apparent difference may be ascribed to the different

* When the eruption has begun a short time, there generally can be no doubt of its true nature. Minute red points appear upon the face and neck; they soon become innumerable, run together, and within twenty-four hours form continuous patches over the trunk and extremities. The colour is a bright scarlet, not seen in measles, nor in any other disease, and most vivid at the flexures of the joints and in the loins. The skin, cursorily examined, seems smooth; but if it be inspected with care, it will be found to present minute asperities like those of the cutis anserina. The small points of the skin become a little inflamed, so that the roughness depending upon them had not the coarseness felt in the measles.—See Elliotson's Clinical Lect. in *Lancet* for 1830-31, p. 393.—Ed.

stages of the disease in which a physician is first consulted, and his inability of fixing very accurately the commencement of the febrile incursion. Dr. Plenciz, on this account, pursues a middle course, and avails himself of an allowable latitude: "About the second or third day," says he, "and sometimes later, the red, unequal eruption makes its appearance."—(*M. A. Plenciz, Med. Vindom. Tractatus de Scarlatinâ*, 1776.) Generally speaking, the more violent the attack the sooner the efflorescence is thrown forth; and hence, during a severe and extensive range in Newcastle-upon-Tyne in 1778, Dr. Clark tells us that, where it began with great vehemence, the eruption was often observed on the first day; but commonly it did not make its appearance till the second or third, and sometimes not till the fourth.

We have seen that rosalia has been often confounded with measles, to which, indeed, it bears, in many cases, no small degree of resemblance. The following distinctive characters, therefore, may be of use to prevent a mistake.

The efflorescence of the measles does not appear till two days later than that of scarlet fever; and, though it consists at first of broad patches amid the general suffusion of red, stigmatized with interspersed dots, the dots are of a deeper colour, and are never lost in the efflorescence. It commences, moreover, with symptoms of a severe catarrh [the eyes have a watery, tender appearance; and the patient sneezes and coughs; the face is flushed, and the head very heavy. Frequently, however, the cough does not come on during the first three or four days]. Such symptoms do not belong to scarlet fever; and the measles are without that restlessness, anxiety, and depression of spirits, by which the latter is peculiarly distinguished.

[In the early period of scarlet fever, there is this difference between it and smallpox: in the last, there is frequently intense pain in the loins, and great tenderness of the epigastrium; symptoms not appertaining to scarlet fever. If a person, therefore, be taken ill suddenly, and an eruptive disease be suspected, and yet there is no violent pain in the loins, and no extreme tenderness of the stomach, there is no reason to apprehend smallpox.—(*Elliotson's Clin. Lect. in Lancet for 1830-31, p. 392.*)]

From the great determination of blood to the cutaneous vessels, an effusion of coagulable lymph sometimes takes place in the papulous elevations, which is not entirely absorbed by the time the efflorescence subsides; and hence there is occasionally, though not often, an appearance of vesicles, sometimes nearly empty, and sometimes nearly filled with a pellucid fluid, according as the effused serum has been more or less carried off. I have seen them exhibit the semblance of minute chickenpox; and they have been thus noticed by many writers, particularly by Dr. Rush (*Medical Inquiries and Observations*, p. 123, Philadelphia), Dr. Withering, and Dr. Plenciz: the last of whom compares them to white miliary spots; and ex-

pressly states, that he observed them on the sixth or seventh day from the commencement of the eruption, chiefly in the hands and feet: in other words, at the time when the turgid cuticular vessels had contracted, and the efflorescence was on the decline. On examination, he farther tells us, that they appeared to be nothing more than cuticular elevations filled with minute bubbles of air. More correctly, perhaps, they were quite empty, the effused serum being carried off by absorption. M. de Sauvages has made this form of the disease a distinct species, as scarlet fever with him constitutes a distinct genus (*Tractat. de Scarlatinâ*); and as the effused fluid, when its finer parts are first absorbed, occasionally appears thick and opaque, and has some resemblance to minute pustules of smallpox, he has distinguished it by the name of *scarlatina variolodes*.

There is another peculiarity which the disease sometimes exhibits, and to which the attention of the profession has of late been particularly called by Dr. Maton.—(*Med. Trans.*, vol. v., art. xi.) The disorder, in the case alluded to, showed itself in a large family, and evinced all the common symptoms of a mild rosalia; and, like rosalia, it proved itself contagious, for every member of the family, elder or younger, to the number of eight, received it in succession. But its singularity was the great length of interval between the time of exposure to the attack, in those who sickened nearest to each other in the order of its descent, and any sensible effect on the system; which, instead of being, as in ordinary cases, four, five, or six days, was, upon an average, not less than twenty-one days; varying, in different individuals, from seventeen to twenty-six days. And, on this account, in conjunction with one or two other signs of minor importance, Dr. Maton, though he at first regarded the disease as a modification of rosalia, was afterward inclined to believe it a new complaint, requiring a distinct designation. Yet, if we reflect how often a similar, or nearly similar retardation takes place in particular families after inoculation from either the smallpox or cowpox, in which we have a much more definite period to calculate from, we shall rather, perhaps, be justified in adopting Dr. Maton's first view of the disorder, and contemplating it as a rosalia modified by a peculiar family temperament, or some other accidental control. In the paristhmitic variety, or that accompanied with sore throat, the eruption is always later in its appearance than in the simple form; in a case I shall have to quote from Dr. Perceval, not less than eight days later; though I have never known it protracted to so late a period as in the modification noticed by Dr. Maton, where the febrile symptoms have taken place as early as usual from the time of exposure. The efflorescence in the measles, however, sometimes evinces a like procrastination, and has appeared as late as the twenty-first day.—(*Buchholz's Todt Med. Chir. Bibl.*, band i., p. 86.)

In the second or PARISTHMITIC VARIETY, the morbid virus is chiefly directed to the fauces, instead of to the surface of the skin generally,

It is the scarlatina *Septorrhæpes* of Swediaur. And hence, in some cases, the cutaneous efflorescence is very slight, and consists of a few scattered patches of flush, instead of a diffused sheet. The rash, moreover, appears later by a day or two, sometimes even a week; probably delayed by the same cause that interferes with its general spread over the skin, being the local irritation about the throat. [It comes and goes, and when the disease inclines to terminate, the termination is not complete at once; but the desquamations will sometimes continue for weeks.] If the throat be minutely inspected, this last symptom will be found to commence very early; for though no complaint is usually made of uneasiness in the throat previously to the febrile symptoms, yet, if it be closely examined, the velum pendulum palati will be found redder than natural, and sometimes the uvula will appear to be a little inflamed, the pulse being at this time only slightly disturbed, or hurried rather than feverish.—(Dr. Sims, *Memoirs of the Med. Soc. of Lond.*, vol. i., p. 394.) Dr. Willan asserts, that this takes place as one of the first effects of the contagion, and describes it as “a dark-red line, extending along the velum pendulum palati and the lower part of the uvula.”—(*Cutaneous Diseases*, loc. cit., p. 269.) Gradually, however, the tonsils become enlarged, and exhibit a florid redness on their surface which extends over the whole range of the palate, its velum pendulum, the uvula, and the posterior part of the fauces; the tongue assumes a high-red colour,* the papillæ over its entire surface are greatly elongated, and very tender to the touch; there is often a considerable stiffness in the muscles of the neck and lower jaw; the throat is rough and straitened from the second day of the eruption; and deglutition is performed with difficulty.

All the common symptoms are more violent; there is more shivering at first, and afterward more intense heat of the body,† the temperature of which rises to 107°, 108°, or 111°; the fever is severer, accompanied with nausea, vomiting of bile, and languor; considerable inquietude and anxiety, headache and delirium; evidently proving a copious determination to the head, as well as to the fauces. The pulse is feeble, the respiration quick; the throat becomes excoriated, and throws off a large quantity of minute, superficial, whitish sloughs, which intermix with the increased flow of viscid mucus, and augment the difficulty of swallowing. The sloughs generally separate about the fifth or

sixth day, or at the decline of the efflorescence; but sometimes they remain a day or two longer.

This is the ordinary course; but, in many cases, the symptoms run still higher; and the disease is alarmingly dangerous from its irruption. The pulse is small, indistinct, and irregular from the first; there is a stupid, heavy coma, or violent delirium, with deafness; the ulcerations in the throat are deeper and broader, and covered with dark instead of with whitish sloughs; the tongue is lined with a black, chappy crust, and is exquisitely tender; the breath is fetid; the rash, extensive from the commencement, assumes a livid hue, with intermixed patches of ghastly paleness; and death ensues shortly after the seventh day, sometimes on the sixth.

The affection of the throat, in this last and most virulent attack, bears so near an approach to the malignant paristhmitis, and its peculiar symptoms commence so early, that some pathologists of great authority, and particularly Dr. Cullen and Dr. Withering, have regarded it rather as a variety of paristhmitis or cynanche than of rosalia, whence, in Dr. Cullen's Synopsis, it occurs under the designation of *cynanche maligna*. But, as the scarlet or crimson eruption must be contemplated as a pathognomonic symptom, this is to give us two distinct diseases, with the same essential signs; and Dr. Cullen has done this; for, while he places this most virulent form of rosalia under his genus cynanche, he continues it, in the less virulent form under which we have just described it, as a subdivision of his genus scarlatina. The distinction, however, is altogether unnecessary, and leads to no advantage, either pathological or practical. With the exception of a higher degree of danger in the one than the other, from the fever assuming the character of a more malignant typhus, both forms of the disease are the same; they are equally produced by a specific virus; equally contagious, and at times epidemic; accompanied with a similar rash; demand a like mode of treatment; and even, according to Dr. Cullen's own admission, so frequently run into each other as to be extremely difficult of discrimination. In consequence of which, few later writers have allowed any such distinction whatever. De Haen, therefore, had reason to say, as he does, apparently in reference to Dr. Cullen's arrangement, that different and improper names have been affixed to scarlet fever by different writers; but that varieties in climate or constitution produce the distinctions under which it has been described.

Dr. Withering, however, who was contemporary with Dr. Cullen, embraced and strenuously supported his view; contending that, in scarlet fever with sore throat, the fever is inflammatory, and, in sore throat with scarlet fever, it is putrid. Yet, in describing the treatment of this inflammatory fever, he seems to have lost sight of his critical characteristic; for he tells us that its nature is debilitating or sedative rather than antonic; and condemns both purging and bleeding, as the pulse will not allow of these evacuations.

* In the mildest form of the disease the tongue is red; but if there be much inflammation of the mouth, the tongue is not only red, as if the mucus upon it were sprinkled with grains of Cayenne pepper, but the papillæ are so elongated as well as red, that they project considerably through the mucus.—(See Elliotson's Clinical Lectures, op. cit.) “The disease attacks the interior of the mouth and fauces, and it even affects the conjunctiva.”—Id. in *Med. Gaz.* for 1833, p. 101.—Ed.

† Even in the mild form of the disease, where the throat is scarcely affected, the heat is very intense.—Elliotson, op. cit.—Ed.

In endeavouring still further to lay down the distinctive characters of the two, he observes, after Dr. Fothergill, that the *angina gangrenosa* (sore throat with scarlet rash) usually commences in the winter or the spring, and chiefly attacks persons of delicate habits, as women and children; while the *scarlatina anginosa* (scarlet rash with sore throat), on the contrary, usually commences in the summer or autumn, and commonly fastens upon the vigorous and robust. The scarlet rash, however, of Newcastle-upon-Tyne in 1778, seems to have reversed this rule in its most essential point; for Dr. Clarke, to whom I have just referred, and who has given a very minute and interesting history of this epidemic, tells us, that it made its first appearance in June, extending from Newcastle over many towns and villages in the neighbourhood; that it was most frequent in August, September, and October, declining about December; and that it raged chiefly among children and young persons, although a few adults exposed to the contagion did not escape.* Dr. Clarke therefore concludes, that both these diseases proceed from the same specific contagion, and ought rather to be considered as distinct forms of the same exanthem, than as distinct affections. It is accurately, also, observed by the same writer, that the epidemic of 1748, which Dr. Fothergill has so ably described under the name of putrid sore throat, is essentially the same as that noticed by Dr. Cotton in his letter to Dr. Mead, and which he then denominated scarlet fever, from an objection to any alteration of the name in common use.

The subject ought not to be closed without adding the following note from Dr. Perceval's manuscript comment on the author's volume of Nosology, already noticed on many occasions. It adds a high authority to the present arrangement of this form of the disease; and contains one or two remarks, which very agreeably display the observant tenour of the writer's mind.

"*Cynanche tonsillaris* and *maligna* I consider with you as a species of rosalia. All have been produced by the same specific contagion, which in one instance was imported here (Dublin) from England in a Pandora's box, containing plumed soldiers which had served to beguile the convalescent hours of a young family, and were sent by them as a present to their quondam playmates in this capital. We have had no severe visitation of rosalia in this place for upwards of ten years. In some instances, besides, I have traced the progress of contagion from England, and believe it loses something of its ferocity by the way. Do you think it comes from the continent? A remarkable case occurred to me of *rosalia paristhmica*, characterized most distinctly with symptoms of what is called *cynanche maligna*. This, with sunk pulse, great prostration of strength, and haggard countenance, ran a course of seven days without eruption;

during which time it was treated with wine and bark, which removed the affection of the throat. On the eighth day, after a rigour, a fever supervened of rather an inflammatory type, with a rosalia eruption. After proper evacuations, the patient recovered."

That rosalia, under every form, is contagious, and sometimes epidemic, is now admitted without a question; and for the later appearance of the efflorescence in the paristhmite than in the simple variety, I have endeavoured to account. But, whether some countries are more disposed to favour its appearance in the form of an epidemic than others, and particularly, whether under this form it be more common to England than to Ireland, as hinted at by Dr. Perceval, I have no data to determine.

There are three modes by which this, or indeed any other disorder, may become epidemic, using the epithet in its general sense, as importing a disease, of whatever sort, that contaminates the atmosphere of a district or neighbourhood. It may proceed from a specific miasm, generated from local or accidental circumstances in the atmosphere itself, as in the miasm of intermittent and often of remittent fevers; from a like miasm generated in the body of a sick individual, and communicated to the atmosphere, as in typhus; or from a peculiar temperament in the atmosphere, predisposing the entire population that inhale it to a common morbid affection. Of any specific miasm originating in the atmosphere, and producing rosalia, we have no proof whatever: but we have abundant proof of its issuing from the bodies of those who are sufferers under it;* and, if I mistake not, of a peculiar temperament or constitution of the atmosphere in a particular district or season, that predisposes to its general production; for it often becomes common to many families so simultaneously, that they have had no power of communicating it directly or indirectly to each other. And hence, however it may be favoured by external concurrent circumstances, we have good reason for believing that the miasm is always ingenerated; and that

* It is not exactly known how long a person is capable of communicating the contagion after he has had the disease; perhaps, according to Dr. Elliotson, not longer than two or three weeks, unless desquamation of the cuticle proceed; and then the exfoliations appear to be so impregnated with the poisonous secretion of the skin, that they may give the disease as long as they continue to be formed. How long they may retain the infection, after separation, seems uncertain. The contagion of scarlet fever often continues very long in a house or hospital into which a case has been admitted. Thus, Dr. Elliotson mentions a patient with scarlet fever, who was admitted into a particular ward, and, for nearly two years afterward, all the children and young men placed in the same ward took the fever, though the ward had been thoroughly whitewashed and cleaned.—(See *Lancet* for 1830-31, pp. 392-394.) The fact communicated to our author by Dr. Perceval, of the transmission of the contagion from England to Ireland in a box of toys, exemplifies its tendency to adhere a good while to articles which have been handled or worn by patients.—Ed.

* Observations on Fevers, especially those of the continued type, and on the Scarlet Fever attended with ulcerated sore throat, &c., 8vo., 1779.

the disease, when communicated, is always by specific contagion.

We may hence account for its being in a pure and healthy, or unpredisposing atmosphere, but slightly infectious: for, in treating of the laws of febrile miasm, which, under different circumstances, originates both within and without the living body, we had occasion to observe, that when generated in the former manner, it appears to be less volatile than when in the latter, and less readily impregnates a periphery of pure air; whence the infection of typhus, which is commonly derived from this source, may be more easily avoided than that of intermittents or even remittents. The miasms of all the exanthems seem subject to the same law, as they also probably issue from a specific affection of the living body; and hence all of them are comparatively confined in the range of their actions, though some radiate their influence to a much greater distance than others, and are not so soon dissolved or decomposed.

We may hence, also, see why the contagion of rosalia is received much more readily at some periods than at others. Nothing is more common than for a sporadic case of rosalia to occur in a family without communicating itself to the surrounding children, although no pains may have been taken to keep them separate; while, a few months afterward, it may possibly be received from a neighbour's house, merely by an accidental visit for a few minutes. In the one case, there was no predisposition in the habit to receive the complaint; in the other, the altered state of the atmosphere has, perhaps, produced such a predisposition in a very high degree, and prepared the way for the disease to become a very general epidemic.*

What this peculiar state of the atmosphere is has not yet been very accurately ascertained. It does not seem to depend altogether upon the season; though, commonly speaking, rosalia is more frequent towards the close of the summer, the common harvest-time of all debilitating diseases; and we also perceive that it is usually checked, at all periods, by a cold, dry, and bracing air, and hence is less frequent in the winter. But, with these exceptions, it has been found to range as an epidemic nearly equally from February to November, and sometimes through the whole of this term without ceasing; or only slackening its career when a keen dry breeze has sprung up from the north or the east.

We see, also, another peculiarity in this disease, and that is in its ordinary limitation to children; and we see this character accompany it equally, whether the disease be sporadic or epidemic. Or, in other words, we behold the predisposing state of the atmosphere observing

the same restriction as the disease itself when it operates independently of any such predisposition. Adults, indeed, do not entirely escape, but their attacks are rare, and, for the most part, less violent.*

The remote cause of rosalia, then, is a specific virus, or a specific miasm generated in the living body. Of its occasional or exciting causes, separate from the predisponents just adverted to, we know nothing. It has sometimes seemed to follow a cold, and, at others, a surfeit of the stomach; but, as these are perpetually taking place without producing such effect, and as rosalia has often occurred where nothing of the kind could be traced, we can lay very little stress upon such casualities.

All exanthems and nearly all fevers produce an influence on the system that renders it less susceptible of the same complaint for a certain period of time afterward: yet the period varies, from the plague, which exempts but for a few weeks, to the smallpox and measles, which usually extend the exemption to a term equal to that of a man's life; in consequence of which these disorders, except in a few anomalous cases, never appear but once in the same individual. Scarlet fever seems to hold a middle range. It renders the system far less susceptible, and, perhaps, for several years; but the influence, in many individuals, wears off by degrees, and does not protect the whole of a man's subsequent life. Yet, as rosalia is a disease of children and young subjects rather than of others, it is not often that persons suffer from it a second time, though examples of such a recurrence are occasionally to be met with.†

[Hahnemann is well known to be an admirer of what is termed *homoeopathia*, according to which doctrine diseases should be opposed by remedies, the effects of which are similar to the diseases for which they are given. Having observed that small doses of belladonna produced heat and dryness in the throat, and cutaneous affections, he conceived that belladonna might prove a preservative against scarlatina. About ten years after this suggestion had been made, Berndt put it to the test of experience in an epidemic scarlatina that prevailed in Custring in 1818 and 1819, and, out of 195 children who were freely exposed to the infection after being put under the influence of belladonna, only 14 took the disease. It would appear likewise, from the statements of Dr. Dusterberg, that belladonna has the power of rendering the consti-

* This is contrary to the result of the editor's observations, which coincide with the statement made by Dr. Tweedie:—"It has been generally observed," says he, "that scarlatina proves more severe to adults than to children; and that when it attacks pregnant or puerperal women, it is often fatal."—Ed.

* Independently of atmospheric influence, there are constitutional peculiarities which render some individuals insusceptible of the contagion of scarlet fever. Many persons are in this state, not merely adults, but children; and, though much exposed to the disease, never catch it. Scarlet fever is not by any means so unfailing a visiter, either of children or adults, once in their lives, as the measles and smallpox.—Ed.

† Dr. Elliotson believes, that its recurrence in the same person is more frequent than that of smallpox or measles. In two thousand cases, however, Dr. Willan never knew it to take place in the same individual a second time. The extreme of infancy is least liable to rosalia, as well as measles.—See *Lancet* for 1830-31, p. 392; and *Med. Gaz.* for 1833, p. 100.—Ed.

tution, for a time, insusceptible of the contagion of rosalia. During the epidemic prevalence of this disorder at Gütersloh in 1820, he gave daily to such children as had not been attacked from ten to twenty drops of a solution of three grains of extract of belladonna in three drachms of canella-water; and he assures us that none of the children who had continued this medicine a week were attacked with rosalia, though continually exposed to its contagion. It is also stated that every child that did not take belladonna, and was exposed to the contagion, had scarlet fever.—(*Hufeland's Journ. der Practischer Heilkunde*, 1822.) Whitewashing, cleanliness, free ventilation, and the use of the chlorides, should never be omitted in dwellings where scarlet fever has prevailed. The linen of the sick should always be put, as soon as removed, into water containing the chloride of soda or lime.]

Rosalia is at all times a disease of debility; it prostrates both the body and the mind, but it has, in many cases, a peculiar tendency to weaken the absorbent system, and incapacitate it for carrying off the fluids that are exhaled into the internal cavities of the body, and hence to produce dropsy. This calamitous sequel usually creeps on insidiously and without suspicion, and does not distinctly show itself till the twelfth or fourteenth day, and often considerably later, when the patient and his friends are flattering themselves that all danger is over. It commences with a peevishness, and a feeling of drowsiness and increased weakness and languor: the face is found to swell, and the urine to decrease in quantity, and to assume a somewhat bloody appearance, like the washings of flesh. The leuco-phlegmacy of the face extends gradually to the hands, feet, abdomen, and scrotum, till the whole body becomes puffed up. "I have known these swellings," says Dr. Perceval, "to attack all the cavities, the ventricles of the brain not excepted, and in one instance fatally, upon an eruptive affection so slight as hardly to be noticed. The child was not confined, but went out, and was exposed to air.*"

This last hint should not be dropped in vain; for the torpitude produced on the mouths of the absorbents by a sudden or injudicious exposure to cold air, on recovering from rosalia, is one of the most common causes of this lamentable result: and hence we see, also, why it should be more common in winter than in summer, and in children than in adults, from the greater delicacy of their age.† Dr. Withering confirms

* If rosalia be severe, there may ensue discharges from the meatus auditorius, sore ears, suppurations in the parotids, and absorbent glands of the neck; pulmonary disease, and diarrhoea; or the fever may be followed by chronic pustular diseases of the skin, called rupia and ecthyma, but which, as Dr. Elliotson observes, are much more common after smallpox. After rosalia simplex there is often a tendency to anasarca, which usually shows itself at the end of the second week, after the decline of the rash.—See Professor Elliotson's Lect. at Lond. Univ., as published in *Med. Gaz.*—Ed.

† Dr. Elliotson does not adopt our author's hy-

the instance just offered by Dr. Perceval, that it is occasionally to be found after the mildest form of the disease; but adds, that it follows chiefly its malignant or worst species.

The curative treatment need not long detain us. In slight cases of the simple variety, we may say, with Dr. Sydenham, that the disease hardly calls for medical assistance of any kind. When the fever is mild, it forms, as we have already observed in respect to exanthems of all kinds, the natural means of cure, by determining the specific poison to the surface. An emetic may assist this determination, and has hence been almost always found serviceable; and, if the bowels be confined, an aperient may follow; but violent purging will add to the irritation, and distract the remedial course that is taking place.*

In the paristhmatic variety, the determination, instead of being to the skin generally, is powerfully deflected to the throat and head, and the fever is alarming from its violence. The therapeutic intention is here to counteract this determination of the febrile action, always having regard to the nature of the fever, as well as to its severity.

Bleeding is the most direct and obvious means of reduction; but it is open to the same objection as in typhus; with the additional fact that we have here to deal chiefly with children, who have at all times less surplus of strength to spare than adults. Dr. Plenciz is, however, a strenuous advocate for the use of the lancet, and Dr. Armstrong has recommended it still more lately. Where the head is manifestly oppressed from congestion, it may be risked as a mode of local relief, and may be so far of service; but it is a risk at all times, and ought by no means to form a part of the general curative plan. With the exception of typhous miasm, there is nothing that so much exhausts, or rather, perhaps, suppresses the sensorial power, as the miasm of rosalia; nor is there any evacuation that adds so immediately to the direct debility of the system as venesection, and consequently, none that ought to be so studiously

pothesis of a torpitude of the absorbents: for, though he admits that the dropsical swellings following rosalia are most frequent in winter and in cold damp weather, he believes that they are almost always of an inflammatory nature. As in other inflammatory dropsies, he says, the face is affected the very first. He believes, that when effusion occurs in the chest, there is inflammation or sub-inflammation of the pleura; and so, with respect to the abdomen, there is peritonitis; and, with respect to the head, arachnitis.—Ed.

* At the present day, emetics are not so generally given in rosalia as they were some years ago. It is now ascertained that, in simple cases, little more is necessary than mild aperients, except keeping the patient cool, and purifying his chamber by the occasional admission of fresh air, and sprinkling it and the bedclothes with a solution of the chloride of lime or soda, which may also be introduced into the vessels used for the purposes of nature. This practice is particularly recommended by Dr. Elliotson (*Clinical Lect.*, op. cit., p. 395), with a view of lessening fetor, and preventing the extension of the contagion.—Ed.

avoided as a general rule. And hence, often as the practice has been introduced by different individuals, it has never been common or established. Even Dr. Withering, who denominated the fever inflammatory, rigidly abstained both from bleeding and purgatives, and confined himself, in the onset of the disease, to emetics.*

Vomiting, which has just been recommended in the first species, is still more necessary in the present; for it not only tends to take off the dry burning heat of the skin, by relaxing it, but unloads the fauces of the mucous and serous fluids that gorge and distend them.

Dr. Withering prohibited purgatives as well as bleeding. But, in doing this, he discovered still further the trammels of hypothesis; for while he conceived that emetics tend directly to throw off the matter of contagion from the organ in which he supposed it to be chiefly concentrated, he conceived at the same time that purgatives, on the contrary, only promote its diffusion along the course of the intestinal canal. This reasoning, however, cannot be allowed: the system should not be weakened by their violence, but their use can rarely be dispensed with. Calomel, as operating upon all the excretories, is commonly to be preferred to any other cathartic, or may be conveniently combined with rhubarb.

The great inquietude that characterizes this disease has induced many practitioners to try opium; but it rarely affords relief in any form or combination, and generally renders the head worse. Ammonia is in every respect a far more useful medicine; it takes off the languor, and stimulates the secretions, especially those of the skin, without quickening the pulse. In the form of subcarbonate, it should be given in doses of half a scruple, dissolved in a large spoonful or half an ounce of water, every three or four hours:† and, in this way administered, it has a highly beneficial and powerful effect upon the local inflammation of the throat. Oc-

asionally also, and in the intervals, we should employ some of the acids, whether vegetable or mineral, which are always grateful to the patient, and seem, more than any other internal means, to diminish the burning heat of the skin. But our chief dependance for this purpose must be upon Dr. Currie's bold and happy plan of employing cold water freely. Sponging will rarely be found sufficient, or rather will rarely be found of equal advantage with affusion; the fluid may, indeed, in this case, be dashed against the patient till the heat is subdued, and the process be repeated as fast as it returns. The refreshment is often instantaneous, and operates like a charm; and seems to show, not merely a refrigerant, but an exhilarating power; the skin immediately becoming softer and moister, as well as cooler. [One caution is requisite, however, viz., only to apply the cold water when the patient is not perspiring, and when the skin is parched and hot.]*

The throat must, in the meanwhile, be deterged with antiseptic gargles of oxymel and port wine, port wine negus, of chloruret, or chloride of soda and lime, and tincture of myrrh, or any of those already noticed under malignant parithmitis; or fumigated with the vapour of mineral acids.† Blisters may also be applied with good effect. Dr. Withering objects to them; but general experience is in their favour.

In severe cases, Dr. Plenciz (*Tractat. de Scarlatina*) had recourse to the aurum fulminans, as recommended by De Haen (*Rat. Med. Continuata*, tom. i., part 1, 8vo., Vienna), and speaks warmly of its success. Its design was to operate on the bowels and bladder, and it was given in combination with calomel, rhubarb, and squills. I have never tried it, nor can I very clearly trace out the path by which any benefit may be expected from it. Wine and nutritious food may be allowed (chiefly, as the editor conceives, in the advanced, or typhoid stage), but somewhat less freely than in malignant quinsy. The convalescent state requires

* Account of the Scarlet Fever in 1778, 8vo. No one can entertain a doubt that, when the symptoms indicate inflammation in the head, chest, or abdomen, the practitioner should not dispense with bleeding; nor should he be deterred by any unreasonable fear of typhus and debility from employing the lancet, when the symptoms above alluded to are serious and pressing. The internal inflammation is then the principal source of danger, and leaves no alternative. The debility must be combated when it arrives. If the inflammatory symptoms run high, Dr. Elliotson approves of venesection; but, in general, he deems topical bleeding sufficient, and praises the good effects of fresh air, the lowest possible regimen, cleanliness, few clothes, and keeping open the bowels. It is only when inflammation of important organs comes on that he is an advocate for general bleeding, finding that any local inflammation in ordinary parts will only require topical bleeding.—Ed.

† If the disease show a very considerable gangrenous tendency in the throat, if the pulse be very soft and feeble, Dr. Elliotson recommends the same treatment as in typhus fever. "Among the internal stimulating medicines which it is necessary to give at the last," says he, "carbonate of ammonia is one of the best, with the excep-

tion, perhaps, of wine." All impartial practitioners must agree with this eminent professor, that ammonia has no peculiar power over the disease.—Ed.

* If the eruption recede prematurely, Dr. Elliotson advises the warm bath, and friction, with stimulating applications, unless the patches be prevented from coming out by inflammation of any internal parts; then stimuli are to be avoided, and leeches employed.—See Elliotson's Lect. delivered at Lond. Univ., as published in Med. Gaz. for 1833, p. 131.—Ed.

† Gargles of the chloride of soda or lime are now generally preferred. When there are dark-coloured sloughs on the throat, which cannot be removed as portions of lymph can, the gargle should be made stronger than that for other cases, in which Dr. Elliotson recommends two ounces of the common solution to fßss. of water. When the patient is unable to employ them properly himself, as is the case with children, and with other individuals severely ill, they should be thrown over the affected parts of the throat with a syringe. Cold or even iced drinks will be found very grateful, as relieving the excessive heat of the throat and mouth.—Ed.

great care ; and, on account of the tendency to dropsical swellings, a damp cold atmosphere should be especially avoided.*

[Dr. Paul has lately detailed an interesting case (*Edin. Med. Surg. Journ.*, No. xc., p. 55), in which the disease, besides being remarkable for its severity, exhibited the peculiarity of petechiæ and profuse hemorrhages coming on in the convalescent stage : under these circumstances, the good effects of the sulphate of quinine were particularly manifest.]

* Dr. Ryan was called to a patient who had been convalescent from scarlet fever a month, at the end of which time he went out at two o'clock, on a cold day in the spring, and returned in a short time completely anasarous, and died at two next morning.—(*Manual of Midwifery*, p. 685, ed. 2.) The anasarca and dropsies following rosalia seem to Dr. Elliotson to be most advantageously treated with purgatives and leeches. In all cases purgatives are recommended, and topical bleeding also, if there be local dropsy. In intense cases he even sanctions bleeding from the arm.—(*Clinical Lectures*, op. cit.) While Dr. Good regards the anasarca and dropsical effusions, consequent to rosalia, as depending upon torpidity of the lymphatics, caused by injudicious exposure to cold damp air, Dr. Elliotson refers them to a degree of inflammation in the parts or cavities affected. Andral supposes them to be connected with the interruption of cutaneous perspiration, produced by the extensive efflorescence on the surface of the body ; but this doctrine is hardly tenable, when it is recollected that no such consequence usually arises from erysipelas and other affections of the skin, however extensive. With respect to wine, ammonia, and nutritious food, as recommended in the text, they can only be allowable after all tendency to inflammatory action in the system is over, and the patient is in a very low debilitated state.—Ed.

† On the subject of Enanthésis Rosalia, we have been favoured by Dr. J. W. Francis, of this city, with the following remarks :—

"However various," says Dr. Francis, "may be the methods of cure in rosalia adopted by different physicians, all admit the serious character of the disease, and its too often fatal termination. In the United States it frequently appears epidemically, in places of diversified condition, in populous cities, and in scattered villages ; in the pure air of the country, and in the vitiated atmosphere of a crowded and heterogeneous population ; and it would be difficult to assert in what sort of location it often proves most destructive. Its fatality, as recorded in our annual bills of mortality, is truly alarming, and seems to reflect little credit on the skill of our most competent prescribers ; in the city of New-York alone, during the past six years, no less than fifteen hundred have perished by it. Were greater accuracy exercised to ascertain from what particular causes this vast destruction of human lives by this pestilential disease occurred, some adventitious circumstances might doubtless be found, which would plead in extenuation of the inefficient results of the best efforts of medical skill. Indeed, this specific disease may rage in the boudoir of the rich as well as in the hovel of the needy. Nevertheless, the mixed population of New-York, the mass of foreign and indigent poor, who, with their depraved habits and vitiated morals, annually scatter themselves among its better inhabitants, may with great truth be enumerated as of these aggravating causes. The scarlet fever appears sporadi-

SPECIES II. ENANTHESIS RUBEOLA. MEASLES.

RASH IN CRIMSON, STIGMATIZED DOTS, GROUPED IN IRREGULAR CIRCLES OR CRESCENTS ; APPEARING ABOUT THE FOURTH DAY, AND TERMINATING ABOUT THE SEVENTH ; PRECEDED BY CATARRH ; FEVER A CAUSA.

Of the earliest accounts we possess of measles, by the Arabian writers called *AL-HASBET*,

cally at all times among us ; but the seasons of its greater prevalence, those in which it often assumes the type and potency of an epidemic, are the latter part of the autumn and in the winter months. There are exceptions to this rule, however, in the records of its appearance elsewhere. Dr. Callaghan, in his account of the epidemic angina which prevailed at Pittsburgh, Penn., in 1830, tells us, that it commenced with the setting in of warm weather, about the middle of May, the thermometer ranging from fifty to seventy-two degrees, with southerly winds and frequent showers.—(*Am. Journal of Med. Science*, vol. viii.) Professor Williams, in his history of the disease as it occurred in Deerfield, Mass., in the years 1830 and 1831, mentions that it prevailed extensively through New-England, and that in many towns it was very mortal. At intervals, it continued to prevail from June, 1830, to the time of his writing, November, 1831. The month of May, 1830, was cold and uncomfortable.—(*Am. Journ.*, vol. ix.) For the greater part, it occurs most extensively after seasons of extreme moisture and great variations of temperature : early infancy and youth are most liable to it ; but examples at times present themselves of the infant of a few weeks of age, as well as the advanced adult, being subjected to its influence ; recently, one of our periodicals contains an account of its fatal occurrence in an adult aged eighty. With old subjects it is often severest in its attacks : I have seen it in both classes, and its formidable recurrence in the person of a middle-aged man, after an interval of seven years. The immunity of the constitution from a second attack is probably less than from that of measles. It almost always has proved fatal to the pregnant female.

"That scarlet fever depends upon a specific contagion is admitted by all, I believe, who tolerate a contagious principle in any disease. The distinguished Dr. Dewees is the only American writer of repute who seems to doubt its contagious character : at least he affirms he has never seen any decided proof that it has communicated itself in any one instance. Nevertheless, in actual practice, he says it will be safest to act under such a conviction. For my own part, I think we are brought to the alternative of rejecting *in toto* the doctrine of contagion in every form of febrile disease, if it is not allowed to be a means of diffusing scarlatina. In private families I have known the several members to become affected from an individual case : Dr. McLean tells me he has attended nine members of one family, who were attacked in succession by it : and we need not advert to its sweeping malignity when it has prevailed in hospitals, alms-houses, public schools (as at Ackworth), and other places where many persons are congregated.

"The luminous history of rosalia, and of its distinctive features, given in the text, supersedes all minute detail on that head : and the division of scarlatina into the *simplex*, *anginosa*, and *maligna*, is so universally adopted, that for practical

الغصة, the origin of the name of rubeola, and the frequency with which it was at first mistaken for rosalia, some notice has been taken

purposes it may as well be preserved, though somewhat at variance with the disposition of the subject in the detail by Dr. Good. It is usually from the third to the sixth day after exposure to the contagion that the complaint manifests itself. On the second or third day of the disease, the febrile irritation is considerable; but it may be so on the very first; sometimes we encounter no fever whatever throughout the whole course of the complaint; sometimes the efflorescence puts on its peculiar character almost at the invasion of the disease; and at other times we scarcely can perceive any cutaneous discoloration during its entire existence: sometimes we encounter scarlet fever followed by sore throat; at other times sore throat is followed by scarlet fever: the nature of the former type is perhaps more generally inflammatory, that of the latter more of a typhoid character. Accidental causes may however vary this circumstance, and the most malignant type may arise in the course of a case which at first was of an inflammatory form; while occasionally the latter may halt in its career, and lose its most alarming features. Such is the varied aspect of this Protean disease: an acknowledged febrile complaint, at times without symptoms of fever: an eruptive one, with, at times, no development of cutaneous disorganization. The duration, also, of scarlet fever, exhibits an extraordinary difference in different subjects, according to its type, the predominance of certain symptoms, and the accidental occurrence of peculiar circumstances. In its mildest variety it may continue for some six or ten days; in its aggravated form it may as speedily terminate, or last as many weeks: and the sequelæ of the disease, when it has committed its most serious ravages, have occasionally been to destroy the equilibrium between the absorbent and secretory systems, incurable deafness, &c. &c. One of the most lamentable instances of this last sort which I can bring to recollection, was that in the person of the late mathematician and geographer, John Eddy, of this city.

"The treatment of rosalia must therefore be regulated by many concurring circumstances: in its simplest form it is often almost supererogation to interpose art where nature is so judicious in her operations: in other cases, mild aperients, sudorifics, simplicity in diet, and attention to cleanliness, may often suffice. In its complex form with sore throat, our indications are of a more discriminating order, and challenge our severest judgment and most effective capabilities. I think I have already noticed the prominent circumstances which should be kept in mind when called to a case of scarlet fever. A difference in pathological opinions must necessarily lead to a corresponding difference in our curative means; as, for instance, whether we deem the existing state of disordered action to depend mainly upon the asthenic or sthenic diathesis, upon debility or increased energy. Too exclusive an adherence to either belief has been the prolific source of evil: the practice of viewing scarlatina as a disease of debility, has induced many to recommend, early, bark, wine, alcohol, and the diffusible stimuli, with cordial nourishment, after the method of the older alexipharmic prescribers, and to deprecate all antiphlogistic medicines. After this manner, in order to support the strength, have many epidemical or pestilential disorders at various periods been treated; I need not add with

under the last species. In its perfect form, it is unquestionably contagious from a specific miasm, though we shall presently have to notice one variety that is inactive in this respect. Like

what pernicious results. On the other hand, without due consideration of the specific character of scarlet fever, of the laws which regulate febrile infection, and of the uniform influence which diseases of such origin have in their tendency to induce a greater expenditure of the vital powers, other prescribers have urged, even in the advanced state of the complaint, the antiphlogistic method by copious bleedings, emetics, drastics, cold affusion, and other potent agents; on the ground that all the morbid phenomena depended upon an active inflammatory diathesis. Of the consequences of such a pathology we have too many fatal examples.

"In the treatment of scarlet fever, let us ever recollect the specific nature of the cause of the disease; the variable aspect of the complaint while it runs its course; and its uncertainty as to duration; how specious its promises of proving mild or severe, simple or complicated; and be impressed with the facts which pathological investigation has furnished us. Several writers have recorded the diseased appearances which post-mortem examinations present. Beside the various conditions, the results of morbid action, exhibited in the mouth, throat, and contiguous glands, inflammation, or its consequences, in different and distinct parts, the mucous membrane has been found thickened, effusions of tenacious matter obstructing the passages and air-cells of the lungs; an engorged state of those organs, and sometimes of the liver; a surcharged condition of the peritoneal lining; and often, in the brain, a preternatural vascularity, arachnitis or serous effusion between the arachnoid and pia mater, or in the ventricles. The early appearance of a copious efflorescence may be pronounced a favourable harbinger of the character of the disease; its deficiency is often the cause of severer symptoms; when it is suddenly repelled we must prepare to encounter increased evils on the affections of the throat, and more unmanageable local congestions of the brain or viscera.

"Scarlet fever, therefore, is in its nature essentially inflammatory; but we must bear in mind the disposition which it has, even in its milder form, but especially in its more aggravated type, to partake of the typhoid character: its forming or active stage is of brief duration, say some three or four days; while after that period, in common with other disorders of specific febrile contagion, it assumes a tendency towards a typhoid disease. Our active means of relief ought therefore to be regulated by this important circumstance, and be early enforced; and these, I need hardly repeat, are ever to be regulated by the fact, that if we prostrate the energies of the system too much, we run the greater hazard of encountering augmented difficulties, protracted recovery, and an uncertain cure.

"Emetics stand conspicuous among our efficient means of relief; they unload the mucous surfaces of the fauces and neighbouring parts, and by their general relaxing influence, lessen heat, and arrest internal congestion. Cathartics, administered so as to occasion a previous state of the *primæ viæ*, diminish in several ways the sources of irritation, and unless given to an immoderate extent, are not to be dreaded either as transferring diseased action, or as causing greater prostration. Laxatives or mild aperients may perhaps suffice; but an occasional dose of calo-

rosalia, also, it is at times epidemic, and probably from the same cause,—a general predisposition in the population of the affected district

mel, united with pulvis purgans, some few grains of calomel alone, or with rhubarb, followed by salts or magnesia, or the infusion of senna and manna, will in most instances be all that a just discrimination asks. Long ago Tozzetti (Bursarius) was more than once surprised to find that diarrhoea in this disease, both at its outset and during its progress, proved salutary. Bloodletting from the arm, and leeches to the throat, are so often serviceable, that they may be fairly enumerated among our most approved aids; and the apprehensions of evils which some of the best writers on the history of this disease entertained some twenty or thirty years ago, are demonstrated to be untenable by an improved pathology and the results of modern practice. Indeed, nature is not backward in some instances in anticipating the physician by a salutary hemorrhage from the nose. When inflammation of the throat runs high, and a greater disposition to cerebral congestion exists, venesection will be found indispensable. Antimonials, either as James's powder, or in the still more manageable form of the tartar-emetic solution, exercise a salutary power: their agency in diminishing the action of the heart and circulation, in controlling febrile irritation, and equalizing the functions of the economy, is the best recommendation for their use. Blisters have their advocates: but the application of them ought to be early, within the first day or two after the disease manifests itself; and then local determinations would plead hardest for their service. Indeed, the condition of the surface in scarlet fever seems too often obnoxious to the action of cantharides, and even when cerebral pressure occurs, I would have them to act upon the more remote parts. Like remarks apply to sinapisms, stimulating embrocations, &c. A powerful means of arresting the malignant or ulcerous condition of the throat, is the application of the lunar caustic in weak solution, delicately pencilled over the affected surface. This practice has been pursued in numerous instances by Dr. Hugh McLean, of this city, for thirty years past, with gratifying results.

"Soon after the philosophical Currie, of Liverpool, first published his Medical Reports on the use of cold water in fevers, his suggestions were adopted with an ample confidence of their saving efficacy in the management of scarlet fever; the extremely high temperature created in this disease, it was inferred, would be speedily reduced by cold aqueous ablutions, and striking instances of the efficacy of the plan occasionally occurred. But this means of controlling inordinate heat in scarlet fever with safety and promptitude, is not at present looked upon in the same favourable light as formerly: in milder cases of the disorder, cold ablutions are unnecessarily severe; and in aggravated cases, they must be abandoned on the score of inducing more alarming congestions. Many, I believe, have paid the forfeit of existence by the injudicious application of cold water: hence American physicians more generally, at the present day, employ tepid spongings of water, or of vinegar and water. I must advert to another error of practice, which it will be admitted we have detected at no small sacrifice of human life; I allude to the preposterous design of inducing salivation in scarlet fever, in order the better to secure the safety of the sufferer. The use of mercury to its warrantable extent I have endeavoured to specify. As in a majority of febrile dis-

or country to receive its contagion, perhaps to originate it, from some peculiar but unknown temperament or constitution of the atmosphere.

eases where there is local disorganization and general fever, it is extremely hard to create any sensible mercurial influence on the salivary glands ere the disorder has obtained a prominent sway, so in scarlet fever we have, I think, two powerful obstacles to our securing the wonted benefits of mercury: inordinate fever, which is too general yet to allow the stimulating effects of mercurials, and the local mischief of disorganization in some essential part, which equally forbids its employment: in fine, the disease is too rapid in its march to be checked by the slow progress of salivation. The mortality of scarlet fever would be more within our control, and cease to be the topic of such consternation, were this heroic practice less popular. This at least is my opinion, founded upon a tolerably ample survey of the subject.

"I forbear to dwell upon the medicinal and dietetical measures to be adopted for the purpose of renovating the system after the acute and active course of scarlet fever is passed through. It is so analogous to that demanded by typhus as to supersede at this time further minuteness.

"The anasarous and other dropsical conditions which are not uncommon consequences of scarlatina, challenge an additional observation. This uncertain disease is still further characterized by the uncertainty of its manner of termination. Dropsical effusions occur sometimes when the eruptive appearances have not been fairly developed; and they are liable to ensue when the eruption has been suddenly repelled. They may follow even when the eruption has been ample and preserved its wonted characteristics. I am inclined to infer, that from the inefficient action of mercury, by its adding to the irritability of an already grievously harassed system, it also frequently is the source of these effusions. Be this as it may, we find almost invariably great tenderness over the whole abdomen, the evidence of sub-acute inflammation. We therefore have our indications well pointed out: bloodletting in some instances, in others free leeching over the abdominal region; diuretics, as squills, nitre, cream of tartar, the lytta, &c. I have in this position of affairs given the elaterium in doses of one sixth or one fourth of a grain, blended with the cream of tartar, two or three times a day. This hydragogue cathartic has relieved the oppression by copious alvine discharges; and, this object accomplished, we may proceed as in a passive state of the system.

"I have said nothing of opiates in scarlet fever; the indications for their employment must be like unto those which influence us in the management of general fever. Plethora, general or partial, may render them very doubtful adjuvants to our sources of cure: but this exception applies not with the same force to the compound powder of ipecacuanha.

"The greater prevalence of scarlet fever within late years compared with a prior period, and its extraordinary fatality, have led me to communicate to you these cursory observations. I know of no prophylactic; and we are left to combat it. True indeed, in Germany, the belladonna is asserted to be preventive; and yet in that country, where this discovery is so lauded, scarlet fever is at this day more rife and fatal than ever. In this opinion I am fortified by the learned Dr. Wm. Leo-Wolf.—(See his Abracadabra, &c., New-York, 1835.) I may be excused from noticing the homœopathic treatment—assuredly the advocates of this system among us have no special reasons to boast

[It has generally been supposed that measles are not contagious before the eruption has appeared; but certain facts lately recorded tend to prove that this opinion is not correct.*]

It occurs under the three following varieties :

- a *Vulgaris.* Rash slightly prominent, extending over the mouth and fauces; harsh, dry cough, inflamed watery eye.
- β *Incocta.* Rash running its regular course, with little fever or catarrhal affection; affording no certain security against the common or regular disease.
- γ *Nigra.* Rash about the seventh or eighth day assuming a black or livid hue, interspersed with yellow; prolonged in stay; and accompanied with extreme languor and quickness of pulse.

The only predisposition or exciting cause of rubeola that we are acquainted with, is the peculiar constitution of the atmosphere just referred to. And, under the influence of this cause, the FIRST VARIETY usually shows itself as an epidemic; generally commencing in the month of January, and ceasing soon after the summer solstice. There seem, however, to be some other exciting causes than a peculiar state of the atmosphere or of the season; for we meet with a few scattered cases of it in almost every month of the year, evidently proving an ingenerate origin, and that the atmosphere is not auxiliary to its diffusion, from its continuing to be merely scattered; yet possessing its ordinary principle of contagion, which only appears to be less generally active, because there is a less general predisposition, in those who have never undergone it, to be acted upon.

It occurs most usually in children, though no age is altogether exempt from it [and it is generally more severe in children than adults]. As rosalia is accompanied with a typhoid fever,† rubeola is accompanied with a catarrhal; and hence, the opening symptoms consist of some degree of hoarseness, with a harsh dry cough, and frequently uneasy respiration; the eyelids are tumefied, the vessels of the conjunctiva turgid and inflamed, the cheeks are wet with a flow of acrid tears, and the nostrils loaded with serum, that excites an almost perpetual sneezing; the head aches or is drowsy; and the stomach, from sympathy, rejects its contents. On the fourth day the rash makes its appearance,

and assumes the character described in the specific definition. The stigmatized and pathognomonic dots are sometimes at first attended by so general a flush as to be lost in them, and to give the appearance of scarlet fever. I have already noticed several signs by which the two diseases may be distinguished, and the following may be added to the number. In scarlet fever, there is no cough, the eyes do not water, and the eyelids are not red and swelled. In measles, the papulae are more acuminate, of a crimson instead of a scarlet hue, and do not appear till two days later than those of scarlet fever*.

In smallpox the fever abates as soon as the eruption makes its appearance. In scarlet fever this is by no means the case, and as little so in measles; the vomiting, indeed, subsides; but the cough, fever, and headache grow more violent; and the difficulty of breathing, weakness of the eyes, and indeed all the catarrhal symptoms, remain without any abatement till the eruption has completed its course.

In rosalia we have also seen, that the sooner the efflorescence breaks forth after the febrile attack, the slighter and more favourable the disease. The same occurs in rubeola. The ordinary period we have already stated to be the fourth day, but it occasionally appears on the third, when the patient commonly escapes with but little inconvenience.—(*Van der Haar, Waarnemingen.*) A few rare examples may be found of its exceeding, instead of anticipating, its proper term; and this so considerably, that Buchholz gives us an instance of its not appearing till the twenty-first day: thus precisely rivalling the singular anomaly of scarlet fever already quoted from Dr. Maton.—(*Tode Med. Chir. Bibl.*, b. i., p. 86.)

On the third or fourth day after the eruption first appears, the redness diminishes, the spots fall off in branny scales, which sometimes, however, are scarcely perceptible for their minuteness and tenuity; leaving a slight discoloration on the skin, with considerable itching. On the ninth day from the beginning, where the progress has been speedy, and on the eleventh where it has been slow, no trace of measles remains. The eyes, however, in many cases, continue still inflamed, and the cough is followed with severe peripneumonic symptoms, which may terminate in phthisis. Yet these sequelae rarely occur, except where the treatment has been improper, or there is a predisposition to consumption from a stromous state of the lungs or some other phthisical diathesis.

If, on inoculation for smallpox, rubeolous contagion should have been previously received into the system, the variolous action will generally be, though not always, suspended till the measles have run through their proper course, when the inserted virus will resume its power, and the variolous eruption follow in its due order. This

of their triumphs. The infinitesimal practice offers a problem for mathematical scrutiny, and I leave it with you."—D.

* See Rust's Mag., Feb., 1827. It is both a contagious and an infectious disease.—Ed.

† This statement, as a general one, cannot be received as correct; rosalia may become typhoid; but is not necessarily so in all, or even the majority of cases.—Ed.

* The crescent or semicircular form of the patches in measles, attended with tenderness of the eyes, cough, &c., will generally leave no doubt about the nature of the disease. It is on the face that the characters of the eruption can be most plainly seen.—Ed.

quality of suspension, however, is not peculiar to the measles. "I have known," says Dr. Perceval in his manuscript comment on the present species, "bex *convulsiva* yield the *pas* to variola, and then resume its station." In like manner, consumption is generally suspended during the entire course of pregnancy, and recommences its inroad on childbirth.

Measles in their more perfect form, which is that we are now contemplating, may be said, as a general rule, to occur but once in the course of a man's life;* for though, as Dr. Baillie observes (*Trans. of a Soc. for the Impr. of Med. and Chir. Knowledge*, vol. iii.), a few instances of a second attack are to be found, *exceptio probat regulam*, they are so rare as rather to maintain, than disturb the law.—(*Roberdière, Recherches sur la Rougeole*, Paris, 1776.) The cases described by Dr. Baillie, however, are very striking, and show a family, rather than an individual susceptibility. His first narration is that of five brothers and sisters, who had it in succession a second time, with one exception, after an interval of six months; the expected case affording an interval of twenty-one years. His next narrative is that of two sisters, who had a repetition of measles after an interval of four months. Dr. Willan asserts that he never met with an instance. The anomaly is unquestionably less frequent than in scarlet fever, and shows that the influence produced by the rubeolous action on the habit is more rooted and effective.

In its ordinary course, measles is a disease unaccompanied with danger. It is in fact a catarrhal fever with a specific eruption. The fever, as we have observed already respecting exanthems in general, is necessary to a certain extent, for the purpose of throwing the virus upon the surface: as inflammation in a certain extent is necessary to produce healthy suppuration. But a small degree of pyretic action is in both cases sufficient; for if this be exceeded, the natural means of cure itself becomes the disease, rather than the morbid condition it is intended to remove.

In all instances the extent of the eruption will depend upon the fever, whenever the latter is in excess. And hence our attention is to be mainly directed to the fever itself; for, by diminishing the fever, we necessarily diminish the eruption also. In measles, therefore, the remedies we have already enumerated for a catarrh, are those we are to have recourse to. An emetic is always useful on the incursion of the disease; and should be succeeded by cooling aperients and demulcents, the skin being kept moist, and its heat subdued by mild diaphoretics.

Dr. Cullen recommends bloodletting during every period of the disease; and it has often been practised at its commencement.† It is

rarely, however, that this can be called for, except in the case of pneumonic inflammation; and as such an affection does not commonly appear till the close of the measles, we should, generally speaking, as recommended by Sydenham, reserve bloodletting till this period, and not exhaust the patient's strength beforehand; and the more so, as even here the fever has sometimes proved a synochus, and terminated in a typhous form, as particularly noticed by Sir William Watson in the children of the Foundling Hospital in 1763 and 1768, who gives to this modification the name of putrid measles (*Medical Observations*, vol. iv.; *Hoffman. Opp.*, tom. ii., p. 67); if, indeed, this were an example of the genuine disease, of which there is some doubt; though there is little doubt, that in a few constitutions the disease has taken this turn. "In a charity-school where measles prevailed," says Dr. Perceval, in commenting on this species as given in the Nosology, "typhous infection was introduced; hence the variety *a* changed to *γ*." It is highly probable that some such accidental cause occurred in producing Sir William Watson's modification.

Exposure to cold, so peculiarly serviceable to smallpox, has, from a supposed analogy, been recommended also in measles by some rash practitioners, and adopted by others. All fair analogy, however, is against the practice: the fever in measles is directly catarrhal, and the analogy should be drawn, not from smallpox, but from catarrh, in which exposure to cold would, in the opinion of every one, be absurd and mischievous; nor can any thing be so likely to produce pneumonic inflammation, which, in truth, is most commonly the result of carelessness upon this very point. The room should be large and airy, free from currents of cold, but not hot; the drink warm, the food light, diluent, and in a liquid form. If the cough be troublesome, it will be useful to breathe the steam of warm water, not through an inhaler, but over a large basin, with the head covered with a flannel large enough to hang over its edges; and by this means, the inflamed eyes will also have the benefit of the relaxing vapour. If the oppression of the chest, pain, and coughing should return, as they are apt to do on the disappearance of the eruption, venesection or cupping must again be had recourse to, however they may have been employed antecedently. Opium does not, in this case, afford the relief we might expect: it increases the heat and restlessness, but rarely conciliates sleep. A supervening diarrhoea proves the most favourable crisis, and should be very cautiously corrected. And where it does not take place naturally, it may be wise to imitate it by gentle laxatives.

From a peculiarity of constitution, or some accidental influence exercised over it at the

* Few individuals escape the measles: the disposition to it is less frequent than that to smallpox.—Ed.

† "It is always necessary to observe carefully whether there is peripneumonia, or bronchitis, or pleuritis, and to treat it just as if no measles were present; to take blood from the arm or jugular

vein, or apply leeches, &c. One would not pay great attention to these symptoms before the eruption occurs; but if they be severe, when the eruption comes out, blood should be taken. Moderate purging is proper, and low diet."—Dr. Elliotson's Lect. at Lond. Univ., as published in *Med. Gaz.* for 1832-33, vol. xi., p. 70.—Ed.

time, the rubeolous rash is sometimes found to run through its regular course with little fever or catarrhal affection, as though it were a simple cutaneous eruption, and without appearing to afford an immunity to the individual against a future attack; constituting our SECOND SPECIES. This has usually been called, and especially by the German writers, spurious measles; but as it occurs most frequently when the genuine measles are epidemic, and is doubtless a result of their contagion, it is less properly a spurious than an imperfect or immature rubeola; and I have hence exchanged the term *spuria* for *incocta*. Dr. Willan denominates it *rubeola sine catarrho*; but, as the genuine measles themselves, capable of affording emancipation, have sometimes appeared with very slight catarrhal symptoms, *incocta* seems preferable. "Some," says Dr. Heberden, "have been so fortunate as to have the measles appear after suffering so very little from fever, or any of the preparatory symptoms, that they could hardly say they had been ill." In this case, the constitution is protected by a natural insusceptibility of the disease; which is the best protection that can be enjoyed. In the case of imperfect measles, it is only operated upon by some temporary influence: and hence, as soon as this influence ceases, the common susceptibility returns.

The THIRD VARIETY, OR BLACK MEASLES, seems to consist in an intermixture of dark, discoloured, or petechial spots from effused blood, with the proper rubeolous rash. It is found chiefly in persons of debilitated and relaxed fibres: and the dark patches will sometimes remain for ten or twelve days after the commencement of the eruption, with no other symptoms of fever than a quicker pulse and an increased degree of languor. It is rarely of serious consequence, unless a typhous infection be accidentally communicated, as mentioned by Dr. Perceval, and usually yields with ease to an infusion of bark with sulphuric acid.

Inoculation has been tried for the measles by employing the acrid serum from the eyes, or from minute vesicles that sometimes appear between the patches of the rash. Dr. Home, not being able to obtain a contagious ichor from either of these quarters, drew blood from a turgid cutaneous vein, where the eruption was most confluent, and, impregnating a dossil of cotton with it, he applied the cotton to a wound made in the arm. It has occasionally succeeded, but more frequently failed; nor does it seem to operate with any certainty in producing a mild modification; for many of the cases of inoculated measles have been quite as severe as we might reasonably have expected from a natural attack. It is, in truth, a very unnecessary caution in a disease which, in its ordinary range, excites so little alarm, and never leaves any blemish, like the smallpox, on the skin.

[While the editor coincides with the author on the question of inoculating for the measles, he deems it proper to mention that it is a point on which much difference of opinion has prevailed. This inoculation was performed with seeming advantages by Home and Horst, and it

has been recommended by Vogel, Perceval, Brown, Monro, and Tissot. On the other hand, it has been condemned by Cullen, Girtanner, Rosenstein, Vaidy, and Montalçon. In 1822, it was again tried by Professor Speranza (*Bibliotheca Italiana*, Agosto, 1825; also *Ed. Med. Journ.*, No. xc., p. 218), of Mantua, in many instances, all of which proved mild. A slight cut was made into one of the most vivid of the large spots with a lancet, the point of which was covered with the blood effused. With this, some small punctures were made in the arm, and a bandage applied.]

SPECIES III.

ENANTHESIS URTICARIA.

NETTLE-RASH.

RASH IN FLORID, ITCHING, NETTLE-STING WHEELS; APPEARING ABOUT THE SECOND DAY; IRREGULARLY FADING AND REVIVING, OR WANDERING FROM PART TO PART; FEVER A MILD REMITTENT.

THIS, like the last species, is rather a troublesome than a dangerous complaint,* though it is always attended with some slight disorder of the constitution, as headache, drowsiness, coldness, and shivering, succeeded by great heat, and a white fur on the tongue. But the stomach seems chiefly to suffer; and hence there is not unfrequently pain and sickness in this organ, with great languor, faintness, and anxiety. And, as a sympathetic affection, the eruption has often followed any violent disturbance of the stomach alone, as surfeit, cold cucurbitaceous or other indigestible vegetables, mushrooms, crab-fishes, shrimps, herrings, muscles,† cupreous or other mineral poisons, introduced into the stomach by mistake.

The exciting cause, however, of genuine idiopathic nettle-rash, is usually concealed from us; for it often makes its appearance without any of these irritants, or, indeed, any other that we are acquainted with; and hence Dr. Heberden was inclined to believe that the skin itself is often the chief seat of the disorder, and that the stomach and the system only suf-

* Rubeola, on account of its tendency to bring on inflammation of the bronchial membrane, lungs, or pleura, is a more serious disorder than urticaria. The latter rarely proves fatal; but many children die of measles. An examination of the bills of mortality in some months of the year, would afford ample proof of what is here stated.—En.

† Other articles of food might be mentioned as producing urticaria—for example, strawberries, some kinds of honey, cherries, fresh pork, and goose; also fish, at some particular seasons, especially mackerel, oysters, &c. Aibert (*Monographes des Dermatoses*, vol. i., p. 128) mentions its occurrence in a butcher, after skinning the body of an emphysematous cow; the vapour which escaped from the intestines and cellular tissue suddenly caused all the phenomena of urticaria, which was very stubborn: and Gibert (*Manuel des Maladies spéciales de la Peau*, p. 19) states instances where it has been caused by affections of the mind.—D.

fer secondarily.* He has hence contemplated it as a modification of lichen, closely connected with the prickly heat of the West Indies, the *essera*, or rather *eshera* إشر of the Arabian writers. The resemblance is close; but there are characters by which the two diseases may be distinguished with tolerable ease. In nettle-rash, the efflorescence is in scattered wheals, with few papulæ; in lichen, in scattered papulæ, with few wheals. In the latter, the itching is more mordicant and aculeate; the eruption, instead of terminating in a few days, runs on to an indeterminate period, and, however irritating, produces little or no fever, and but a slight constitutional affection of any kind.

In Sauvages, on the contrary, nettle-rash is treated of as a scarlet fever under the name of *scarlatina urticata*. But its character, as given in the specific definition, is sufficient to distinguish it from any form of rosalia, which has no wheals, or elevated beds with a defined outline, and no sensation of stinging.

The nettle-rash occurs chiefly in summer, and more frequently among persons of the plethoric or sanguine habit, especially those who indulge too freely in eating and drinking. In children it seems sometimes to be connected with teething, or irritation of the bowels. The eruption commonly takes place at night, after the febrile symptoms just noticed have prevailed for about thirty or six-and-thirty hours: and, on this account, the Arabians elegantly and correctly denominated the coloured wheals

نات آيل (benat-allil), "offspring or daughters of the night."

By the length of the precursive symptoms, the idiopathic disease is distinguished from the sympathetic affection, so closely resembling it, which is occasioned, as already observed, by crapulence, or substances introduced into the stomach that disagree with it. In this last case, the general swelling and eruption take place immediately, and subside as soon as the occa-

sional cause is removed. Wheals of a similar appearance are sometimes found, with other peculiarities, as of a whiter hue, or interspersed with small tubercles, or of very small diameter, except when they unite in clusters: some of these sorts trouble the skin permanently; others vanish and reappear several times in the course of the day; others subside for a week or two, and then rally and reoccupy their stations. But all of them are of chronic duration, are little accompanied with fever, and cannot be considered correctly as varieties of the idiopathic disease. They occur, however, as such, in Dr. Willan's treatise.

A cooling regimen, and subacid diluents, with a free exposure to pure air, generally succeed in effecting a cure of nettle-rash, without any other medical treatment. A gentle laxative or two, however, should be added to the domestic means,* and, if the itching be very troublesome, it may be often allayed by the use of camphorated vinegar.†

Dr. Willan describes a single case in which urticaria proved fatal.—(*Cutaneous Diseases*, p. 401.) The patient was a man of about fifty years of age, who had impaired his constitution by hard labour and intemperance. The precursive symptoms were all violent, and the sickness and languor were followed by fainting-fits; and he had great pain in the stomach, which was increased by pressure. The fever was considerable, and soon attended with delirium. While the rash was most vivid, his internal complaints abated; but he gradually got worse, and died on the seventh day. Here, however, the urticaria seems to have been only symptomatic. It afforded him relief, and offered the only chance of a recovery.‡

* About four years ago, a lady in Charlotte-street, Bloomsbury, was attacked with severe pain in the stomach, occasional sickness, and febrile symptoms, followed by an affection of the skin, which her family supposed was erysipelas; but it turned out to be urticaria. In this case emetics and purgatives may be said to have failed; for, though they gave partial relief, it was only temporary, and every night fresh wheals came out, and the febrile symptoms underwent an exacerbation, until bleeding was practised, which at once stopped the disease. The editor particularly noticed, in this instance, how very rapidly changes occurred in the look of the eruption; so that, while he was in the room, the rash in some places would almost fade away, or change its appearance and form, and assume an increased redness. Dr. Elliotson, in his valuable lectures, relates several facts, showing the efficacy of venesection as a means of relieving urticaria. If the cause be in the stomach, he does not object to an emetic.—Ep.

† The local applications preferred by Dr. Elliotson for alleviating the itching, are the chlorides of soda and lime, and lotions containing prussic or nitric acid.—Ep.

‡ This affection may be intermittent, a case of which is mentioned by Cazenave as accompanying a quotidian intermittent fever: it was cured by Fowler's arsenical solution, after other means had failed. Prof. Dewees seems to have been the first who recommended this remedy for this purpose. Quinine, however, is generally preferred.—D.

* Med. Trans., vol. ii., p. 173. According to Dr. Elliotson's observations, the most frequent cause of urticaria is the application of cold, especially when the body is heated. It is perhaps sometimes induced by sudden heat. It will frequently arise from an emotion of the mind, or from certain ingesta. In some, almonds and the kernels of various fruits will occasion it, or rather the skin of such kernels, in consequence of its containing hydrocyanic acid, which will now and then have the same effect. So intense is the idiosyncrasy of some persons with respect to its excitement by muscles, that Dr. Elliotson heard of a woman in whom urticaria was induced by one teaspoonful of water in which muscles had been boiled. In some people, he says, malt liquor, white wine vinegar, and common spirits will produce it. Many persons on taking copayva become covered with nettle-rash.† He has known it excited by sulphate of quinine, opium, and subcarbonate of iron in treacle.—Ep.

† Dr. Hewson, of Philadelphia (N. A. Med. and Surg. Journal, vol. v.), has mentioned a case of this kind.—D.

GENUS II.
EMPHLYSIS.
ICHOROUS EXANTHEM.

ERUPTION OF VESICULAR PIMPLES FILLED PROGRESSIVELY WITH AN ACID OR COLOURLESS, OR NEARLY COLOURLESS FLUID; TERMINATING IN SCURF, OR LAMINATED SCABS.

THE term emphlysis is derived from the Greek *ἐμ* or *ἐν*, "in, intra;" and *φλύσις*, "a vesicular tumour or eruption." *Ἐμφλύω* is usually employed among Greek writers nearly in the same sense as *φλύω*. In the present system it will be found employed more strictly, and in opposition to *ἐμφλύω*; so that, while emphlysis, from the latter, imports an eruption of vesicles, whether large or small, produced by or accompanied with *internal and febrile affection* essentially connected with it, ecphtysis, from the former, imports an eruption of vesicles simply cutaneous or *superficial*; or if, in a few varieties, combined with internal affection, not necessarily or essentially associated. Of the last, therefore, we shall have to treat in the third order of our sixth class, entitled ECCTRICA.

The genus EMPHLYSIS includes the following species:—

- | | | |
|--------------|-------------|-----------------------------|
| 1. Emphlysis | Miliaria. | Miliary Fever. |
| 2. ——— | Aptha. | Thrush. |
| 3. ——— | Vaccinia. | Cowpox. |
| 4. ——— | Varicella. | Waterpox. |
| 5. ——— | Pemphigus. | Vesicular or Bladder Fever. |
| 6. ——— | Erysipelas. | St. Anthony's Fire. |

SPECIES I.
EMPHLYSIS MILIARIA.
MILIARY FEVER.

VESICLES SCATTERED OVER THE BODY, OF THE SIZE OF MILLET-SEEDS; TRANSPARENT-RED, AFTERWARD MILKY; PRECEDED BY A PRICKING SENSATION; SIGHING, ANXIETY, AND SOUR SWEAT.

THE disease takes its name from MILIA, "millet-grains," in consequence of the resemblance of its vesicles to the seeds of this plant in size, and, when matured, in colour. There is a doubt when it first made its appearance, and another doubt, among some pathologists, whether it be ever any thing more than a symptom of some other complaint.

It has been treated of at least for a century and a half, and that, too, as an idiopathic malady. It is said to have appeared first of all in Saxony: and the oldest writers assign two varieties to this disease, distinguished in Germany by the names of *Rothen Friesel* and *Weisse Friesel*, or red and white miliaria (*Sindner, Betrachtungen des Rothen und Weissen Friesels*, Schweidnitz, 1735), but perhaps unnecessarily, as both varieties seem in most, if not in all instances, to be only different stages of the same affection. The vesicles are at first red, from the colour of their under surface, or inflamed base, being transmitted through the transparent pellicle; they are afterward opaque

and milky, from absorption of the more attenuate part of the fluid, or some other change. In a few cases, however, the red hue seems to have continued throughout; and, in others, the white hue to have appeared from the commencement: a variation in the nature of the secretion, and in the mode of its absorption, producing this difference of effect.

From the redness of the vesicles on their first eruption, this disease has also been denominated, by many writers on the continent, PURPURA; and has hence been confounded with the petechial or flea-bite-like spots that appear in scurvy and putrescent fevers; and the rather as miliaria is also a disease of debility. Ploucquet seems to have intermixed all these, as well as pemphigus, and described them under the common name of miliaria.—(*Initia Biblioth.*, v., pp. 564, 565.) In like manner, Gerike's dissertation on this disease is entitled *De Morbo Miliari, alias Purpurâ dicto* (Hal, 1773); and Juck's, *De Febre Miliari, vulgò Purpurâ rubra et alba, seu chronica*.—(Erfort, 1716.)

From the minuteness of its vesicles, whose elevation can often only be ascertained by the finger, this species treads close upon the general complexion of the genus *enanthesis*, or rash-exanthem, and, during its red appearance, is often called a rash; and hence another cause of confusion and intricacy. By Linnéus and Parr, it is on this account defined nearly in the same terms as *rubeola*, so far as relates to the eruption; and at Leipsic, in 1650, where it is said to have been contagious or epidemic, was unquestionably mistaken for *rosalia* or scarlet fever. As a symptom it sometimes accompanies inflammatory fevers, but more generally those of atony. It is certainly at times attended with flea-bite spots, or petechiæ, and Huxham speaks of it as sometimes giving rise to them: an observation confirmed by a like statement of Boncerf (*Hautesierk, Recueil*, ii., p. 217): and hence another reason why it has occasionally been treated of under the term *purpura*.

The eruption makes its appearance at an uncertain period after the commencement of the introductory fever; usually, however, on the third or fourth day. It seldom shows itself upon the face; but is first visible upon the neck and breast, and thence spreads progressively over the entire body. The febrile attack is usually somewhat severe in all its stages; the pricking sensation occurs during the hot fit, and is like that of pin-points struck into the skin; the sweat is copious, but proves, by its sour and old smell, that it is a morbid secretion, and hence affords no relief. The disease runs on, with variable remissions or exacerbations, for seven or even fourteen days, and has sometimes extended to twenty-one days, commonly terminating in a critical and natural sweat; the red transparent vesicles, as already observed, gradually assuming a whiter hue, and losing their transparency; and about the fifth day drying in minute crusts or scales; which, in some instances, are succeeded, as in the case of *aphtæ*, by a new crop of vesicles, that pass through a like course. Notwithstanding the anxiety

and depression of animal spirits which so peculiarly mark this exanthem, it commonly maintains through its entire range a mild character, undisturbed by any alarming symptoms. In some instances, however, either from the constitution or peculiar circumstances of the patient, or the peculiar temperament of the atmosphere, it puts on a malignant character, and proves fatal in a few days.*

Such a character it seems to have exhibited in the departments of the Seine and Oise in France, in the autumn of 1821, where also it committed a very extensive havoc as an epidemic. M. Rayer, who has given a valuable history of its range in this quarter, tells us that it usually commenced with symptoms of general restlessness, which were soon succeeded by a copious perspiration, that continued through its entire progress, whether it terminated in recovery or death. The eruption, which as usual appeared on the third or fourth day, was general or partial, discrete or confluent. And as the transparency of the vesicle was in some instances without a red basis, and continued till desquamation, he adds to the two varieties of red and white miliaria a third, which he distinguishes by the name of phlyctenous. He tells us also that, on dissection, the mucous surface of the stomach and intestines generally showed some proof of inflammation; an appearance which was likewise traced in various instances in the lungs, and even the brain or its membranes. The cause of the epidemic seems obscure; the air, however, was humid, and the face of the country is considerably mapped with marsh-land.

We have no clear proof of its being contagious; and Stoll (*Rat. Med.*, ii., pp. 58, 169), and most pathologists with him, deny that it is so. It is found, indeed, more frequently as a secondary, or symptomatic, than as an original affection of any kind. Cullen denies that it is ever otherwise than symptomatic. But this is to speak, as we have already seen, in too prescriptive a tone. The author himself, indeed, has lately had a clear and well-marked example of its idiopathic appearance in a young gentleman of a bilious habit, thirteen years of age, in which the vesicles were very numerous, but distinct. They passed through the two stages of a red and milky hue, and terminated on the seventh day in branny scales, unconnected with any other ascertainable disease: and M. Planchon has given abundant instances of the same kind.—(*Dissertation sur la Fièvre Miliare*, &c., Tournay, 8vo.) Professor Frank affirms that it is often epidemic, and in some parts endemic (*De Cur. Hom. Morb. Epit.*, tom. iii., sect. 322, p. 131, 8vo., Mannh., 1792); but his description seems to combine the symptoms of other diseases with those of genuine miliaria, so as to make it a mere satellite upon a more imposing potentate.

Dr. Cullen, however, conceives it to be nothing more than an eruption occasioned by a stage of sweating protracted till it has produced debility, in any fever whatever. But, in this case, we should expect it most frequently in the clammy sabural sweats of typhus fevers, in which it is only occasionally to be met with, and certainly less frequently than in other fevers.*

In few words, miliaria, when idiopathic, is an eruption accompanied with a mild typhus for the most part, though not always, and a peculiar irritability of the skin. And where the same eruption appears as a symptom of some other disease, it is probable that a like irritability of the skin prevails.

It is, however, unquestionably a disease of debility, and has sometimes, like rosalia, been followed by cellular or abdominal dropsy. And to this character of weakness our eye should be directed in attending to its cure. Every thing that heats and stimulates should be avoided. The bowels should be cleared of all irritating materials by mild laxatives; and, if offensive breath, or any other symptom, should indicate defecation of the stomach, an emetic should be given at the first. Cooling drinks, light bed-clothes, and a cool atmosphere, will in every case be of essential service; and the patient may be allowed to lie with his hands and arms out of bed.

By these means alone, Dr. Cullen thinks he has frequently prevented military eruption in lying-in women and others, where it might have been expected as a concomitant. But where it has actually appeared, he adds to this regimen the use of tonic and antiseptic remedies, particularly Peruvian bark, cold drink, and cold air.

Purgatives, however gentle, have been objected to by many pathologists; but, when not carried beyond the strength of the patient, they rarely fail to be of service. "I am convinced by experience," says Sir George Baker, "that the prudent application of this practice to the military fever has been of singular advantage: and it is worthy of observation in this place, that the symptoms of the measles are often rendered less formidable, when, during this disease, the patient has every day two or three evacuations by stool."—(*Med. Trans.*, vol. li., art. xix., p. 300.)

In many instances, however, something more specific than this general plan will be found necessary. In his own practice, the author has endeavoured not merely to check but to change

viduals between the ages of twelve and forty years.—D.

* The editor lately attended, with Dr. Pinckard, a gentleman in Gower-street, who had had a severe inflammation of his lungs, and being very fearful of cold, he kept his room exceedingly warm, so that during his convalescence he was always in a profuse perspiration, which had a remarkably sour smell, and became attended with an extensive military eruption over the sides of the neck and shoulders. Dr. Elliotson has frequently seen the same cutaneous affection on the hands in acute rheumatism, and he states that they are common in measles and scarlet fever.—Ed.

* This disease appeared epidemically at Wirttemberg in 1801, and raged with such malignancy and violence, that it is compared by Kreysig, who described it, to the plague or cholera: it was confined, with but few exceptions, to indi-

the perspiration; and hence, while, from an early period of the disease, he has employed tepid ablation or sponging, which is always highly refreshing, he has given small doses of antimonial powder, with infusion of roses containing a surplus of sulphuric acid; and has rarely continued this course for four-and-twenty hours without finding the sweat less copious and of a more natural quality. And where the languor has been distressing, he has added camphire in the form of pills, giving a scruple or half a drachm in the course of the twenty-four hours.

That the skin is in a state of peculiar irritation is highly probable, from our being sometimes able to excite a like eruption by wearing a shirt of coarse flannel or horse-hair. And hence Dr. Darwin gives one example of miliaria, as he calls it, "produced by the warmth, and more particularly by the stimulus of the points of the wool in flannel or blankets applied to the skin, which by cool dress, and bedclothes without flannel, soon ceased." He has distinguished this affection by the name of *miliaria sudatoria*; but it ought rather to be regarded as a variety of intertrigo, or fret.

SPECIES II. EMPHLYSIS APHTHA. THRUSH.

VESICLES GRANULAR, ROUNDISH, PEARL-COLOURED; CONFINED TO THE LIPS, MOUTH, AND INTESTINAL CANAL; TERMINATING IN CURD-LIKE SLOUGHS; OCCASIONALLY WITH SUCCESSIVE CROPS.

APHTHA is derived from the Greek *ἀπρω*, "accendo," "to burn or inflame." Like the preceding species, this eruption, though at one time supposed to be papulous, is now generally admitted to consist of minute vesicles, containing a whitish or milky fluid when matured; and hence in a nosological arrangement it naturally follows miliaria.

This disease is found under three varieties, a white, a black, and a chronic:—

- | | |
|-----------------|--|
| α Infantum. | Appearing in infants soon after birth; and often extending from the mouth to the intestinal canal; mostly with slight febrile symptoms, and white sloughs. |
| β Maligna. | Accompanied with great debility of vascular action; usually ascending from the larynx into the mouth; sloughs black; fever a typhus. |
| γ Chronica. | Protracted and exacerbating; with great emaciation and hectic fever; extending through the whole range of the intestinal canal. |
| Chronic thrush. | |

The disease consists in a peculiar irritation of the whole mucous membrane, and particularly the mucous glands of the mouth and fauces,

producing minute vesicles and sloughs. [On dissection, irregular patches of inflammation, slightly elevated above the surrounding parts, and often covered with minute vesicles and ulcers, are found on various portions of the mucous membrane of the intestines, especially the ileum.—(*Abercrombie, in Edin. Med. and Surgical Journ.*, July, 1820.)] In the second and third species, some of the smaller bloodvessels are also eroded at the mouth, and hence the sloughs become livid or ulcerated.

All the varieties, therefore, occur only under circumstances of considerable debility; and hence, while the first is usually found in infancy, the two last are mostly an accompaniment of low fevers, old age, or cachexies.

The WHITE THRUSH, or that of infancy, commences in the mouth. The angles of the lips are usually first beset with the eruption, probably from their exertion and fatigue in the act of sucking. From thence it spreads in scattered papulæ over the tongue and cheeks, till at length many of the papulæ coalesce, and the eruption appears in patches, or strata. The fauces become next affected, and it descends thence through the œsophagus into the stomach, and travels in a continuous line through the entire course of the intestines to the rectum, the feces being often loaded with aphthous sloughs.

In very mild cases the disease restricts itself, or by judicious management is restricted, to the mouth, and terminates in a single separation of the curd-like crusts. But it usually proceeds further; and a second, and even a third crop, takes the place of that which disappears. The general health is, in the meantime, but little disturbed, though the stomach is disordered, the pulse is often a little quickened, and the infant is rendered fractious. But in an unhealthy habit, when the food is innutrient, and the frame weak and atrophous, the under-surface of the vessels ulcerates, the ulceration spreads more widely and deeply, a low fever ensues, and the little patient sinks beneath its malignancy.

In the mildest form, this eruption seems to be highly acrimonious: for the nipple of the nurse is sure to be affected. There is little doubt, moreover, that the acrimony is specific and contagious: though, in order to multiply itself and preserve its peculiar powers, it seems necessary that it should come into close union with the same membrane, or a membrane of the same structure, as that which originates it. *Sine proximo contactu*, says Professor Frank, *communicari hunc morbum, non facile concedimus.*—(*De Cur. Hom. Morb.*, tom. iii., § 367.) Hence the nipple, though corroded by the sharpness of the humour, does not produce aphthæ, nor does the ulceration spread beyond the reach of the acrid ichor: but it has been received by kissing the infected lips of an infant; and has in this manner propagated itself to adults as well as to children.

But, beyond this, we have good authorities for believing it at times to be epidemic. For, not only all the children of the same family, how cautiously soever separated from one another, but many of those of the same neighbourhood,

have been known at times to suffer from it simultaneously. Yet whether in this case the epidemic be the result of the specific matter of the exanthem, floating as an undissolved miasm in the atmosphere, or whether any particular intemperament of the atmosphere itself predispose the body to the generation of aphtha, is unknown.

In the cure of this species, our first object should be to remove all acrimonious materials from the primæ viæ by a laxative or emetic, or both, and thus, as far as we can conjecture concerning it, root out the primary source of disease. We must at the same time carefully examine the health of the nurse of the infant, if the infant be at the breast, and particularly as to the nature of the milk, and the freedom of the nipple itself from all primary disease, so that the child may not have a foundation laid for it in this quarter. If the child be weaned, we must be particularly attentive to the nature of the food, and the mode of its preparation, concerning which nurses, when left to themselves, are often too careless. And we have next to prevent the multiplication of the papule by syringing off the acrimonious fluid as well as we are able with diluting or detergent gargles, and expediting the separation of the sloughs by inviscating astringents, as bole armenic, alum, borax, or catechu, intermixed with mucilage or honey. These astringents, however, must not be made very sharp; for in this case we shall hurry off the little sloughy curds too rapidly, irritate the tender surface of the new skin, and produce a new crop of eruption; which is perhaps excited more frequently by our being thus too busy and precipitate, than by any other means whatever. If the disease have descended into the stomach and intestines, a mixture of rhubarb and magnesia, or a little castor-oil, given occasionally, will be the best medicines.

The second variety, or BLACK THRUSH, is sometimes found idiopathically in old age, when all the vital resources are failing, and the constitution is sinking apace; but it is more commonly a concomitant on acute debilitating diseases; as in typhus, or malignant remittents. Stoll affirms, that, in all these cases, the disorder commences not in the mouth, as in infants, but in the stomach, and works its way both upwards and downwards (*Rat. Med.*, 167); and, from the pain and cardialgia that are often complained of antecedently, there seems ground for this opinion. Birnstiel makes the same remark, and compares the feeling to that of a tense cord extending from the cardia to the navel.—(*Sterblichkeit im Krankenhaus zu Bruchsal.*) This variety is also said to be at times epidemic, and, by some, contagious. But it should be observed, that, in most of these cases, aphtha has appeared as a concomitant of other diseases, and probably as the result of them. Thus, when it is affirmed by Muguet to have been decidedly contagious at Paris on a particular occasion (*Raulin, Von Erhaltung der Kinder*), an alarming typhus seems to have been present also. Stoll gives the same account of it, but it was then united with military fever; and on another occasion, when it appears to have had pretensions to an

epidemic range, it was combined with a prevailing intermittent.—(*Fontanus, Annal.*, p. 59.)

In all these cases the mode of treatment must depend upon the nature of the particular case. In the drooping of old age, we can only palliate; and our best palliatives will be cordials, as port wine negus, or wine itself, and stimulating nutritive food; where the aphtha is dependant upon some other affection, it can only be remedied by remedying the parent disorder.

In very cold northern, and especially in cold marshy climates, aphtha, in one of its varieties, is said to occur frequently in all ages, and often without fever. As we have already seen that it is very generally the result of a reduced state of health and vigour, this is by no means improbable; and the best means of opposing it is warmth, a pure and unstagnant air, exercise, and a generous diet.

The third variety, or CHRONIC THRUSH, seems chiefly also to have its first seat in the stomach, or some adjoining viscus.

It has been described by Hillary under the name of *aphthoides chronica*, and more lately by Dr. Latham under that of *cachexia aphthosa*. It is more frequently found in hot than in temperate climates, from the inroad which is so often made upon the strength of the constitution by the permanent excitement of the climate.

"A slow hectic fever," says Dr. Latham, "with a pulse weak and a little quicker than natural, marks the commencement of this disease. Pimples on the edges of the tongue, with superficial blisters within the mouth and fauces, next succeed; and a corresponding heat and soreness of the stomach more or less accompany this and every stage of the disease."—(*Med. Trans.*, vol. v., art. vi.) The whole intestinal canal soon afterward becomes affected, and diarrhœa, and, not unfrequently, dysentery, are the consequence. The irritation then subsides, as though the disease had worn itself out; but there is not vigour enough in the constitution to heal the ulcerations; and, the original cause continuing, fresh exacerbations take place, and every symptom is more aggravated, usually accompanied, moreover, with a fearful despondency. These repeated recurrences gradually exhaust the system, and the patient at length sinks beneath their persevering assaults.

Dr. Thomas has given a good account of this affection as it has occurred from time to time in the West Indies.—(*Modern Pract. of Physic.*)

During the exacerbations, opium seems to afford the best relief; while, in the intermissions, light bitters and other tonics should be had recourse to. For the distressing irritation that often exists in the throat and rectum, Dr. Latham is bold enough to recommend gargles and injections of diluted litharge-water; the latter in combination with laudanum.

SPECIES III.

EMPHLYSIS VACCINIA.

COWPOX.

VESICLES FEW OR A SINGLE ONE; CONFINED TO THE PART AFFECTED; CIRCULAR, SEMI-

TRANSPARENT, PEARL-COLOURED; DEPRESSED IN THE MIDDLE; SURROUNDED WITH A RED AREOLA.

This disease attracted attention in the county of Dorset about forty or fifty years since, as a pustular eruption derived from infection, chiefly showing itself on the hands of milkers who had milked cows similarly disordered. It had been found to secure persons from the smallpox; and, so extensive was the general opinion upon the subject, even at the time before us, that an inoculator who attempted to convey the smallpox to one who had been previously infected with the cowpox, was treated with ridicule. A formal trial was made, however, and it was found that no smallpox ensued. About the same time, a farmer of sagacity of the name of Nash, duly attending to these facts, had the courage to attempt artificial inoculation on himself; and the attempt is said to have succeeded completely. Similar facts and numerous examples of them were accordingly communicated to Sir George Baker, who, having engaged not long before in a most benevolent though highly troublesome controversy respecting the cause of the endemic colic of Devonshire, was unwilling, notwithstanding his triumph, to tread again the thorny paths of provincial etiology. Gloucestershire, however, another dairy county, had witnessed the same disease, with similar consequences; and the same opinion generally prevailing in distant districts of both counties, afforded proof that the power thus ascribed to cowpox was not wholly visionary.—(*Evidence delivered before the Committee of the House of Commons, 1821.*)

Dr. Jenner, then resident at Berkeley in Gloucestershire, pursued this hint with great judgment and unabated ardour. He was at first foiled by not distinguishing between the genuine cowpox and an ineffective modification of it, or a spurious disease of nearly a similar appearance to which the same animal is subject, but which is no preservative against the smallpox; and found another difficulty in determining the period of time within which the vaccine virus maintains its prophylactic power. Having at length, however, made himself master of the distinctive characters of the genuine vesicle, he ventured to publish the discovery in 1798, and to recommend inoculation with the virus of vaccinia as a substitute for variola. The result is known to every one: the discoverer was justly and liber-

ally remunerated by parliament, and vaccine inoculation has passed with rapid progress over every quarter of the world, from the arctic circles to the extremes of Asia and Africa, and been adopted by civilized and uncivilized nations, by blacks as well as by whites, by the Fin, the Hottentot, and the Hindoo.*

[The exemption from smallpox, enjoyed by individuals who contract pustules or sores on their fingers and hands by milking cows which have a certain disease on their udders and teats, is a fact that has been more extensively known from time immemorial, than the foregoing observations would lead us to suppose. Not only has evidence been adduced, satisfactorily proving that such fact was known to farmers and others having the management of cattle in the principal dairy counties of England, but that it had been remarked by the same class of persons in other countries, as the department of the Meurthe in France, various parts of Germany, Norway, and Spain. In Ireland, the disease in the cow is called *shinach*, an expression derived from two Celtic words signifying *udder* and *cow*; and it is hence concluded that a knowledge of the complaint in that animal must have existed there from a period of high antiquity. Some facts, mentioned by Humboldt in his work on New Spain, leave no doubt that the inhabitants of the Andes have long been in possession of the same information as the dairy farmers of England. Another fact, understood by this class of persons, and received by them traditionally, is, that cows which have once had the disease, do not suffer from it a second time. But the most curious circumstance revealed of late years, is the still greater information that was possessed on this subject by the ancient Hindoos; for in the Sanscrit language there is a work, imputed to Havyantori, from which it appears that the Hindoos, at a very remote period, were not only aware of the preservative power of the vaccine matter against the smallpox, but actually practised vaccination. The passage to which a reference is here made is cited in the article *VACCINE*, Dict. des Sciences Méd., where is also quoted a document drawn up by Chaptal, the object of which is to prove that vaccination was suggested in France as early as the year 1781, by M. Rabaut, a Protestant clergyman of Montpellier. The scheme, it is even asserted, was made known by this M.

Britain, respecting the United States of America," by Robert Walsh, Philadelphia, 1819.

It is due to the reputation of Dr. Benjamin Waterhouse, of Boston, to state, that by his zeal and activity the cowpox was first made known among us. Being at that time Professor at Harvard University, Cambridge, he declared his belief in the statements he had received from England. He procured some vaccine virus, and subjected his own son to the test of experiment. Hence Dr. Waterhouse has been styled the *Jenner of the United States*.—(See Thacher's Practice of Physic, second edition, Boston, 1826.) For minute details of the early progress of vaccination in the United States, see the several contributions of Dr. Waterhouse and others to the American periodical publications.—D.

* It deserves to be mentioned as an historical fact, that the blessings of the vaccine disease were promptly realized in North America: soon after the invaluable discovery of vaccination was made abroad, it was adopted by physicians of the United States with the utmost enthusiasm.

In fact, the individual states seemed to vie with each other in their efforts to extend its blessings, and it was promptly communicated by the American government to the Indian tribes. Hence there is little or no ground for the statement of James Moore, in his "History and Practice of Vaccination," that "in the United States the vaccine had to struggle with a long and violent opposition;" an assertion wholly destitute of truth.—See "An Appeal from the Judgment of Great

Rabaut to an English medical gentleman residing in the family of a rich Bristol merchant named Ireland, then at Montpellier, and who promised to communicate the proposal to Dr. Jenner. This seems, however, more like a little national jealousy, than a fair claim to the honour of the discovery; for no evidence is brought forward to prove that the hint was ever really transmitted to Dr. Jenner, and, if it were really thrown out at Montpellier in 1781, it seems to have been thrown away: for, fifteen years afterward, that is to say, in 1796, when Jenner first vaccinated the human subject, it still remained, as far as the French were concerned, in silent oblivion.*]

The disease, in its present state, may be said to embrace the four following varieties:

- | | | |
|---|---------------------------------|---|
| a | Nativa.
Natural cowpox. | Genuine cowpox, as it ordinarily appears on those who accidentally receive it from the affected cow. |
| β | Spuria.
Spurious cowpox. | An ineffective modification of cowpox, or a different but resembling disease, incapable of preserving against smallpox. |
| γ | Inserta.
Inoculated cowpox. | The genuine cowpox, as it appears on inoculation. |
| δ | Degcner.
Degenerated cowpox. | Cowpox degenerated in its specific power of preservation from unknown causes. |

In the NATURAL FORM OF COWPOX, or as immediately received by milking or otherwise handling a diseased animal, the vesicles are more or less numerous, and appear on the hands or such parts as have been in contact with the affected udder; of a bluish or azure teint, whence Hebenstreit's proposal to call the disease *glaucina*: the fluid at first limpid; afterward opaque and purulent; often with enlargement of the axillary glands, and considerable fever.

Most frequently the vesicles make their appearance about the joints or extremities of the fingers; their figure is circular, and there is a slight dip from the circumference to the centre. The fever opens with its usual symptoms of lassitude, pain in the head, limbs, and loins, rigour, vomiting, and a quickened pulse; the head sometimes continues affected after these preparatory signs have gone off, and is even accompanied with delirium. The inflamed and ichorous tubercles, having suppurated, burst in three or four days from distention, and become troublesome sores, healing slowly, and occasionally assuming a phagedenic appearance. The fever in the meanwhile abates, and ceases altogether about the seventh day. The fluid discharged from the ulcers is highly contagious;

* With respect to the Hindoo claim, it should be recollected, that attempts at interpolation and forgery by the Hindoos upon their own authorities and records are not uncommon. Captain Wilford was actually imposed upon by his pundit, respecting a pretended history of Noah and his sons.—See Life of Sir William Jones.—Ed.

and the eyelids, lips, nostrils, or any other part of the body, are sure to become inoculated with it, if scratched or rubbed with the fingers accidentally charged with it.

In the affected cow itself the tubercles are still larger, or rather consist of vesicles, surrounded by a broad and circular erythema: the animal droops considerably and yields but little milk. The ulcers are foul and often obstinate.

In the SPURIOUS COWPOX, or the disease to which cows are subject that bears a near resemblance to the genuine, and is often confounded with it, though destitute of its prophylactic power, the vesicles are less uniformly circular; purulent from the first; without the bluish teint; with little or no central depression. Whether this, in the animal itself, be strictly a variety of a common species, or a distinct species of a common genus, has not been accurately determined. But it is now fully ascertained, that this affection of the cow produces no security by inoculation, and was the cause of much confusion and many failures at first, and possibly may be of some in the present day.

In the INOCULATED COWPOX from genuine virus, the pathognomonic signs are the following:—vesicle single, confined to the puncture; cellulose; bluish-brown in the middle; fluid clear and colourless to the last; concreting into a hard, dark-coloured scab after the twelfth day.

In propagating the disease from the inoculated vesicle, the fluid should be taken before the ninth day, and from as early a period as it can be obtained. After the ninth day it is usually so inactive as not to be depended upon.

If the fluid be not transparent, it forms a decisive proof, either that it is spurious or imperfect. The puncture should be made as superficially as possible; for if much blood be drawn, the fluid may become so diluted as to be rendered ineffective, or may be entirely washed away.

As smallpox by inoculation is uniformly a far milder disease, and accompanied with a smaller crop of pustules, than when received naturally, cowpox by inoculation undergoes a like change. There is sometimes a little increased quickness of pulse and constitutional indisposition; and, in very rare instances, a few pustules have been thrown forth around the areola or even on the limbs; but, with these occasional exceptions, the eruption, as already noticed, is confined to the single vesicle produced by the puncture, and there is scarcely any perceptible fever.

The general progress is as follows. The puncture disappears soon after the insertion of the lancet; but, on the third day, a minute inflamed spot becomes visible. This gradually increases in size, hardens, and produces a small circular tumour, slightly elevated above the level of the skin. About the sixth day, the centre of the tumour shows a discoloured speck formed by the secretion of a minute quantity of fluid; the speck augments in size, and becomes a manifest vesicle, which continues to fill and to be distended till the tenth day: at which time it displays in perfection the peculiar features that distinguish it from the inoculated

variola pustule. Its shape is circular, sometimes a little oval; but the margin is always well defined, and never rough or jagged; the centre dips, instead of being polarized, and is less elevated than the circumference.

About the eighth day, when the vesicle is completely formed, the disease exhibits something of a constitutional influence; the armpit is painful, and there is perhaps a slight headache, shivering, lassitude, loss of appetite, and increase of pulse. These may continue in a greater or less degree for one or two days, but always subside spontaneously, without leaving any unpleasant consequence. During the general indisposition the vesicle in the arm becomes surrounded with a circular inflamed halo or areola, about an inch or an inch and a half in diameter, which is the pathognomonic proof of constitutional affection, how slightly soever the internal symptoms may show themselves. After this period, the fluid in the vesicle gradually dries up; the surrounding blush becomes fainter, and, in a day or two, dies away imperceptibly; so that it is seldom to be distinguished beyond the thirteenth day from inoculation. At this time the vesicle hardens into a thick scab of a brown or mahogany colour; and, if not separated antecedently by violence or accident, falls off spontaneously in about a fortnight, leaving the skin beneath perfectly sound and uninjured. The entire progress of the inoculation scarcely opens a door to any medical treatment whatever. No preparatory steps are called for, as in smallpox; and all that can be necessary is a dose or two of some aperient medicine, if the constitutional indisposition should be severe or troublesome.

[Besides the above described circular inflamed areola, as a test of vaccination having extended its effects to the system, another criterion has been suggested by Mr. Bryce; whose experiments prove, that if, during the regular progress of cowpox, a second inoculation be performed a certain number of days after the first, the affection produced by this second inoculation will be accelerated in its progress, so as to arrive at maturity and again fade at nearly the same time as the affection arising from the first inoculation. About the end of the fifth or beginning of the sixth day from the first vaccination, is the period preferred for the experiment. —(*Bryce's Pract. Obs. on the Inoculation of Cowpox*, 2d edit.)]

There is a variety of vaccinia denominated DEGENERATE COWPOX by Sir Gilbert Blane in his evidence upon this subject before the Committee of the House of Commons, of which the following may be regarded as the character. Produced by inoculation; vesicle amorphous or uncertain; fluid often straw-coloured or purulent; areola absent, indistinct, or confused with the vesicle; scab formed prematurely. The cause of this degeneracy has not yet been sufficiently pointed out; but it is now well ascertained, that inoculation from this species will not prevent the smallpox; and hence a variety of mistakes in the early practice before the fact was discovered.

Vaccine virus seems to undergo a spontaneous alteration in a certain period of time, whatever be the caution with which it is preserved; but there are some circumstances that seem to favour this alteration more than others, although we know but little of the nature of these circumstances. Even in passing through the human subject in the form of inoculation, it appears to be modified, and to be rendered milder; for a person immediately inoculated from the infected cow uniformly suffers more than one person inoculated from another. It has been proved, however, that the fluid loses nothing of its specific power after a certain number, and even a long series of transmissions from individual to individual; for cows have been inoculated with it in this state of repeated descent, and have exhibited the disease in all its natural violence. Yet, if the second variety be a modification of this disease, and not a distinct eruption, it bears witness to a change in the qualities of the virus taking place in the animal itself from some undiscovered cause.

It ought also to be stated, that the genuine cowpox itself has not proved a permanent prophylactic in particular habits or idiosyncrasies, of the nature of which, however, we know nothing. But the cases in which it has failed are very few; and, in almost every instance, the smallpox occurring afterward seems to have been changed from its natural course, and rendered milder and of shorter duration; the pustule rarely exceeding the fifth day before it has begun to turn, and the fluid generally passing at once from an ichorous or limpid into a concrete or indurated state, without the intervention of pus. While, therefore, the absolute infallibility of the prophylactic power of cowpox inoculation is no longer to be maintained, enough still remains in support of its pretensions of being one of the most important discoveries in medicine, and one of the greatest blessings that has ever been conferred on mankind; as has been sufficiently proved in an admirable article published by the French Imperial Institute, and drawn up by three of its brightest ornaments, MM. Berthollet, Percy, and Halle, of the date of August 17, 1812.

For the failure of success in many hundreds of instances that have been triumphantly brought forward by its enemies, there is no difficulty in accounting; but there are others which are not to be disposed of in the same manner, and which irrefragably establish its inefficacy from causes that elude all explanation.* It was at one time conjectured by our own National Vaccine Establishment, that many of these cases of failure were to be ascribed to the use of a

* Among the various hypotheses advanced by writers to account for the failure of the prophylactic power of vaccinia, may be mentioned that of Dr. Leo-Wolf, now of New-York: in his work "Ueber die Gefahren der bisher befolgten Maassregeln zur Verbreitung der Kuhpocken-Empfang, Hamburg, 1822," he advances the opinion that the changes produced in the system by *puberty*, destroy in many cases the protective power of *kinepock*.—D.

single puncture alone, in consequence of which two or more punctures were recommended on each arm. This hypothesis, however, seems now to be abandoned; and indeed, after the numerous and cautious experiments upon the subject of inoculation for the smallpox by Camper, which have abundantly shown that a single effective puncture proves as secure, and produces as large a crop of pustules, as any number up to seven, which was the highest he thought worth while to try (*Dissertatio de Emolumentis et optimo Methodo Insitionis Variolarum*, Groning., 1774), it is not a little singular that it should ever have been adopted; and the observation of Professor Thomson is far more worthy of attention. "I have not been able," says he, "to discover, after the most minute attention, that any difference of effect whatever in the modifying power of vaccination has depended upon the skill of the operator, or upon his peculiar mode of performing the operation."—(*Historical Sketch*, &c., p. 398.) The real merits of the case, however, are summed up with great candour and judgment in the following passage of a subsequent report of the public establishment just alluded to. "After every reasonable deduction we are compelled to allow, that too many cases still remain on undeniable proof, to leave any doubt that the pretensions of vaccination to the merit of a perfect and exclusive security in all cases against smallpox were admitted at first rather too unreservedly. Yet the value of this important resource is not disparaged in our judgment; for, after all, these cases bear a very small proportion to the number of those who are effectually protected by it." Eight only are stated by the metropolitan stations, out of nearly 67,000 vaccinated since the establishment of the board; and "we have undoubted proofs, from experience, that, where vaccination has been performed perfectly, smallpox occurring after it is almost universally a safe disease; and, though ushered in by severe symptoms, has hardly ever failed to be cut short, before it had reached that period at which it becomes dangerous to life."—(*Report of April 12, 1821.*)

There was some cause for alarm, however, in the information formerly communicated by Dr. Gregory, physician to the Vaccine Hospital, that the table kept at this establishment manifests that the prevalence of smallpox after vaccination is on the increase. "From this table it appears," says he, "that in the year 1810, the proportion of cases of smallpox succeeding vaccination to the whole number of admissions, was as one in thirty; in 1815 as one in seventeen; in 1819 as one in six; in 1821 as one in four; and during the year 1822, as one in three and a half."—(*Cursory Remarks on Smallpox, as it occurs subsequent to Vaccination*, &c.; *Med.-Chir. Trans.*, vol. xii., part ii.) This is, indeed, a fearful diminution of protective power. But, as I have already noticed the wonderful loss of energy which the genuine virus of the cow undergoes in passing through the human subject in the form of inoculation, even for the first time, it is possible that its increasing inertness

may depend upon the innumerable transmigrations from individual to individual that it has now sustained; and that we ought, at given periods, or after a given number of successive inoculations, to return to the primary fountain for a recruit.

[The hypothesis of a diminution in the energy of vaccine lymph, by its being repeatedly transferred from individual to individual, is entirely destitute of proof. As far as the eye can be trusted, vaccine lymph produces the same sensible effects on the skin, and presents in other respects the same properties at the present day, which it did in 1799 and 1800. "I know, in point of fact," says Dr. Thomson, "that the vaccine virus which has been used at the Royal Public Dispensary here and in other parts of Scotland for a series of eighteen years, still continues to produce in those who are inoculated with it the very same appearances which it produced on the first trials that were made with it, and that these appearances agree exactly with those which have been delineated and described by Dr. Jenner as characteristic of cowpock."—(*On Varioloid*, &c., p. 315.) As an anonymous critical writer well remarks, the supposition of a change in the anti-variolous power of cowpock is inconsistent with the historical facts of the case. It is not the fact that vaccination fails to afford the protection against smallpox which it once did. Vaccination never afforded perfect or absolute immunity from smallpox contagion; and it furnishes at the present moment as much security as it ever did. Its influence was indeed exaggerated, and it was supposed to be an absolute preventive of smallpox, because persons who had undergone vaccination were found insusceptible of the inoculated smallpox. At the era of the introduction of vaccination, it so happened, that no great smallpox epidemic existed, and there was consequently little or no atmospheric contagion to communicate the disease in the most effective mode. As soon, however, as the variolous contagion began to prevail epidemically, it was found, not that vaccination had lost its power, but that it never possessed more than a relative influence over smallpox. The correctness of this conclusion, it is argued, appears not only from the results of the experiments performed by Dr. Woodville in the Smallpox Hospital of London in 1799, but from the phenomena of the epidemic of 1816, 1817, and 1818, in various parts of the country, and even in several countries of Europe. It was then observed, that the persons who had undergone vaccination at the time when the practice was first introduced, and who consequently had been vaccinated with lymph which, according to the hypothesis of deterioration, must have been in its original purity and strength, were not less liable to smallpox, and suffered the disease with no less severity, than those who had been vaccinated only a few months before, and at all intermediate periods. Dr. Thomson has seen several instances, and heard of others, in which the varioloid disease, during its prevalence in Scotland, had attacked individuals who had been inoculated at an early period of the practice with vaccine matter ob-

tained from the most authentic sources. On the whole, the conclusion is unavoidable, that unless it could be shown that the occurrence of smallpox in the persons of the vaccinated was confined exclusively to those who had been subjected to this process within the last few years, the hypothesis of deterioration in the lymph, and change in its properties, must be rejected. —(*Edin. Med. and Surg. Journ.*, No. lxxxix., p. 391, et seq.)

With respect to Dr. Gregory's report, it merits particular notice, that it does not pretend to give an account of the average number of cases of smallpox after vaccination in society at large, but only the proportion of such cases in the total number of admissions into the Smallpox Hospital. The proportion might, therefore, partly depend upon what cases were fortunate enough to be admitted; and, if all that applied were received, the increasing number of examples of smallpox, after real or presumed vaccination, only proves that such cases are becoming more common. As a material deduction also from the alarming tenour of this report, it is to be recollected, that the circumstances taken as a criterion of the parties having undergone vaccination, are not such as a cautious reasoner would consider by any means conclusive. "All cases," says Dr. Gregory, "are here entered as having undergone vaccination, where the cicatrices were apparent, or (if that criterion were wanting) where the patient had a distinct recollection of the arm having risen, and of the general progress of the disease."—(See *Med. Chir. Trans.*, vol. xiii., p. 325.) Neither the scar, the patient's own recollection and judgment of the progress of the disease, nor even those of his friends, for vaccination is generally done upon infants, can be entitled to absolute confidence. The editor of this work has had occasion to see two supposed examples of smallpox after vaccination; but, when the history of the cases was inquired into, the only inference that could be depended upon was, that the parties had been inoculated in their infancy with supposed vaccine lymph; but no particulars of what followed the inoculation could be obtained from the surgeons who performed the operation, and saw the progress of the vesicles. As for the value of unprofessional evidence on such points, and of a conclusion drawn from the look of the cicatrix, which may follow any festering sore or slough consequent on a puncture, it is not what ought to be rated too high. In short, nothing can be implicitly depended upon but the history and all the particulars of the alleged vaccination, delivered by a well-informed medical practitioner.]

The only case that has ever occurred to myself in which vaccination has not seemed to produce any influence whatever upon the character of subsequent smallpox, is one I was attending while writing the first edition of this work. The patient was Mr. Alfred Phillips, of Christ's College, Cambridge, about twenty years of age, who had been vaccinated when an infant by Dr. Jenner. The eruption was of the distinct variety, but, for this variety, as full as

possible over the whole of the face, body, and limbs; the fever had been very considerable, and every part was severely hot, sore, and tumefied, so that the eyes were nearly closed, and always opened with difficulty in the morning; and the spaces between the pustules, which, however, were few and small, were of a fiery red. The pimples made their appearance on the third day from the accession of the fever; they ripened regularly, and were, on the eighth day of the eruption, very large, and a few of them just beginning to turn brown on the apex, so that it is not necessary to follow up the description any further. [The editor has seen two cases in which smallpox was exceedingly severe after presumed vaccination, and not at all modified by the influence of the effects of the latter disease on the system.]

It is possible that there are other animal poisons which may in like manner act as a prophylactic against smallpox, and destroy the susceptibility to this disease in the human frame; for the same effect seems to have followed from inoculation with the sanious discharge from the heels of horses afflicted with the disease called *grease*. And Dr. Jenner, who, on his first directing his attention to the nature and effects of cowpox, applied himself also to this subject (*Inquiry into the Causes and Effects of the Variola Vaccinae*, pp. 27, 37), felt persuaded, at that period, that the two fluids of cowpox and of grease from the heel of a horse are precisely the same, and capable of affording a like emancipation. He conceived the sanious fluid of the grease to be the original disease, and the cowpox in the cow itself to be nothing more than a casual inoculation, produced by the cow's lying down in a meadow where the affected horse had been previously feeding, and her udder coming in contact with the discharge which had dripped on the grass and lodged there: and he endeavoured to show the identity of the fluids by the identity of their effects in respect of the smallpox. So far as can be judged from the few cases before us, performed, indeed, in different countries, but still few in respect to the number necessary to establish a positive proof, greasepox seems to have succeeded as well as cowpox; and hence blacksmiths and farriers who have been infected by the grease, have been for ages considered as generally unsusceptible of variolous contagion; and it is possible, therefore, that there may be, as already observed, other animal poisons possessed of a similar power. But it is not necessary to search for them; none can surpass and none be expected to equal the cowpox process in respect to cleanliness, simplicity, and little disturbance to the system; while, on the contrary, the mere idea of using the matter of grease from the horse's heel, excited from the first so deep and extensive a disgust, that cowpox inoculation had nearly fallen a sacrifice, from the supposed union of the two diseases. It was fortunate, therefore, for Dr. Jenner, and the triumph of his discovery, that a minute attention to the subject gave sufficient proof that there was no foundation for his opinion; and that, whatever be the pro-

phylactic power of the matter of the disease called grease, this disease is by no means the origin of the natural cowpox, and has no connexion with it.

[To the foregoing account the editor subjoins a summary of certain important inferences, deduced from the researches of Dr. Thomson, Mr. Cross, Dr. Stoker, Dr. Barnes, and others, as laid down by the anonymous critic already quoted.—(*Edin. Med. Journ.*, No. lxxxix.)

1st. Though the action of cowpox on the human body renders it very nearly, if not altogether, unsusceptible of inoculated smallpox, it does not extinguish its susceptibility of smallpox through the medium of atmospheric contagion, particularly when the disease prevails extensively as an epidemic.

2dly. The action of cowpox diminishes this susceptibility very considerably, and (mostly) renders the action of smallpox on the human body, when it takes place, much less severe; changing very completely the character of the disease, and depriving it of its usual malignity.—(*Thomson*, p. 87.)

3dly. One attack of smallpox diminishes, but does not extinguish, the susceptibility to a second attack in the same individual. This second attack may appear either in the form of regular smallpox, or in the anomalous or spurious forms to which the names of chickenpox, sheepox, swinepox, silquosepox, bladderpox, &c., have been applied. In general, if the first attack is regular smallpox, the second is one or other of the irregular forms, and *vice versa*. Early life predisposes to these attacks.

4thly. The full and complete action of cowpox diminishes the susceptibility to smallpox, and, in the majority of cases, modifies its action in a much greater degree than a previous attack of smallpox itself does. No facts warrant the conclusion, that this modifying or controlling influence of the vaccine action is altered by the interval of time from the date of vaccination.—(*Thomson*, p. 34.)*

5thly. While the practice of inoculating smallpox continues, it is injurious in perpetuating and disseminating the infection of a dangerous, severe, and not unfrequently a fatal disease.

6thly. The substitution of cowpox, by diminishing the extent of the operation of this infection, tends indirectly to diminish the disease generated by it, and the evils resulting from it.†]

* Some doubts on this subject are entertained by some respectable American practitioners, and hence they recommend vaccination after a certain period; but those who have had the best practical opportunities for studying this disease, are of opinion that vaccination, *when properly performed*, requires not to be repeated.—D.

† By many persons cowpox is believed to be nothing more than a modification of smallpox, which is a disease that will certainly affect the cow. Clothes have been taken from patients labouring under smallpox and laid on cows, and they have had the disease called cowpox. If, then, vaccinia be really smallpox modified, we can not wonder, as Dr. Elliotson has observed, that it

SPECIES IV.

EMPHLYSIS VARICELLA.

WATERPOX.*

VESICLES SCATTERED OVER THE BODY; GLABROUS; TRANSPARENT; PEA-SIZED; IN SUCCESSIVE CROPS WITH RED MARGINS; PELLICLE THIN; ABOUT THE THIRD DAY FROM THEIR APPEARANCE BURSTING AT THE TIP, AND CONCRETING INTO SMALL PUCKERED SCABS, RARELY LEAVING A CICATRIX.

THE waterpox appears under the four following varieties, distinguished chiefly by the shape of the pimple:—

- | | |
|---|---|
| <p><i>a</i> Lentiformis.
Chickenpox.</p> | <p>Vesicles lentil-shaped, or irregularly circular, flattened at the top; fluid at first pellucid, then whitish; afterward straw-coloured.</p> |
| <p><i>β</i> Coniformis.
Swinepox.</p> | <p>Vesicles acuminate; fluid pellucid throughout.</p> |
| <p><i>γ</i> Globularis.
Hives.</p> | <p>Vesicles globular and larger; fluid at first whey-coloured, afterward yellowish.</p> |
| <p><i>δ</i> Corymbosa.
Clustering waterpox.</p> | <p>Vesicles clustering upon a common, but broader base; redder at the first, and later in appearance; febrile symptoms outlasting the eruption.</p> |

Several of the varieties are sometimes intermixed, and the fluid, about three days after the eruption, occasionally becomes thickish as well as yellowish in the first and third, and possesses a purulent appearance (*Frank, De Hom. Morb.*, tom. ii., p. 170); whence, in various instances, they have been mistaken for smallpox. The eruptive fever in chickenpox is also sometimes considerable; and hence another cause of the same mistake, a mistake that has not unfrequently led to serious and even fatal consequences, by putting those who have had the disease off their guard against variolous infection. And where this error has been committed, and the smallpox has afterward been received, it has led to a second mistake, by inducing the patient to believe that he has had the smallpox a second time.

The two diseases, indeed, were long confounded by physicians of the highest character: they were regarded alike by Morton; and even in Sauvages, varicella is described under the name of *variola lymphatica*.† This, however, is a subject we shall further examine into under

should generally afford immunity from the latter disease to those who have once had it. The cowpox, however, is far milder than smallpox, and strictly a contagious disease, not, like the latter, infectious.—See Dr. Elliotson's Lect. at Lond. Univ., as published in *Med. Gaz.*, vol. xi., p. 305.—Ed.

* Little Smallpox.

† See upon this subject the remarks under *Empyis Variola*, or Smallpox, Gen. III., Spec. 1, of the present Class and Order.

SMALLPOX.* Suffice it for the present to observe, that varicella is *adequately* ascertained to originate from a peculiar specific contagion; and the characters by which it is sufficiently distinguished from smallpox are, that its fluid, except in a few anomalous cases, is limpid throughout; the disease, in short, is vesicular; and that, as early as the third or fourth day from the eruption, it concretes into crusts, which are thrown off without indenting the cutis;† while, in smallpox, the fluid consists of pus as soon as formed, and does not concreate into crusts till the seventh day, and often much later. Like the smallpox, it does not attack the same person a second time, excepting in a few anomalous constitutions, that establish rather than oppose the general rule. “I wetted a thread,” says Dr. Heberden, “in the most concreted pus-like liquor of the chickenpox which I could find, and, after making a slight incision, it was confined upon the arm of one who had formerly had it: the little wound healed up immediately, and showed no signs of any infection.”—(*Medical Transactions*, vol. i., art. xvii.)

In the ordinary course of the first three varieties, the pyretic symptoms are so slight as not to require medical attention; and sometimes there is no fever whatever. The eruption makes its appearance chiefly on the back, and is often confined to it; and the number of vesicles varies from 20 to 200. I have sometimes, however, known the eruption preceded by almost as severe febrile signs of shivering, sickness, headache, and pain in the limbs, as that of smallpox, but the symptoms have always subsided when the vesicles have appeared.

In this case an active purge should be administered, succeeded by some diluting drink; and the patient should be confined to a quiet, spacious, and well-ventilated room, with a cool dress, till the febrile symptoms have left him.

For the fourth variety I am entirely indebted to the observant and indefatigable eye of Dr. Heberden; for it has never occurred to me, nor is it to be found in the table of the Nosologists. “This disorder,” says he, “is preceded for three or four days by all the symptoms which forerun the chickenpox, but in a much higher degree. On the fourth or fifth day the eruption appears, with very little abatement of the fever; the pain likewise of the limbs and back still continues, to which are joined pains of the gums. The pocks are redder than the chickenpox, and spread wider, and hardly rise so high, at least not in proportion to their size. Instead

of the little head or vesicle of the serous matter, these have from four to ten or twelve. They go off just like the chickenpox, and are distinguished from the smallpox by the same marks; besides which, the continuance of the pains and fever after the eruption, and the degree of both these, though there be not above twenty pocks, are, as far as I have seen, what never happen in the smallpox.”—(*Med. Trans.*, ut suprà.)

SPECIES V.

EMPHLYSIS PEMPHIGUS.

VESICULAR, OR BLADDERY FEVER.

VESICLES SCATTERED OVER THE BODY; TRANSPARENT; FILBERT-SIZED; WITH A RED INFLAMED EDGE, BUT WITHOUT SURROUNDING BLUSH OR TUMEFACTION; ON BREAKING DISPOSED TO ULCERATE; FLUID PELLUCID, OR SLIGHTLY COLOURED; FEVER A TYPHUS.

THE term *pemphigus* is derived from the Greek *πέμφιξ*, “flatus, bulla,” and hence *inflation*, bladder, bubble. The idea of flatulence, however, is seldom connected with this disease in modern medicine, though very generally in ancient. The term, in the sense in which it is now commonly understood, was perhaps first employed by Sauvages, and has since passed into common use. It is still doubted by many, whether pemphigus is entitled to be considered as a distinct and idiopathic disease; and whether all its varieties and modifications may not resolve themselves into certain peculiarities of erysipelas or pompholyx, the latter of which consists of similar vesicles, or bullæ, without fever; or into mere symptoms of typhus or plague. Gulbrand appears to have been of the former opinion; and hence he has denominated the disease *erysipelas vesiculare* (*Act. Soc. Med. Hafn.*, tom. i.): Dr. Cullen seems to have been of the latter at the time of drawing up his definition, and still later, at that of drawing up his First Lines, in consequence of which he dismisses it, in a single paragraph, as an affection concerning which he can say nothing. But the fourth edition of his Synopsis contains a subjoined note, which intimates that his opinion was altered in consequence of having seen a patient shown him by Dr. Home, and who was labouring under this disease, as an idiopathic affection, at the time. And when to this we add the authority, not merely of the earlier writers, Bontius, Seliger, and Langhans, but of Frank, Withers, Clarkson, Christie, Ring, Braune, and Dr. Stewart of Aberdeen, it would be unpardonable not to allow it a distinct place in a general system of nosology.*

* Gen. III., Spe. 1, of the present Order, Empy-
esis Variola. With regard to the question, whether varicella is only a mild and modified form of smallpox, Dr. Elliotson thinks that we are not in possession of all the information required to enable us to deliver a positive opinion.—Ed.

† After this disease Dr. Elliotson has frequently seen *ecthyma*, and *rupia*, and pitting take place, in the same manner as after smallpox. He had the smallpox himself, and was not pitted at all; but the chickenpox came afterward, and left several pits.—See Lect. at Lond. Univ., as published in *Med. Gaz.*, vol. ii., v. 308.—Ed.

* Pemphigus may make its appearance as an idiopathic disease, or as sympathetic of some visceral inflammation; or its bullæ may occur during the course of other diseases, more especially those of the skin, principally erysipelas, herpes, prurigo, scabies, and varicella. It is asserted by some writers, that the bullæ of pemphigus are occasionally found on the mucous membrane of the stomach and intestines. Rayer admits the occasional existence of bullæ on the mucous mem-

Upon a careful review it appears to offer the three following varieties, which run parallel with those of Dr. Willan, though not exactly taken from him :—

- a* Vulgaris. Vesicles appearing on the second or third day, occasionally not till the fifth or sixth; in successive crops: often extending over the mouth and intestinal canal; fluid, on bursting, yellowish; some of the vesicles livid, with a livid base.
- β* Glandularis. Preceded by tumefaction of the neck and throat; vesicles chiefly seated on the fauces and conglobate glands; occasionally producing abscesses; highly contagious.
- γ* Infantum. Vesicles irregularly oblong, with livid edges and commonly flattened tops; appearing successively on different parts of the surface of infants a few days after birth; on breaking, purplish.

We shall have occasion to observe, under *VARIOLA*, that Frank, who made a different division of pemphigus, undertook to include under it varicella, crystalline, and hornpox, and many of the forms of disease which have been denominated spurious smallpox.

The *FIRST VARIETY*, or common pemphigus, is the *pemphigus major* of Sauvages, a very marked case of which is given in a communication of Dr. David Stewart to Dr. Duncan of Edinburgh.—(*Edin. Med. Comment.*, vol. vi., p. 79.) It appeared on a young private of the seventy-third regiment, who had for a fortnight or three weeks antecedently been unwell from a sudden retrocession of measles, produced by an exposure to cold, and afterward to a damp unventilated apartment. He was received into the hospital at Aberdeen April 15, at which time he complained of headache, sickness, oppression about the præcordia, thirst, sore throat, difficulty of swallowing; his tongue was foul, his skin hot, pulse from 110 to 120, rather depressed. The whole surface was interspersed with vesicles of the size of an ordinary walnut; especially the breast and arms. In the interstices, the appearance of the skin was natural; and the distance from one vesicle to another was from half an inch to a hand's breadth or more. The disease did not seem to be contagious, as the patient was a solitary instance of it, both where he resided before and

after his reception into the hospital. His chief medical treatment consisted in bark and port wine, with acidulated drinks; many of the vesicles broke, and discharged a bloody and most offensive ichor; the cutis, upon a rupture of the vesicles, was for the most part sound, of a deep-red hue, and in some places livid. A new cuticle was gradually produced: and on April 27, being twelve days from his reception into the hospital, he was dismissed perfectly cured.

In this case the bullæ do not seem to have reached below the throat in an internal direction, nor lower than this region in the severer case described by Seliger. In the first instance the vesicles appeared abruptly, and had burst and were healed in seven or eight days. In Seliger's case they issued more gradually, and in successive crops, ran through a longer period, and were not healed till the twenty-first day.—(*Ephem. Act. Nat. Cur.*, dec. i., ann. viii., obs. 56.) Dr. Frank gives a case of a like kind, that continued to migrate over different parts of the body for sixteen days, accompanied with difficulty of breathing, subsultus, and pain at first in the region of the liver, but afterward in the chest, assuming the guise of peripneumony.—(*De Cur. Hom. Morb. Epit.*, tom. iii., p. 266.) In a case apparently of the same kind, published by Dr. Dickson, there is evident proof of the disease having extended from the fauces throughout a considerable part of the alimentary canal: here also the vesicles appeared in successive crops, especially on the ninth, tenth, and thirteenth days, each crop continuing four or five days before it burst; the fever was accompanied with delirium, but abated on the fifteenth day on the appearance of the catamenia, and the bullæ healed in succession without any trouble.—(*Trans. of Royal Irish Acad.*, vol. i., 1787.) None of these appear to have been contagious.*

I cannot speak of pemphigus from personal knowledge; but in all the above instances, the fever was of a low or typhous type; and the disease seems to have approached the nature of erysipelas, and was treated successfully by the means usually employed for the latter.†

For what little knowledge we possess of the *SECOND OR GLANDULAR VARIETY*, the contagious pemphigus of Dr. Willan, we are chiefly indebted to Dr. Langhans, a Swiss physician, who observed it in the spring and through the summer of 1752, in the lowlands of his own

* In the abdominal viscera, the changes most frequently observed in fatal cases of pemphigus are redness, softening, and ulcerations; the ordinary effects of gastro-enteritis.—Dr. Corrigan, *op. cit.*

† According to Dr. Corrigan, the fever which sometimes precedes or accompanies the bullæ of pemphigus, makes no approach to the regularity of the fevers of measles or scarlatina; but is, on the contrary, very irregular in its nature and duration. It may be a short inflammatory fever, or of a low typhoid type, or it may assume the characters of an intermittent. The period of the fever, when the eruption occurs, seems also to be equally uncertain.—See *Cyclop. of Pract. Med.*, art. *PEMPFIGUS*.—ED.

brane of the mouth, but denies their existence in the stomach and intestines. The case recorded by Dr. Dickson disagrees with Rayer's view, though it was certainly unconfirmed by any post-mortem examination, the patient having recovered.—Dr. Corrigan in *Cyclop. of Pract. Med.*, art. *PEMPFIGUS*.—ED.

country.—(*Act. Helvet.*, tom. ii., p. 260.) It commenced with a sense of tension in the fauces, and a slight pain spreading behind the ears to the anterior part of the thorax, accompanied with the symptoms that mark the first stage of fever, but not succeeded by a hot fit. A greenish bilious matter was sometimes thrown up from the stomach, and the pulse was feeble. The neck swelled externally and internally about the fauces, bullæ were observed of the size of a filbert, producing little pain, and containing a yellow ichor of an offensive smell. Soon afterward similar vesicles were found scattered sparingly over the body and limbs, which, if not broken or opened, collapsed on the second, third, or fourth day, and dwindled into whitish crusts. During this period the tumour of the neck often suppurated, or other suppurating tumours formed in some of the conglobate or conglomerate glands, as the parotid, axillary, or inguinal; and the virus of the disease being thus discharged by different outlets on the surface of the body, the patient recovered. But if, before this translation to the surface, there were a sense of weight and anxiety about the thorax, a large abscess was formed internally, and on its bursting the patient died from suffocation. Or, if the matter lodged in the external vesicles were by accident repelled before any glandular supuration took place, he died almost as suddenly.

M. Langhans compares this disease to syphilis, but apparently with little reason; and Dr. Cullen and Dr. Frank, with not much more, to *rosalia paristhmica*. The cause, like that of the sweating sickness, is altogether unknown, and like this disease also, after having ravaged with great fatality for a certain but a shorter period of time, happily for Switzerland, and perhaps for all Europe, it vanished, and has been heard of no more. Sauvages, indeed, quotes a description of pemphigus from Thiery, which, by some writers, has been supposed to be the same; but the account is so brief, and at the same time so loose and indistinct, that it is impossible either to arrange or reason about it.

The glandular pemphigus of Switzerland, according to M. Langhans, was both contagious and epidemic; so contagious, indeed, as to spread through numerous families with great rapidity, and so malignant, that all persons affected by it died. This last assertion, however, compared with what follows, appears to be a little overcharged; for the author proceeds, as already observed, to point out under what circumstances patients recovered from it; and lays down a remedial process, which, "though at first," says he, "I employed it with anxiety and hesitation, I can now with pleasure recommend to all persons labouring under the complaint, with the most sanguine hope that it will effect a speedy cure."

This successful practice, as in the sweating sickness, consisted in exciting a strong determination to the surface by active sudorifics; and at the same time supporting the strength with camphire and other cardiaca. He commenced his process, however, by venesection, which was sometimes repeated, and where there

was danger of an abscess in the lungs, unquestionably with great judgment.

The INFANTILE PEMPHIGUS* appears, as already noticed, most commonly a few days after birth; but in one case adverted to by Dr. Willan, as late as ten months after this period. The vesicles show themselves on the neck, upper part of the breast, abdomen, groin, scrotum, and inner parts of the thighs. They arise successively, break, and expose a surface that heals with difficulty, and more generally enlarges its boundary, and wears out the little patient with pain, restlessness, and want of sleep. Warm cordials, as camphire and the aromatic confection, with a little port wine negus, form the best means of supporting the strength; and laudanum must be had recourse to where the want of sleep requires it.

SPECIES VI.

EMPHLYSIS ERYSIPELAS.

ST. ANTHONY'S FIRE.

VESICATION DIFFUSE; IRREGULARLY CIRCUMSCRIBED; APPEARING IN A PARTICULAR PART OF THE BODY, CHIEFLY THE FACE, ABOUT THE THIRD DAY; WITH TUMEFACATION, AND ERYTHEMATIC BLUSH: FEVER USUALLY ACCOMPANIED WITH SLEEPINESS, OFTEN WITH DELIRIUM.

In describing the genus erythema, I endeavoured to point out a distinctive line between that inflammation and erysipelas, which are so often intermixed and confounded even by good writers; and observed that the first bears the same analogy to phlegmon as the last to smallpox. Phlegmon is local inflammation tending to supuration; erythema local inflammation tending to vesication: smallpox is an idiopathic fever producing a phlegmonous efflorescence; erysipelas an idiopathic fever producing an erythematic efflorescence. Smallpox is always contagious: erysipelas occasionally so: phlegmon and erythema have no such tendency.

[The plan of classing erysipelas with the exanthemata does not receive the universal sanction of medical writers. In particular, Mr. Lawrence does not concur in its propriety. "If we were," says he, "to construct a natural arrangement of diseases, we should, perhaps, find sufficient reason for separating erysipelatous affections altogether from the febrile exanthemata. The latter form a natural order, well characterized by the fever preceding the local disease, by their origin from a single specific cause, namely, contagion, by their regular periods of efflorescence and decline, their definite duration, and by their generally affecting an individual only once in his life. Erysipelas (here, it is to be observed, Mr. Lawrence uses the term in the sense of the author's erythema) arises from various causes, among which it is doubtful whether contagion is to be included; it is often

* Sometimes named *gangrenous pemphigus*; it is the *rupia escharotica* of Bateman and Bielt. Dr. Corrigan describes, under the name of *chronic pemphigus*, what Bateman calls *pompholyx diutinus*, and Aibert darte *phlyctenoides confluyente*.—Ed.

not preceded by fever; its course is various and uncertain, its duration indefinite, and it attacks the same individual repeatedly.”—(*Med. Chir. Trans.*, vol. xiv., p. 34.) Now, although the erysipelas of Dr. Good is, in imitation of Cullen, restricted to the febrile disorder that is followed by erythema, or erysipelatous inflammation, as an effect, it must be admitted that it wants many of the striking features pointed out by Mr. Lawrence as characterizing exanthemata in general. At the same time, the distinction of erysipelas as a fever leading to erythema, or erysipelatous inflammation, as a regular event, ought undoubtedly to be discriminated from other cases, in which the local affection comes on first, and whatever disturbance of the system ensues is merely the effect of it.]

The varieties of this species are very differently given by different writers; by many of whom they are multiplied most unnecessarily. Dr. Cullen makes even the *herpes Zoster*, or shingles, a variety: but this is strangely to confuse simple cutaneous diseases with idiopathic fevers. For that erysipelas, when genuine, is an idiopathic fever, dependant upon or productive of a specific virus, is clear, because it has often, though not generally, been found contagious, and is capable of propagation by inoculation. “When the acrimonious lymph,” observes Dr. Willan, “contained in the phlyctenæ or vesications of a genuine erysipelas is inoculated or casually applied to that of the disease from which the virus was derived.”—(*On Cutaneous Diseases*, p. 514.) And he has added a case, in which the mother of a young girl, severely affected with this disease, appears to have received it in consequence of having nursed her.

Dr. Wells has strengthened the doctrine of its contagious property by a variety of facts and cases, that can scarcely, I should think, be read by any one without conviction.—(*Trans. of a Soc. for the Impr. of Med. and Chir. Knowledge*, vol. ii., p. 213.) One of his examples extends to four individuals, who received the disease in succession, after direct contact or near approximation with each other; and another gives us a like chain of not less than six in descent, all of whom, indeed, he did not attend personally, but the history of whom, as communicated to him by one of the affected, was confirmed by Dr. Pitcairn, who had been consulted by two of the rest, and was privy to the general fact. Dr. Pitcairn also communicated to Dr. Wells the following highly important statement in addition:—“A lady, immediately after delivery, was attacked with a fever, which was accompanied with an affection of her skin somewhat like erysipelas; her child, about three days after its birth, was seized with that species of erysipelas the French call *la gelure*, which first appeared about the pudenda, and afterward extended itself to other parts of the body, among the rest to the face. Both the lady and her child died, after a few days’ illness; and about

eight days after the death of the child, the lady’s mother and servant-maid, both of whom had attended it during its illness, were attacked with erysipelas of the face, from which both of them recovered.” The opinion of Dr. Baillie, as communicated to Dr. Wells on another occasion, is to the same effect; to which Dr. Baillie seems to have been more especially led, by having observed in “a part of the years 1795 and 1796, that the erysipelas of the face was much more frequent in St. George’s Hospital than he had ever before known it to be: that many persons were attacked after they came into the hospital, and that the number in a particular ward was much greater than in any other.”*

This last remark seems to give some countenance to the further opinion that erysipelas becomes occasionally an epidemic, or operates through the medium of the atmosphere, as well as by direct contact; though, whether the atmosphere, in this case, be impregnated with the specific miasm of the disease, or merely predisposes the body to a more ready generation of it, has no more been determined than in the case of various other exanthems that evince a like power. Dr. Parr asserts broadly, “we have four times seen it epidemic; and more than once we have had reason to suspect that it was communicated by infection.”†

At first sight it might seem easy from these accounts to subdivide erysipelas into the two varieties of contagious and unctagious; but,

* See also “Cases illustrating the Contagious Nature of Erysipelas, and its connexion with a severe Affection of the Throat,” by J. Stevenson, M. D., in *Edin. Med. Chir. Trans.*, vol. ii.

† Dict. in verbo. The doctrine of erysipelas being contagious is much more doubted at the present day than that of its being sometimes epidemic, and prevailing extensively in particular situations, seasons, and states of the atmosphere. Some of the cases published by Dr. Stevenson, of Arbroath, to illustrate the contagious nature of erysipelas (see *Edin. Med. Chir. Trans.*, vol. ii., p. 128, et seq.), appear to the editor to be only an epidemic form of sore throat, sometimes involving the larynx, as described by Bretonneau, and noticed in this work, under the head of bronchlemmitis. The possibility of any textures, except those of the integuments, being truly the seat of erysipelatous inflammation, is doubted by Mr. Lawrence. The editor, however, will not venture to deny Mr. Hunter’s position, that, when there is a tendency to this form of inflammation in the habit, every inflammation, whether external or internal, may partake of its character in some respects, and be, for instance, more disposed to spread. Mr. Hunter’s opinion, perhaps, has received some support from three cases mentioned to the Medical and Chirurgical Society of Edinburgh, by Dr. Abercrombie, Dr. Hay, and Mr. Bryce, where the inflammation appeared to have spread from the fauces to the external surface, the part of the skin first affected having been, in the first two cases, at the orifice of the nostrils, and, in the last, at one of the lachrymal ducts.—(See *Edin. Med. Chir. Trans.*, vol. ii., p. 135.) The facts published by Dr. Wells, and some others by Mr. Bury, of Farnham (*Med. Gaz.*, July, 1833), are among the strongest adduced in support of the occasionally contagious nature of erysipelas.—Ed.

as it is most probable that the power of communication depends alone upon the peculiar diathesis of the person who receives it, as being endowed with a susceptibility of the disease not possessed by others, we can make nothing of this discrepancy : and shall hence examine it under the following varieties, founded upon other circumstances :—

- a **Locale.** Limited to a particular part ;
Local erysip- cuticle raised into numerous
elas. aggregate distinct cells ; or
the cells running into one or
more blebs or large blisters.
- β **Erraticum.** Travelling in successive patch-
Erratic erysip- es from part to part : the
elas. earlier patches declining as
new ones make their ap-
pearance.

LOCAL ERYSIPELAS generally exhibits itself on one side of the face, or on one of the limbs. In the former case, the disease begins with coldness and shiverings, which alternate with irregular flashes of heat, and other symptoms of pyrexia. Dull aching pains are felt in the head, neck, and back. The swelling usually appears in the course of the second night or the third day ; though I have sometimes known it take place within a few hours after the attack : the redness disappearing when pressed upon by the finger, but returning as soon as the pressure is removed. The eruption fixes on one side of the nose, or the cheek, temple, or forehead ; is of a dark-red colour, smooth and soft, and attended with a sensation of heat and tingling. The redness and swelling extend gradually over the affected side of the face ; and spread, in some cases, to the scalp, and to the side of the neck, or the upper part of the breast. Hence the face appears much disfigured ; the mouth is drawn to one side ; the eyelids are turgid, and close up the eye ; the fever increases, and is often attended with delirium. On the fourth and fifth day vesications arise on different parts of the diseased surface, especially about the centre ; but with an increase rather than a diminution of the fever. The vesicles or bullæ are of different sizes, and have an irregular base. The fluid contained in them is at first clear and watery ; it afterward becomes straw-coloured or opaque, occasionally slightly livid, without losing its transparency. The cuticle gives way in a few places, and the fluid oozes through the cracks. About the eighth or ninth day, and sometimes sooner, the redness changes to a brown or yellowish hue, the bullæ subside, and the cuticle dries and desquamates, or scales off. Occasionally, both sides of the face are affected at the same time ; but sometimes the morbid half is separated from the sound by an exact line drawn across the forehead, down the middle of the nose to the chin. The fever subsides about the eighth or ninth day, but sometimes after its cessation it returns suddenly with as much violence as at first, and continues two or three days longer. A sanious fluid, approaching the nature of pus, is sometimes found in parts of the vesication : and from this circumstance

Dr. Cullen has distinguished one variety of the disease by the name of *erysipelas phlegmonodes* : and has been copied by Dr. Willan. "A circumscribed cavity," says Mr. Pearson, "containing laudable pus, is never seen in the legitimate erysipelas.* Where a purulent effusion happens in any considerable degree, it affords, when the part is examined, a sensation similar to that excited by a quagmire or morass. In that sort of suppuration which sometimes supervenes to erysipelas, the cellular membrane suffers great injury, and not uncommonly the part is in a gangrenous condition."—(*Principles of Surgery*, § 289.)

When the head is the seat of disease it occasionally swells to an enormous magnitude, and when the case is attended with delirium, it sometimes proves fatal. [Often, particularly when the head is the seat of erysipelas (says Mr. Lawrence), the sensorium is principally affected, and there is pain and oppression of the head, sleepiness, coma, or delirium. The tongue in such cases becomes dry and brown ; but this is frequently owing principally to the circumstance of the patient breathing entirely through the mouth ; the pulse is rapid and feeble, and there is great loss of muscular strength ; in short, the symptoms at length are those called typhoid. In other cases, the circulation and the nervous system are not much affected ; but there are many indications of disordered stomach and bowels, to which the origin of the local affection must be ascribed. But, as the same gentleman has remarked, the local symptoms are preceded and accompanied by fever, which always varies in its character, according to the constitution, age, and general state of health. In the young, strong, and those of full habit, it is decidedly of an inflammatory character ; and blood drawn from a vein exhibits the buffy coat in a greater or less degree. In phlegmonous erysipelas, the general and local symptoms are more violent than in simple erysipelas ; the redness is deeper, and the tumefaction more considerable ; the whole depth of the adipose and cellular textures being loaded with effusion, so that an arm or leg appears of twice the natural size.—(*Lawrence, in Med. Chirug. Trans.*, vol. xiv., pp. 6-9.) As this form of the complaint frequently does not vesicate, and often arises from local injuries,

* The opinion that true pus is never formed in phlegmonous erysipelas is contradicted by daily experience ; but that the pus is very seldom contained in a circumscribed cavity is a fact particularly noticed by Mr. Hunter. Yet, in phlegmonous erysipelas, as Mr. Lawrence has pointed out, matter is frequently deposited in small separate collections, dispersed irregularly in the cellular texture. While erysipelas is what Mr. Lawrence calls *simple*, that is, confined to the skin, and does not materially affect the subjacent cellular membrane, suppuration does not take place. "It may, however," says Mr. L., "become more severe at one point ; and thus we occasionally see the formation of abscess under the skin towards the decline, or after the appearance, of the general erysipelatoous redness."—*Med. Chir. Trans.*, vol. xiv., p. 5.—Ed.

perhaps it cannot properly be classed with St. Anthony's fire, or the erysipelas of our author; but rather belongs to his cases of erythema.] The disturbance of the constitution is generally less violent when the erythema appears in the extremities, than when it attacks the head. The limbs most affected are the legs, in which, probably from their depending situation, the vesications fill rapidly, and break within twenty-four hours from their first appearance. Salmouth relates a case in which the intumescence extended over the entire frame (Cent. i., obs. 32): but this is extremely rare, excepting under the second or migratory form, in which it trails over different parts in succession, till the whole body has been affected.

In the ERRATIC VARIETY, the complaint usually, and particularly in adults, begins its attack in the face, and spreads in succession to the extremities, the patch first formed healing as fresh ones appear below. Sometimes, however, other parts are seized first; and perhaps more frequently so when this variety shows itself in infants; for here the parts about the navel are usually first affected, and the disease winds downward to the sexual organs, which are often very considerably tumefied and inflamed. What, however, is usually denominated the infantile erysipelas, is more commonly a variety of gangrenous erythema, produced, in many instances, by the want of cleanliness, pure air, and nutritive food. The inflammatory blush soon assumes a livid hue, and is sometimes covered with or surrounded by petechiæ: the cuticle is separated to a considerable extent from the cutis, breaks, and exposes a foul and ulcerating surface that almost immediately passes into a state of gangrene. In some instances, nevertheless, these cutaneous efflorescences are probably accompanied with a true erysipelatous fever; for, in lying-in hospitals, the disease is said to have proved occasionally contagious.

The *erysipelas ædematodes* and *e. gangrenosum* of Dr. Willan appear to be misnamed, and consequently misplaced. They are more accurately erythemata, and have already been described under the species *erythema ædematosum* and *e. gangrenosum*.

The usual causes are cold, intemperance, suppressed perspiration, and the other common excitements of fever operating upon an erythematic diathesis, and producing therefore this peculiar efflorescence in connexion with the febrile attack. In almost every instance, there is evidently a diminished vascular action; and hence we meet with the disease far most frequently in persons of delicate habits, women, children, and those who have long resided in warm climates. In one instance, it has occurred to me in a strong hearty man, of plethoric form and sanguineous temperament, well known to the world as a public character; but in this case the diet had, from the patient's boyhood, been exclusively that of vegetables.

[In the preceding paragraph our author is speaking, it is to be remarked, not of the causes of the erysipelatous inflammation, but of the

fever which induces it as a regular effect, and to which he particularly restricts the term erysipelas. In this particular instance, whatever excites the specific fever, whatever state of the constitution imparts to the general disturbance of the system the peculiarity of its being always followed by the erythema, or erysipelatous inflammation of the skin, must be considered as the cause of the disease. This cause we know not, unless it be admitted, which is not commonly believed, that St. Anthony's fire either depends upon contagion, or, as Dr. Good has said, the usual causes of fever operating upon an erythematic diathesis. The inquiry, therefore, if pursued further, would be into the foundation for the doctrine of contagion, and into the circumstances producing an erythematic diathesis, or, in plain language, a disposition to erysipelatous inflammation. It is certain that the fever to which Dr. Good restricts the name erysipelas, is frequently connected with disorder of the liver and stomach.]

It has occasionally happened, and especially where the disease has occurred as an epidemic in some of the high and healthy villages of North Britain, in the heat of a dry summer or autumn, that, instead of diminished vascular action, there has been such a degree of entony and caumatic fever as to call for free venesection from the first, and of this form a few striking examples have been communicated to the author. So, on the contrary, the smallpox and measles, though ordinarily accompanied with cauma, occasionally evince a typhous type, and demand a tonic plan of procedure.

The mode of treatment may be expressed in few words. Venesection was formerly recommended as a part of the ordinary plan, and has been so of late by a few writers. Yet this is to act without discrimination, and to mistake the exception for the general rule. Passing by the modification just adverted to, and those occasional congestions in the larger organs, and especially in the head, which, even in typhus, and still more in such forms of erysipelas, demand a prompt and repeated use of bloodletting, I can conceive very few ordinary cases, in which the lancet has a chance of being serviceable; while the application of leeches always exasperates the efflorescence. As a general plan, we should first cool the body by gentle laxatives, and instantly have recourse to a tonic plan. The bark given largely, as long since warmly and judiciously recommended by Bromfield (*Med. Communications*, ii., 4) and Colly (Id., ii., 3), has rarely failed of success. Dr. Fordyce was in the habit of giving it, in a dangerous state of the disease, in the proportion of a drachm of the powder every hour. He tried it for twenty years, and with growing confidence. Where, however, there is much evening or night exacerbation, it may temporarily be dropped for some warm diaphoretic, as camphire, with small doses of James's powder, or the spirit or compound spirit of sulphuric ether, in saline draughts made with the subcarbonate of ammonia. If the head be much affected, it should be lightly covered with linen wetted

constantly with vinegar and cold water, or equal parts of water and the solution of acetated ammonia: and, if the vesications ooze, they should be frequently dusted with finely-powdered starch, or a powder consisting of half starch and half calamine. The diet should be light and of easy digestion. Opiates have rarely succeeded in procuring sleep; and have generally added to the mental irritation.

[From the foregoing observations it appears, that the author was much under the influence of the doctrine, that the fever, called by him erysipelas, and all kinds of erysipelatous, or, as he terms it, *erythematic* inflammation, are essentially connected with diminished vascular action and debility. Hence his general preference to tonic and stimulating remedies. After what has been explained under the head of *erythema*, in a previous section of this volume, p. 450, et seq., it is unnecessary to insist upon the fact, that the local affection is always of an inflammatory nature; that, abstractedly viewed, it requires antiphlogistic treatment; but that, whether this plan should be adopted or not, must depend upon the stage of the disease, the patient's strength and age, and the type of the fever, whether caumatic or typhoid. Strong, young, and plethoric persons are more frequently attacked with the fever, here implied by *erysipelas*, than our author's remarks would lead us to suppose: and in all such examples, antiphlogistic treatment, including general and local bleeding, purgatives, low diet, &c., is indicated. The application of leeches to erysipelatous parts is found to be perfectly safe. The editor has frequently seen five or six dozen leeches put on the head and face in the course of the first week of the disorder. Nor should free and even repeated venesection be omitted, when the patient is young, strong, or plethoric. An emetic is also frequently of great service in the beginning of the disease, particularly when there is a bitter taste in the mouth, attended with headache and derangement of the stomach.

Emetics must not be employed at random: when the tongue is red, and the thirst excessive, they do harm; when there are no symptoms of disorder of the stomach, they are neither hurtful nor beneficial; but when there is bitterness in the mouth, the tongue has a thick white or yellowish fur upon it, without any subjacent or surrounding redness, and the patient has nausea and eructations, which have the smell of sulphurated hydrogen, emetics are really of great service.—(*Andral, Anat. Pathol.*, tom. ii., p. 224.)]

GENUS III. EMPYESIS.

PUSTULOUS EXANTHEM.

ERUPTION OF PHLEGMONOUS PIMPLES; GRADUALLY FILLING WITH A PURULENT FLUID; AND TERMINATING IN THICK SCABS, FREQUENTLY LEAVING PITS OR SCARS.

EMPYESIS is a term of Hippocrates, and is to be found in the fifth book of his Aphorisms.

It is derived from the Greek *ἐμπύω*, or *ἐμπύειν*, "suppuro." The Greek writers also use, and perhaps more generally, *επύσις*, from *ἐκπύω*, of similar meaning. The same distinction between the terms is made in the present system, as between *emphylis* and *ecphylis*: the former being limited to signify pustular eruptions produced by internal and febrile affection, and the latter to signify those that are merely cutaneous or superficial, or with which internal affection is not necessarily associated.

The genus EMPYESIS contains not more than a single species that has yet been discovered, and that is—

Empyesis Variola. Snallpox.

SPECIES I. EMPYESIS VARIOLA. SMALLPOX.

PUSTULES APPEARING FROM THE THIRD TO THE FIFTH DAY; SUPPURATING FROM THE EIGHTH TO THE TENTH: FEVER A CAUMA: CONTAGIOUS.

WHEN the smallpox first made its appearance in the world, we know not. There is no substantial ground for believing that the disease was known to the Greeks or Romans. It has been thought, indeed, by some persons, that the former have glanced at it under the name of anthrax or anthrace (*Hahn, Variolorum Antiquitates Æ Græcis eruta*, 1731); but the idea is too wild for serious refutation. It is far better ascertained that it existed in Asia, and especially in China, for an incalculable period before it was known in Europe; and, from the accounts of the Jesuits, to which we shall have to refer more particularly presently, it is highly probable that the art of inoculation was practised throughout the Chinese empire before the natural contagion had reached the European shores. About the middle of the sixth century (*Macad, De Variolis*, p. 3), it is supposed to have been conveyed by trading vessels from India to Arabia; and there is no question that the triumph of the Arabian or Saracenic arms introduced it from Africa into the Levant, Spain, and Sicily.

The pathognomonic characters of the genuine smallpox are, pus in the eruptions, and a power of propagating itself both by contagion and inoculation. Perhaps, however, there is no exanthem that is so much affected by accidental influences as the smallpox. Idiosyncrasies of various kinds seem to take off all predisposition to the disease, and to render the body inert to its virus; so that many persons possess a natural exemption, and pass through life without ever suffering from it.* There are other

* A striking occurrence, forcibly illustrating this position of the author, took place on board the well-remembered Jersey prison-ship. In this loathsome receptacle, which was specially appropriated for the confinement of American prisoners, more than one hundred and twenty men were imprisoned, who had never been affected with smallpox either naturally or by inoculation, and

changes introduced into the constitution from numerous causes, which, though they do not take off all predisposition to the disease in every individual to whom they are applied, afford an entire exemption in many cases, and exercise so controlling a power in others, that the general character of the disease, whenever it makes its attack, is greatly modified, and, for the most part, greatly mitigated; so that the accompanying fever is considerably less violent, the secreted fluid, instead of being a creamy pus, is a limpid ichor, desiccating in three or four days, and so far imperfect in its elaboration as to be less capable of propagating itself by contagion or inoculation, or of affording an absolute security against a reproduction of the disease in future: whence many persons, from the writings of the Arabians to those of our own day, are said to have suffered from smallpox, not only twice, but even three or four times in succession. In these accounts, mistakes have, perhaps, often been committed as to the species or even genus of the eruption; but, in various instances, the disorder has been so narrowly watched, and the judgment of the physician who has described it been so sound and unimpeachable, as to leave no fair ground for doubt upon the subject.

Of the nature of the constitutional peculiarities that are thus capable of controlling the exanthem, and deflecting it from its ordinary course, we know nothing; and of the causes themselves, which appear to be numerous, we know only a few. The virus of cowpox, introduced into the system, is now satisfactorily ascertained to be one of these causes, and apparently one of the most powerful. In most cases it affords, as we have already seen, an entire exemption; and, where it does not altogether take off the predisposition, it generally succeeds in giving the disease that modified and mitigated character which has been just noticed. The virus from the ulcerated heels of horses labouring under the disorder called grease (*Jenner, Inquiry into the Causes and Effects of the Variola Vaccina*, 1798), seems also capable, as we shall observe hereafter, of producing a similar control. And, as in most of the more extensive epidemics of smallpox, in every age since its first appearance, we have had numerous examples of such modified and imperfect eruptions, varying in almost every diversity of manner from each other, as well as from the regular pustules, but evidently produced by associating with patients affected with the last, and not unfrequently by inoculation itself from pure pus—examples in which neither of these causes have been present—we are compelled to admit, that there are numerous other causes existing, perhaps other diseases existing as

yet of that number less than two thirds were attacked with the disease, which, however, proved extremely fatal. One would naturally expect, that in such a place the specific virus of smallpox would act with much more violence. This fact was communicated to Dr. Francis by the late Philip Freneau, of New-Jersey, one of the prisoners.—D.

VOL. I.—R r

causes, to which the bodies of those who exhibit such modifications, or anomalous and imperfect sorts, have been previously exposed, and are indebted for so modifying a control, of which also, at present, we know nothing.

Rhazes has given numerous examples of these diversities or aberrations of smallpox, or Al-gridi, as he denominates them, though the more common name was Al-jedder الجدر;

and hence the remarks of John of Gaddesden, “notandum quod variolæ sunt duplices, propriæ et improprie.” (*Ros. Anglie*, p. 1044.) The IMPROPRIÆ it is often difficult to follow up or arrange, in consequence of their discrepancies, and especially their resemblances to other kinds of eruption. More commonly they approximate the form and general character of penphigus or varicella (chickenpox), and have no doubt often been mistaken for the one or the other, especially the latter, of which the severe variolous epidemics that have of late years, after a long dormancy, spread over Edinburgh (*Account of the Varioloid Epidemic*, by John Thomson, M. D., 8vo., 1820), Caithness-shire, and various other parts of Scotland, as well as over many parts of the continent, afford striking examples; as has also the late variolous epidemic among the inhabitants of Colombo, and the Kandyan provinces at Ceylon, as related by Mr. Marshall.*

Many of the cases of this kind, described or collected by Dr. Thomson, to whose indefatigable zeal the profession is under an irremunerable obligation, are peculiarly striking; as they consist of families, the different branches of which, receiving it in succession from each other, evinced in turn almost every variety to which the smallpox can make any fair pretension, distinct, confluent, crystallized or varicellous, and horny; and all of which, in many instances, manifested a power of regenerating and propagating the disease in its purest or pustular form, though this was often lost in several of them. The following case, contained in a letter from Mr. John Malloch to Dr. Thomson, is peculiarly entitled to attention. “No case of smallpox had occurred in this town for nine years till last winter, when an idle boy, who was in the habit of wandering about the country, frequenting markets, &c., happened to be at a house where some of the inmates were said to be ill of smallpox. He himself had been vaccinated some years before. On his return home he was seized with febrile symptoms, and confined for two or three days to bed, when an eruption similar to chickenpox made its appearance. Immediately the fever abated, and in a few days more he left his bed and attended a cattle-market, half a mile’s distance from the town, without experiencing any bad consequences. About a week afterward one of his master’s children was taken

* Some Account of the Introduction of Vaccination among the Inhabitants of the Interior of Ceylon, and of an Epidemic Smallpox which prevailed in the Kandyan Provinces in 1819. By Henry Marshall, Surgeon to the Forces.

ill, and went through the regular stages of smallpox in a mild manner; then a second similarly. A third suffered in a very alarming degree from the confluent kind; a fourth was rather worse than the two first; and the youngest, of eight months old, had what, if the other cases had not occurred, I would, without hesitation, have called chickenpox: for there was little or no fever, and the pustules were filled with a watery fluid, which was not converted into the purulent appearance of smallpox. None of these children had undergone vaccination."—(*Variol. Epidem.*, p. 333.)

It is very singular that in the Kandyan epidemic described by Mr. Marshall, while several cases made a very near approach to varicella, all of them so far deviated from the ordinary character of the variolous secretion as to be devoid of a creamy and consistent pus, and rarely to exhibit more than a whey-like matter, whether the eruption were distinct or confluent, or the fever mild or severe. In other respects, Mr. Marshall observes, the disease did not materially differ from the description given of the smallpox by systematic writers. For some days the eruption was papular; it then became vesicular, each vessel having a depressed point in the centre. During the early stage of the vesicles they contained pure lymph; subsequently they became less pellucid, and assumed a whitish hue; and, when matured, they contained the above whey-like fluid. "In no instance," says he, "that came under my observation, did the contents of the vesicle assume a yellow colour and thick consistence, as is stated to occur in smallpox in Europe."

These, it should be observed, were not cases that had been preceded by vaccination. Many such occurred, but the eruption was here of a still different and more modified, and even a more mitigated kind, still showing the controlling power of the vaccine fluid. This eruption, indeed, was occasionally severe, but uniformly appeared after two or three days' fever. For the most part, it was confined to the fore or the upper part of the body, ranging from one or two to thirty papulæ, and was remarkably uniform in its progress. It consisted of elevated hard pimples, containing a vesicle of pure lymph at their apex. These, by the fourth, fifth, or sixth day, reached their full size, and were soon followed by desquamation.

It not unfrequently happens, that, in dangerous cases, the papulæ do not rise kindly, but assume the form of stigmatized dots, while the surface is circumfused, generally, with a brighter or deeper efflorescence, according to the nature of the habit; under which circumstances the disease makes a near approach to rubeola, and has at times been mistaken for it. Of this form, also, the late Ceylonese epidemic, as described by Mr. Marshall, afforded various instances. "There were a few cases," says he, "where the skin assumed a MEASLY appearance. Under this description of the disease, the surface of the body resembled wet brown or blotting-paper. The fever continued without abatement, and frequently little or no erup-

tion appeared. I am not aware that a single case of this kind recovered."

And where, in the confluent variety, the secreted ichor (for the inflammation is seldom suppurative) is peculiarly virulent, we frequently meet with trails of vesicular and fiery erythema spreading over different parts of the swollen body, not unlike, in appearance, to the ignis sacer of that variety of plague which the ancients peculiarly distinguished by the name of anthrax, and which in the present classification is denominated erythematous plague.—(See Gen. IV., Spe. 1, Var. γ of the present Order.) And the resemblance is still more close, when this form of confluent smallpox is combined with bubonous or other ulcers: of which examples are frequent in hot climates, as in the epidemic attack of smallpox at Aleppo, described by Dr. Russell. "If the sick," says he, "survived the eleventh day, few of them escaped corrosive ulcers with carious bones, or hard swellings in the glandular parts."—(Oct., 1742.) Even in the colder temperature of our own country, the same miserable train of symptoms has sometimes shown itself, as observed by Dr. Huxham, "variola epidemicæ interdum crudo diffuunt ichore, qui subjectam carnem erodit, imò et nonnunquam ipsâ gangrënâ afficit."—(Julio, 1744.)

It is not very surprising, therefore, that the smallpox, on its first discovery, and, indeed, for long afterward, should, according to the variety it assumed, have been confounded with all these diseases, and especially with the measles and chickenpox—from their originating, or, at least, being first noticed about the same period, and consequently being equally new diseases. Hence we are told by Rhazes, that Aaron of Alexandria, who wrote on this disease as early as A. D. 620, arranged the smallpox, measles, and anthrax, or erythematous plague, as products of one common specific contagion.—(*Rhaz. De Variolis et Morbillis, in Continent.*, lib. xviii., cap. viii., 1486.) The last was, indeed, soon thrown out of the list, but the two former continued to be contemplated by most writers as one and the same disease for eight centuries after the era of Aaron.

With respect to the smallpox and chickenpox, there has been more difficulty. A contest of no ordinary magnitude arose in early times upon the subject, in support of which, every nation in Christendom, as in the Holy Wars, for many ages sent forth its champions, and the conflict has been of a still longer duration than the Holy Wars themselves.

In the midst, therefore, of all this confusion of diseases, nothing can have been more called for than a judicious attempt to distinguish the one from the other, and to lay down their respective landmarks; and hence, those who have engaged in such an undertaking have ever been entitled to the warmest thanks of the profession.

Rhazes, in this respect, may be said to have taken the lead. He carried at once the anthrax, or erythematous plague of Aaron, to a distinct genus from al-gridi, or the smallpox; and though he continued this last and measles

الحصبة, (*al hasbet*, rather than *al-hasba*, as commonly written), under the same genus, he arranged them as distinct species, and consequently regarded them as separate diseases; while to the smallpox, thus disentangled and simplified, he assigned pretty nearly the same varieties as have been allotted to it by the most discriminating writers of the present day; for he very accurately describes the distinct, the confluent, and the limpid or vesicular, including the crystalline and horny; and treats of the disease under the opposite characters of benign and malignant.—(*Rhaz. De Variol. et Morb.* See also *Mead's Works*, vol. ii., p. 163, edit. ed. 1765.)

Unfortunately, the limpid or lymphatic smallpox was incautiously denominated chickenpox, by way of distinction from the purulent, by many writers of great authority and talents, as Morton (*Treatise upon Smallpox*, Lond., 1694), Gideon Harvey (*Treatise on Smallpox and Measles*, Lond., 1696), Mead (*De Variol. et Morb. ex Rhaz.*, Lond., 1766); while, which was more common, varicella or waterpox in all its varieties, was designated by the term variola, though regarded as having no real claim to such a term, and hence discriminated from the genuine disease by the adjunct *spurious* or *bastard* variola, of which Van Swieten furnishes us with a striking example. For after having noticed under his description of variola the *steenpochen* (stonepox), *waterpochen*, and *windpochen* (*Comment.*, Aph. 1381, vol. v., p. 11, edit. Lugd. Bat., 4to.), all of which he distinctly characterizes by the name of spurious variola, and observed that he has seen them as frequently epidemic as the genuine smallpox, occasionally, indeed, running a race with the latter, and sometimes succeeding it, he dismisses them altogether, and proceeds with the history of the genuine disease in all its modifications: telling us that, like Dr. Mead, he had met with the crystalline variety, as well in the confluent as in the discrete form, occasionally, indeed, intermixed with the pustular: and that, under this variety, was reckoned by the best writers the siliquose, or that which consists of soft and empty vesicles, but which are sometimes at last filled with pus.—(*Comment.*, ut *suprà*; Aph. 1398.) In much of this he is followed by Sauvages, who, however, regards varicella by name as a distinct variety of smallpox; while with Hoffmann (*Opp.*, sect. i., cap. iii., p. 293, ed. Gen. 1740), he separates it from the crystalline or lymphatic variety, which he makes synonymous with horn or cornoidal pox (*spitzpochen*), and waterpox.—(Cl. III., Ord. II., Gen. II.)

A more pointed discrimination, therefore, became necessary, and a still stricter attention to the specific characters by which smallpox and chickenpox are distinguishable. This was successively undertaken by Fuller (*Exanthematologia*, p. 167, Lond., 1730), Borsiero (Burserius) (*Institut. Med.*, tom. ii.), Hosty (*Mercur de France*, Janv., 1769), Heberden (*Med. Trans.*, i., 427), and Willan; and has been so far accomplished as to have satisfied the profession

generally, although it has not, perhaps, at any time, set the question altogether at rest in the mind of every one.

Of late years, however, the learning and acuteness of many pathologists seem to have put us in no small danger of going back into all the confusion which existed in former times; not in any respect from ignorance of the real nature of the eruptive diseases towards which their attention has been turned, but from a scientific desire to generalize and simplify them.

About thirty years since, Professor Frank, of Milan, dissatisfied with the ground of that general composure of mind which seemed to have taken place on the subject, commenced a new agitation, and undertook to show that chickenpox (varicella), crystalline, and hornpox, and in general all those forms of exanthem, which, since his time, have been called, though with no very classical term, *varioloïd* diseases, belong to PEMPHIGUS as a genus, under which also he places pompholyx. This genus he divides into two species, *p. amplior*, importing the ordinary form of the disease, and *p. variolodes*: “*eamque*,” says he, alluding to this variety, “aut vesicularem (*variola spuria emphysematica*), aut crystallina (*aqueosa, varicella auctorum*), aut solidescens (*variola spuria verrucosa, acuminata, sicca, dura, ovalis auctorum*) appellari vellamus.”—(*De Cur. Hom. Morb. Epit.*, tom. iii., p. 264.) It is not necessary to follow up his argument, since, however well supported, it has for some time been sinking into disrepute; though, amid the versatility of opinion and conjecture which have of late distinguished the medical world, it is not impossible, that, like many far more obsolete doctrines, it may yet revive and have its day again. It is necessary, however, to advert to it as forming one of the first and best supported deviations from the general concurrence of opinion that had for some time been entertained upon the subject.

In the variolous epidemic which prevailed during 1816 at Montpellier, the eruption seems to have presented almost all the diversified forms under which it is ever to be traced, in respect to shape and number of pustules, the nature of their fluid, the length of time which they require in order to be excicated into scales or scabs, and in the duration and severity of the eruptive, as well as in the absence or presence of the secondary fever. The chickenpox (whether pemphigus or varicella), as is often the case, appears both to have preceded and to have accompanied the genuine variola; and the two were in many instances so closely intermixed and alternated, as to render it a work of no ordinary difficulty to draw a line of demarcation. “Never, perhaps,” says Professor Berard, who, in conjunction with Dr. de Lavit, has given an interesting history of this epidemic (*Essai sur les Anomalies de la Variola et de la Varicella*, Paris, 1818), “did the symptoms of chickenpox so nearly resemble those of the smallpox, nor these diseases more fully assume the characters of each other.” The result was, that, although at the commencement of the epidemic they contemplated the two diseases as perfectly distinct,

not running a common race, they were at length inclined to regard them as identic, for reasons highly plausible, and which they advance with great modesty; and thus again enlisted chickenpox under the banner of variola. And since this time, Professor Thomson, of Edinburgh, from an attentive observation of like coincidences in the late variolous epidemy in Scotland, to which we have already adverted, has not only felt inclined to draw the same conclusion, but has, with great industry and force of argument, endeavoured to establish an identity of species between these two eruptions by a copious reference to their history, and the progress of the contest to which they have given rise, as developed in all the standard authorities, foreign as well as domestic, from the accredited date of their origin to the present day.*

It is not a little singular, and tends in the strongest light to show the discursive powers of human genius when aided by the resources of learning, that, at the very moment of this new attempt to combine diseases which have of late years been regarded as distinct, or as claimed in various forms by another genus, Dr. Willan, who had laboured hard to support and rivet such distinction, was engaged in the more arduous task of establishing the identity of smallpox and plague in that variety of the latter which makes the nearest approach to smallpox, and which we have already referred to under the name of erythematous. His researches, which have been published posthumously by his learned relative Dr. Ashby Smith,† are written with an amenity and antiquarian interest that fully entitle them to a place in every medical library, whatever becomes of the question itself, and have, undoubtedly, brought conviction home to the minds of not a few. So that, if the whole of these elaborate lucubrations could maintain their ground, plague, smallpox, chickenpox, pemphigus, and, perhaps, cowpox, greasepox (*Thomson*, ut supra, pp. 146, 387; *Willan*, ut supra, p. 69, note 75), measles, and scarlet fever, would all be resolvable into one common malady, and derivable from one common virus. While, as another learned attempt has been set on foot by a third body of pathologists, of no mean authority or pretensions,‡ to show that plague itself, in this case the primary and original source of them all, does not exist in any shape, nor ever has existed, as a specific disease; and is nothing more than a typhous or malignant fever with an accidental appendage of efflorescences, eruptions, or tumours of various kinds, modified by a host of contingencies (to which, indeed, Dr. Frank is

also a party in his first volume, p. 136), the whole system of pyretology seems, in the present day, to have some chance of being concentrated into a marvellously small compass, and, for the benefit of future students, may perhaps be engraven on a silver penny. But, where the landmarks of diseases are thus successively broken down one after another, till no guiding-post is left, how is the young student to make his way over the trackless common before him?

This view of the subject might easily be carried still further: for, after Dr. Willan had persuaded himself that the erythematous plague of the ancients was nothing more than the vesicular and confluent variety of smallpox, he persuaded himself still further, that the distinct and coherent form of this disease is, in many cases, synonymous with their phlyzacia, lichenes, and cethymata (*Will.*, ut supra, p. 53); thus melting down a multitude of other eruptive affections into the same crucible. Had he lived longer, indeed, it was his intention to have unfolded in a similar way the history of syphilis, which, like all the preceding complaints, he conceived to be of immemorial origin, and, apparently, to have had a close fellowship with them.—(*Miscellaneous Works*, p. 87; foot-note by Dr. Ashby Smith.)

[The leading arguments of Dr. Thomson are, first, that all the cases he had seen of varicella occurred at the same time, and in direct connexion with smallpox, sometimes appearing to originate in it, sometimes to produce it; secondly, that he had never witnessed chickenpox in those whose disposition to variola had been extinguished by an attack of the varioloid disease; and, thirdly, that chickenpox is very rare among those who have not been vaccinated. To these apparently strong arguments it is answered, that Dr. Thomson disregarded the true characters of chickenpox, as determined by the latest and best authors, and confounded with it the vesicular form of the varioloid disease; that though the diseases sometimes alter their characters so as to resemble one another very much, yet, when the term chickenpox is restricted to the unequivocal and most frequent variety of it, described by Mr. Bryce, then it will be found, first, that by natural infection chickenpox never gives rise to any thing else but chickenpox; secondly, that by inoculation it never causes the varioloid disease or smallpox; thirdly, that when it is traced ramifying throughout a family or a district, it reproduces itself in the same form, and with the same mildness, equally in the inoculated, the vaccinated, and the unprotected; and, fourthly, that it reproduces itself as often in its mild form among the unprotected as among the protected, even when it prevails so much as to be accounted epidemic; whereas, all the facts hitherto collected show that when the true varioloid disease prevails epidemically, its form in the unprotected is very often peculiarly malignant.—(*Edin. Med. Journ.*, April, 1820, and January, 1823.)]

It must be conceded to Professor Thomson, that it is often peculiarly difficult, sometimes perhaps unconquerably so, to distinguish by the

* Historical Sketch of the Opinions entertained by Medical Men respecting the Varieties and Secondary Occurrence of Smallpox, &c., in a Letter to Sir James McGrigor, &c., 8vo., London, 1822.

† *Miscellaneous Works of the late Robert Willan, M. D., &c.*, comprising an Inquiry into the Antiquity of the Smallpox, Measles, and Scarlet Fever, &c., 8vo., Lond., 1824.

‡ Heberden, *Observations on the Increase and Decrease of Different Diseases*, particularly the Plague, 8vo., 1821.—Hancock, *Researches into the Laws and Phenomena of Pestilence*, &c., 8vo., 1821.

superficial appearance the nature of the fever, or even the mark that remains on the skin afterward, chickenpox from smallpox; and especially, which is what he particularly alludes to, that modification of smallpox which is so apt to follow vaccinia or cowpox, where the latter has only given the constitution a check, and not an utter exemption. But these approximations are only to be traced in extreme modes of the two diseases, and where they make a considerable divergence from their right and proper course; for, in a pure or perfect state of smallpox and chickenpox, whether we regard them as distinct diseases, or as mere varieties of one common species, there is no difficulty whatever. And even in their widest departure from such state, and their closest approximation to each other, as well in unity of time as of character, they do not more intimately coincide than in the case of various other diseases, of whose distinction there never can be a question. Thus, in idiopathic epilepsy and intestinal worms, the symptoms are often precisely the same; and the existence of the second, at first only conjecturable, is at last only ascertainable by the action of anthelmintics. But worms may also be accompanied with all the symptoms of a genuine hectic, as may this latter with all those of a quotidian or a tertian ague. So measles have often been confounded with rosalia or scarlet fever, and malaria with eczema, or heat-eruption; and it is one of the most important parts of nosology to point out the distinctive marks of such analogous diseases, though a part in which it has not always succeeded.

As there are some disorders that render the constitution less disposed to smallpox than others, of which the cowpox furnishes us with an example, there are also some that render it more so. In like manner, we find the measles generally superinduce catarrh, and very frequently prepare the way for hooping-cough; inasmuch that all these maladies become synchronous. So the chickenpox not unfrequently lays a foundation for the smallpox, and the smallpox may, perhaps, in persons of a particular habit, lay a foundation for the chickenpox; or even the atmospheric intemperament of either of these diseases, when epidemic, may call the other into play; so that both, as we frequently see, co-exist, not only in the same place, but even on the same person. In truth, the same constitution of the atmosphere often favours the growth and spread of various diseases equally; and hence, rubella, varicella, rosalia, and catarrhs, are not unfrequently coincident.

[Here it deserves notice, however, that Dr. Möhl, who has favoured the world with a valuable publication on the present subject, has never seen chickenpox in families where smallpox prevailed at the same time, or recently before; that he has twice or thrice, indeed, seen in such circumstances an eruption resembling chickenpox, but never a disease corresponding exactly with its characters, as they will be presently laid down. On the other hand, Dr. Lüder alleges that he has seen chickenpox produced by the variolous contagion; but his strongest

proof, when carefully examined, amounts to nothing. The eruption was preceded by fever of three days' duration: it assumed at first the papular form, and it seems not to have become vesicular till the third day after it appeared. We shall presently find that this description does not by any means correspond with the description of an unequivocal case of chickenpox.—(*Edin. Med. and Surgical Journ.*, No. xciv., p. 185.)]

The two diseases before us have marks, if I mistake not, so strictly essential as to render it highly incorrect and unscientific to contemplate them as mere modifications of a common exanthem; which, moreover, in various cases, by throwing the practitioner off his guard, might lead to a very erroneous treatment and a dangerous exposure of the person. If these be not to be found in the ordinary distinctions that have been pointed out by Dr. Heberden, Dr. Willan, and other monographists, as resulting from the form and duration of the pock, the consistency of its fluid, and the integrity or dip of the skin after the eruption is over, we must look beyond the obvious symptoms to the intrinsic properties of the respective matters eliminated, and the influence of the two diseases on the constitution in future. And here I think we shall not look in vain.

I. The matter of smallpox is capable of reproducing smallpox by inoculation. It continues true to its own specific character, and possesses this power to infinity. The matter of chickenpox is not capable of reproducing smallpox by inoculation; nor is it often capable of reproducing even its own kind. It will sometimes excite an irritation around the puncture, but it seldom seems to proceed farther. Nor, indeed, does it always irritate locally: for we have already seen that Dr. Heberden, with all his efforts to obtain this effect, found that "the little wound healed up immediately, and showed no signs of any infection."—(*Med. Trans.*, vol. i., art. xvii.) Of the two cases described by Dr. Willan, the first, indeed, affords an example of regular local specific action; "for the vesicle on the inoculated part went through its ordinary course; and, twelve days after the incision, he observed further, that two small red eruptions appeared on the shoulder, and soon became vesicular;" but, in the second case, even the local irritation appears to have been nearly as trifling and unspecific as in the case of Dr. Heberden; on the third day after inoculation, "the small scratches made by the lancet were discernible, but not inflamed." On the fourth, "they were scarcely visible." On the fifth, "a redness with some degree of hardness and elevation appeared at the places punctured, but subsided again on the following day." On the eighth, "no vestige remained of the inoculation." It should be observed, however, that, twelve days after the use of the lancet, two small gnat-bite-like spots appeared on the patient's side, which became vesicular, and that, two days after this, "a considerable number of vesicles, with surrounding redness, appeared on his body; but there were not any on his face." On

the next day "he was free from indisposition, and no further eruption took place." The whole of which general eruption, in consequence of the imperfect action exhibited on the arm, was reasonably ascribed to contagion received antecedently to inoculation; the patient, who was a boy of nine years old, having been the constant playmate of his brother, from whom the fluid was taken, and who had caught the disease at school.—(*On Vaccine Inoc.*, p. 98, 4to., 1806.)

From this slightness of irritability in the fluid of the varicellous vesicle, many practitioners have supposed that it is nothing more than an increased secretion of the serum of the blood, like that which takes place in "any blister produced by scalding or cantharides."—(*Brown's Inq. into the Anti-Var. Power of Vaccination*, p. 223.) This, however, is hardly to be admitted; but it is impossible to reflect upon the readiness with which most cutaneous eruptions, whether merely superficial or constitutional, are capable of propagating themselves by inoculation, as cowpox, plague, syphilis, psoriasis, porrigo, and scabies, in all its forms, as well as smallpox, without a conviction that the fluid of the varicellous vesicle is, at least, one of the most inert of the whole, and consequently something widely different from that of the smallpox.

The power of propagation possessed by genuine smallpox, moreover, is not only, in direct opposition to the power of chickenpox, peculiarly active, but runs through all its varieties, each of which, however deflected from the standard of perfection, has a tendency, though not an equal tendency, to reproduce the same disease, and to model it after such standard: and hence we have a thousand instances of discrete purulent smallpox, generated by inoculation from the confluent or crystalline varieties.—(*Frewen, Essay on Inoculation*, 1749; *Willan, On Vaccine Inoculation*, p. 55.) Not, indeed, that the latter is always as sure in its action, for it often fails from its imperfection; but, wherever it evinces specific power enough to operate, it reproduces the genuine disease, and mostly with a completely matured pustule. In effect, it is rarely that the fluid in the confluent smallpox becomes thoroughly matured or purulent; and yet it is seldom that this has been found unavailing.

II. An incursion of natural smallpox protects the system against the recurrence of small-pox, and an incursion of natural chickenpox against the recurrence of chickenpox; but neither of these affords the slightest security against the other. This protection, indeed, is not universal, and hence we have, in both diseases, a few examples of secondary or even ternary affection; but the rule holds generally, and is not fundamentally disturbed by such anomalies. And hence a full proof that the intrinsic qualities of each virus is distinct, and consequently that the diseases themselves are so.

III. The matter of cowpox, which affords a like protection to the system against smallpox, affords no protection whatever against chickenpox. On the contrary, according to many writers, it seems rather to pave the way for chick-

enpox;—if all the anomalous eruptions which have been regarded as chickenpox since the introduction of vaccination have been fairly entitled to this appellation, instead of to that of spurious smallpox, as they were formerly called; since such eruptions appear of late years to have been more frequent than ever. But of the real nature of several of these we are, perhaps, to the present moment, in a considerable degree of ignorance.

They may, perhaps, be of later origin than either the smallpox, cowpox, or measles, and they may possibly wear themselves out sooner, and give way to other eruptions, of which at present we know nothing. "For it seems deducible," says a learned and highly venerated friend of the author, "that there is not a secretion or exhalation of the human body which may not be so vitiated as to produce diseases communicable to others by contact or respiration, under various fortuitous circumstances of concentration and stagnation, application and action; so that there may be new maladies awaiting our species, which are still to develop themselves under the endless combination of the incidents of human life through endless ages to come."—(*Select Dissertations*, by Sir Gilbert Blane, Bart., &c., p. 214, 8vo., Lond., 1823.)

By the facility with which some of these are capable of producing fresh crops of their own nature in inoculation, they seem to be distinct from varicella; and from their forming no protection against the smallpox, they are evidently distinct from the latter, notwithstanding their frequent approximation to it in duration, and the external qualities of the pustule.

These are marks uncontested, I believe, by any party; and they are sufficiently different to establish a clear distinction in the nature of the two eruptions, and consequently to separate the diseases from each other.

[The diagnosis between smallpox and chickenpox is much better understood at present than it was some years ago. Whoever has attended to the account given of varicella by Mr. Bryce and Dr. Abercrombie, will perceive that the majority of previous authors had included under that designation some varieties of eruptive disorders, which it is impossible to distinguish from the common forms of modified smallpox. And, although many, or rather most cases of the kind, may be proved to have been cases of the varioloid disease, it is at least highly probable that some of them have been cases of chickenpox, but in one or other of its irregular forms, to the occurrence of which it is liable, as well as every other exanthematic disorder. In defining the disease, however, the leading place must be assigned to its most frequent and regular form; and it is obviously to this form alone that we must confine all observations on its origin and contagious nature.]

A great deal of attention has been paid to this subject by Mr. Bryce, Dr. Abercrombie, and the reviewer of Dr. Thomson's work.—(*Edin. Med. Journ.*, April, 1820.) And the result has been, says the critic, whose words we are now quoting, that in opposition to the opinion of Dr.

Thomson regarding the impossibility of distinguishing chickenpox from smallpox, or of embodying in words the idea currently entertained of a pure case of the former disease, we are now in possession of a minute and faithful delineation, which no one can be at a loss to apply in practice. The proper unmodified chickenpox is distinguished, first, by the eruptive fever being generally slight; whereas that of modified smallpox is generally sharp, and of several days' duration; secondly, by the eruption being vesicular from the beginning, or at least from an early period of the first day, not papular, as the vesicular form of the varioloid disease always is for a day or more; thirdly, by the absence of a tubercular basis when the vesicles are fully formed—the vesicles of the chickenpox being hardly accompanied with any swelling around them; while those of modified smallpox are, in the first instance, elevated on solid tubercular bases; fourthly, by the great thinness and fragility of the cuticle covering the vesicles. In applying these characters, two precautions must be observed: on the one hand, the eruption must be seen as early as the second or third day, because, at a later period, the chickenpox eruption sometimes acquires a tubercular base, and the varioloid loses it; and, on the other hand, the judgment must be directed by the general eruption, not by the appearance of a few vesicles differing from the generality. Besides these characters, the critical writer adverts to some others of importance pointed out by Dr. Möhl* and Dr. Lüder.† According to the latter, the varioloid eruption is formed in the true skin, as is shown by the hard elevated base which remains after the lymph is removed by puncture and pressure. On the other hand, chickenpox is situated in the cellular tissue between the skin and cuticle. This may be perceived, as Mr. Bryce formerly pointed out, by opening a vesicle, and examining its edge after the lymph has run out: no excavation or elevation will be perceived, but a surface level with the surrounding skin.

Dr. Möhl agrees with Mr. Bryce and Dr. Abercrombie, as to the rapidity with which chickenpox assumes its proper vesicular structure. He had never seen it on the first day; but, on the second, he has uniformly found it vesicular. He adds another character, not always present however, namely, itchiness of the eruption. And he has given a minute description of the crusts, which he says are characteristic, being irregular, uneven, opaque, of a pale brownish or yellowish colour, formed of the lymph and collapsed cuticle, and falling off, as Dr. Monro pointed out, not in a single piece, like the crusts of variola, but in small fragments.—(*Edin. Med. and Surgical Journal*, April, 1820, and January, 1828.) Both Dr. Möhl and Dr.

Lüder, it appears, have furnished a criterion, which Dr. Thomson himself admits would, if established, show the fallaciousness of his views. "I do not think," says Dr. Thomson, speaking of his hypothesis, "it can well be set aside, till it shall be proved that chickenpox occurs generally in persons who have not had smallpox, or cowpock, and prevails epidemically, without cases of smallpox occurring among them." It is no wonder, says the reviewer, that the records of medicine should have supplied no such example, seeing how imperfectly chickenpox was, till of late, distinguished, and still more how seldom, till lately, a district of country could be said to be without smallpox. But the political condition of Prussia and Denmark has enabled both our authors to present Dr. Thomson with examples of the most unequivocal nature. From the year 1809 (says Dr. Möhl) till 1823, there was absolutely no smallpox in this city; while, during that period, chickenpox was observed every year: and on that account, there is not a Copenhagen physician who entertains any doubt of the specific difference between the two diseases. Between November, 1823, and March, 1825, while smallpox raged in Copenhagen, chickenpox still prevailed sporadically, but without our having ever seen them arise from variolous contagion, or produce variola. When again the smallpox ceased, during the fine summer months of 1825, chickenpox nevertheless continued to occur frequently. Next year, when the smallpox epidemic returned, Dr. Möhl had frequent opportunity of seeing chickenpox, but still always under circumstances which more and more convinced him that it originated in a peculiar contagion, quite distinct from smallpox.—(*Edin. Medical Journal*, No. xciv., p. 168; also, *Dr. Lüder's Treatise*, p. 120.)

That smallpox is not identic with any of the varieties of the lœmus or plague, properly so called, of the Greek writers, is still more easily capable of proof. The variety peculiarly fixed upon by Dr. Willan, is that which was often distinguished by the name of ANTHRAX, the erythematous form of the present classification, in which the body is "covered over with trails of vesicular erythema, producing deep, sanious, and gangrenous ulcerations as it spreads, often to a loss of one or more limbs."

In this last there is, indeed, some resemblance to confluent smallpox, as it sometimes shows itself in cases where the fluid is yellowish, transparent, and immature. But there is no resemblance whatever to the pustular discrete smallpox; and hence Dr. Willan is under the necessity of supposing that the latter are alluded to by the ancients under some other term, and constituted with them another and widely different disease. "As the *angina maligna*," says he. "was for many ages thought generically different from the scarlatina febris, so was the CONFLUENT VESICULAR SMALLPOX deemed a principal branch of the LOIMOS or PESTILENTIAL FEVER: while the DISTINCT and COHERENT VARIOLÆ, with yellowish pustules and a moderate fever, were ranked with phlyzacia, ecthymata, lichenæ agrii, &c. This may be traced up to Hippoc-

* De Varioloidibus et Varicellis, Copenhagen, 1827. Said by the Edinburgh Review to be, perhaps, the best epitome on the subject.

† Versuch einer kritischen Geschichte der bei Vaccinirten beobacht. Menschenblättern, nebst Untersuchung. über die Natur, &c. dieser Krankheit. Altona, 1824.

rates:—he, as well as Galen, speaks of pemphigoid fevers, fevers with phlyctenæ, and the anthracæ, as *pestilential* and *malignant*: and of another set of fevers, in which appear critical, inflamed, and suppurative tubercles or pustules.”—(*Miscellaneous Works*, ut suprâ, p. 59.)

Now the term *AOIMOE*, or *PESTIS*, was employed among the Greeks and Romans, like our own derivative *PESTILENCE*, in two very different senses, a strict or particular, and a loose or general. Under the first it always imported, as plague or pestilence does in our own day, one and the same specific disease; under the latter, it was applied to various sorts of disease possessing any high degree of malignity, whether among mankind or among brutes, as the word *pestilence* is still used among ourselves. But it is immeasurably difficult to adopt the view of this subject taken by Dr. Willan, for the following reasons:—

First, we have no DESCRIPTION whatever of any such disease as smallpox in the writings of any of the Greek or Latin physicians: and all that Dr. Willan or any one else can accomplish upon this point, is to glean a few incidental passages which may be supposed to ALLUDE to it in different places or volumes. Now, if the smallpox existed among the Greeks or early Romans at all, it must have existed as a common and popular disease; and it is impossible to suppose, that, among pathologists so minute in their attention to other diseases, and the descriptions they have given of them, as Hippocrates, Aretæus, Galen, and Celsus, they should not have described smallpox also at large, and assigned some fixed and specific name to this, as well as to apoplexy, cardialgia, catarrh, and opisthotonos, instead of leaving us to seek for it at random under the names of lœmus, anthracæ, eulogia, and various other affections.

Secondly, as the smallpox, if it existed among the Greeks at all, must have had a frequent existence, and its varieties of discrete and confluent, mild and malignant, must have been known to every one, it is impossible, that Hippocrates or Galen could have made that separation between such varieties as Dr. Willan is obliged to suppose; and have contemplated them as distinct diseases, of very different origins, and destitute of all generic connexion whatever.

Thirdly, inoculation for the plague was occasionally tried in ancient times, as it is in our day, and especially for that particular variety of the plague which Dr. Willan especially adverts to as making the nearest approach to the smallpox, and always with the same result. Instead of producing a milder disease, as in the latter case, it uniformly proved fatal. The last attempt of this kind appears to have taken place in the reign of the Emperor Commodus, A. D. 189, and is thus described by Dion Cassius, in his narrative of the plague which overran so large a portion of the Roman territory at this era, and which is admitted by Dr. Willan to have been the modification of plague now alluded to:—“Many died in another way, not only at Rome, but over nearly the whole empire,

through the practice of miscreants, who, by means of small poisoned needles, communicated, on being paid for it, the horrid infection so extensively, that no computation could be made of the numbers that perished.”—(*Hist. Rom.*, lib. lxii.)

Dr. Willan notices this passage of Dion, and very adroitly endeavours to turn it to his own account. “This absurd report,” says he, “is very analogous to the calumnies against our early inoculators.” The inoculators, however, in every other part of the world, when employed upon smallpox, succeeded, in every instance, in triumphing over such calumnies: they were upheld by the force of truth; they pointed to the favourable result of their practice, a result which it was impossible to deny; and hence there is no nation, in ancient or modern times, barbarous or civilized, Asiatic, African or European, as we shall have to observe hereafter, wherever variolous inoculation was introduced, but became gradually sensible of its benefit, and hailed it as an incalculable blessing. Why was not the same triumph obtained by inoculation for the disease before us in Greece and Rome? Why, but for the reason alleged by the historian—that, instead of an incalculable blessing, it proved an exterminating curse, and thus gave a clear manifestation, that this disease was not the smallpox?

Fourthly, that the anthracæ, referred to by Dr. Willan, was not smallpox, but a variety of the proper lœmus or *pestitis*, is clear from its existing in the same quarter of the globe in the present day, and being expressly described as such by pathologists of the highest authority, of whom it may be sufficient to mention Dr. Alexander Russell, whose account of this form of plague, as it appeared before his eyes, we shall advert to in its proper place;* and who was also as accurate an observer of smallpox, which he has in like manner represented as it occurred to him; but who never once dreamed of regarding the two diseases as identical (*On the Diseases at Aleppo*, ch. iv.), or possessing any near connexion.

Dr. Willan, however, relies mainly upon Rhazes, who seems unquestionably to have entertained some ideas upon this subject in unison with himself; for, apparently misinterpreting a few loose passages of Galen in the same way as Dr. Willan has done, and particularly where Galen is treating of phlegmonæ, erysipelata, herpes, and ionthi (*Tr. de Compos. Med.*, sec. loc. de Prognos. à Pulsibus, lib. ii.; and *De Usu Partium*, lib. ix.), he tells us that the smallpox and measles were known to Galen six hundred years before his own era. In answer to which, however, it may be sufficient to quote the following admission on the part of the Greek translator of Rhazes's Treatise on the smallpox and measles (al-gridi and al-hasbet), written in the tenth or beginning of the eleventh century, and dedicated to the reigning emperor, and which he entitles *περί Λοιμικῆς*, “on the PESTILENCE;” for by this name, adopting the vulgar

* Gen. IV., Spe. 1. of the present Class and Order.

meaning of the term, he denominates these diseases:—"It is confessed by all persons conversant with the writings and laborious researches of Galen, that nothing which pertains to medical science, or the cure of diseases, has escaped his penetration. With regard, however, to the pestilence (*Δαιμονία*), he is less explicit than on other subjects: he speaks of it *cursorily*, or in connexion with analogous complaints, but he does not anywhere state distinctly the symptoms or appropriate mode of treatment in it:—strange, that he who first organized the medical art, and defined what had been left indeterminate, should have but slightly noticed a disease to which every man is born liable."

But the most powerful opponent of Dr. Willan upon the whole of this subject, is Dr. Willan himself: who, only a few years before, gave us his opinion upon it in the following form; and it is not a little singular to observe how directly it is controversial of that we have thus far contemplated, while it does not appear that any new facts, or additional evidence of importance, had sprung up before him to produce such a change of sentiment.

On his referring to this celebrated treatise of Rhazes, "he takes it," says Dr. Willan, "for granted, that the smallpox and measles were known to Galen more than six hundred years before his own time, being misled by some incorrect translation of Galen's works into the Arabian language. The passages which he quotes have certainly not the least relation to the diseases above mentioned (smallpox and measles). Indeed, no description of them, nor the slightest collateral hint, appears in the writings of the Greek physicians, which could lead us to suppose they had any knowledge on the subject. Some modern writers have held a contrary opinion, maintaining that Hippocrates and his successors applied to the measles and smallpox the denominations of *exanthemata*, *ecthymata*, *eczematata*, *erysipelata*, *herpetes*, *ANTHRACES*, &c. Now, some of these terms have been strictly defined, and in a way which admits of no such application: the rest are left indefinite, and always intended to express, generally, eruptions on the skin, yet have they not been appropriated to any particular form of them. A controversy founded on materials so slight and unsatisfactory, was carried on with ardour during a part of the last century, but need not at this time be revived, when it is nearly consigned to oblivion."—(*On Cutaneous Diseases*, p. 251, 4to., Lond., 1808.)

In the midst of all this diversity of opinion there is one point at least clear, and universally admitted: I mean, that the earliest distinct description of the disease which has descended to modern times is that of Rhazes. It is contained in his *Almansor*, which was composed about the end of the ninth or the beginning of the tenth century; and in this he quotes from an Alexandrian physician, of the name of Aaron, who had written on the same subject as early as the year 622.

Yet it is very singular that neither Rhazes nor Aaron, so far as their writings have reach-

ed us, make mention of the contagious property of the disease, chiefly accounting for its production by an ebullition of the blood, which they thought particularly incident to the age between childhood and youth. And it is equally singular that it should be asserted by Aaron, as it was also by Avicenna, that the same person is liable to a return of it a second, or even a third time, *præcipuè cum sanguis sit acutus*. Has the disease undergone any change since this period, so as to render those who have not had it more susceptible of its influence, and those who have had it less? In the descriptive part of the disease, little is to be added to Rhazes's statement, and, what is more singular, he recommends the cool treatment. Unfortunately, however, the doctrine of concoction and despumation of the humoral pathologists spread afterward so widely, and was so generally supported, as to put to flight this correct and rational view of the subject; and every attempt was made, by warm clothing and the warm bath, to mature the peccant matter, and drive it in as large a quantity as possible to the surface; by which the slightest cases were violently exasperated, and too often rendered fatal.

The more severe the disease, the sooner the pustules show themselves, thus completely reversing the law of scarlet fever; a remark for which we were first indebted to the sagacious eye of Sydenham. And hence, in the confluent variety, the eruption appears on the second or third day, while, in the distinct, we have seldom any traces of it till the fourth, and often not till the fifth day.

If a patient have accidentally become impregnated with the contagion of the measles before inoculation or being exposed to the contagion of the smallpox, the latter, as we have already observed, will, generally speaking, be retarded in its progress, and not make its appearance till the measles have run through their course, upon the common law, that the constitution is only affected with one disease at a time. But to this common law we have already pointed out various exceptions; and as gout and rheumatism sometimes co-exist, the measles and smallpox occasionally co-exist also. In the year 1769, Mr. King, of the Foundling Hospital, Dublin, inoculated forty-three children of the establishment. On the fourth or fifth day afterward, sixteen of them sickened with the measles, and went through the disease regularly; yet the progress of the smallpox was not retarded or altered; for the pustules of the latter disease appeared as those of the former died away; and both complaints were of a mild character: a like coincidence occurred in the ensuing year, and with a like favourable termination.—(*Edin. Med. Comment.*, vol. iii., p. 443.)

In this case, the common law of retardation seems to have been interfered with by some peculiar constitution of the atmosphere; for the effect was general to all who were under the influence of rubelous contagion. In other cases we have a like interference with the common law of variola, from the idiosyncrasy of individuals, or some temporary but equally occult

power, operating upon the system. There are some persons who seem to possess a natural immunity to its influence, and pass through life without ever being infected, though they may have purposely exposed themselves to the most contaminated atmosphere. There are others, who, though incapable of being affected at one time, lose their emancipation at another. "I know an old nurse," says Dr. Huxham, "and one apothecary, who for many years attended persons, and a great number too, in the smallpox, and yet never had them; nay, many that have industriously endeavoured to catch this infection, by frequenting the chambers of the sick, have done it without effect; and yet some of these persons, some months or years after, have been seized with the smallpox."—(*Treatise on Fever, Smallpox, &c.*)

But not only does the susceptibility of the disease vary in degree at different times and in different persons, but the irritability of the body beneath its influence. Thus, among fifty persons who receive it at the same time, and undergo the same regimen, we may perhaps have as many degrees of violence; some dying beneath its severity, some escaping, though with great peril, and indelibly seamed and scarred, and others evincing little fever, and a very slight eruption. The present author caught it casually in London, when a child about six years old, and passed through it with scarcely any disturbance, and not more than twenty scattered pustules.

In like manner we find, under inoculation, that while some persons throw forth a full crop, and suffer considerably from fever, others have scarcely any febrile symptoms, and no more eruption than the pustule on the puncture; the disease, in this case, exhibiting the same change as occurs in inoculated cowpox, compared with the exanthem as received casually from the cow.

It was at one time doubted, whether this slight appearance afforded protection for the future. There is now no longer any doubt upon this subject. But we may go beyond this, and reasonably conjecture, that those who have passed through the disease with but little inconvenience, are even less exposed to future attacks than persons who have had it in the confluent form, and whose faces are marked with its ravages. For as the degree of violence depends, where there is no error in the treatment, upon the degree of irritability which the constitution manifests under the contagion, and as the irritability and susceptibility march with an equal step, he is most likely to have a renewal of the susceptibility, in process of time, who bears the most evident marks of a greater susceptibility antecedently.

It had indeed been conceived by very distinguished pathologists, that the smallpox can never be had a second time, notwithstanding various assertions in support of this fact; and the argument is thus ingeniously put by Dr. Heberden, who was himself a disbeliever:—"It would be no extravagant assertion to say, that here in England not above one among ten thousand patients is pretended to have had it twice; and whenever it is pretended, it will always be

as likely that the persons about the patient were mistaken, and supposed that to be smallpox which was an eruption of a different nature, as that there was such an extraordinary exception to what we are sure is so general a law."—(*Med. Trans.*, vol. i., art. xvii.)

This remark is forcible, but the actual occurrences are in many, perhaps most of the instances appealed to, still more so. For, from the cause I have just pointed out, those who have had a repetition of smallpox have generally, if I mistake not, been able to exhibit proofs of a prior attack in pits or scars on the face or some other part of the body, manifesting the violence with which the disease ran its course, and consequently the strong predisposition of the constitution towards it, and irritability under its influence. "It is remarkable," says Sir Gilbert Blane, "that almost all the well-authenticated cases of second smallpox have been of those persons who, in the first instance, had undergone it in its most severe and dangerous forms."—(*Select Dissertations, &c.*, p. 209, 8vo., 1822.) Louis XV. of France afforded a clear exemplification of this in 1774; and another still more striking is given, for the ensuing year, in the Memoirs of the Medical Society (vol. iv., 1775), in which, though the first attack was peculiarly severe, the second was more so, and proved fatal. The medical repositories are rich in cases of this kind, some of them so striking and so well established as to prohibit all doubt whatever: and, in the two or three instances which it has fallen to my lot to witness, I have traced the same character; for pits from the prior attack have been visible, while the genuineness of the existing attack was in one instance substantiated by the test of inoculation. In some instances this strong constitutional predisposition runs through every branch of the family, of which Dr. Barnes of Carlisle has given us a striking example in five individuals, sons or daughters of the same parents, who, having all caught the smallpox naturally in the summer of 1818, from which most of them suffered smartly, caught it again in February, 1822, and had it also smartly, though not quite so severely as on the first attack. In both series of affection, the individuals varied in the degree of fever and range of pustules; but in every instance, whether of the first or second series, the eruption was pustular. This account is given in the seventy-sixth number of the Edinburgh Medical and Surgical Journal (vol. xix., pp. 376-378); and the very next article in the same number affords an instance of a family diathesis of the same kind, in four individuals, sons or daughters of the same parents, who were attacked nearly simultaneously with smallpox after having undergone vaccination, which seems to have passed through its course satisfactorily, at different intervals, varying from six to two years. A fifth child, which had not been vaccinated, received the smallpox at the same time, and passed through it in much the same manner, but rather more mildly than one or two of the other instances. The eruption was in every instance distinct and pustular,

though, in one or two, a few vesicles were interspersed.

That erroneous statements upon the subject of a recurrence of smallpox have been very numerous given to the world, is unquestionable; among which we can find little difficulty in placing that of Borelli, containing the history of a woman who recovered from seven distinct attacks of smallpox, and died on the eighth; the antecedent eruptions having doubtless been those of some other exanthem or cutaneous efflorescence; but cases thus clear and incontrovertible are sufficient to establish an occasional departure from the general law, and teach us to look without a scoff upon the assertion of Rhazes and Avicenna, and the far earlier one of Aaron, that the disease occasionally occurs a second, and, in some instances, where there is a strong predisposition to it, even a third time.

A like deviation from the ordinary path of procedure, impresses us in the history of other exanthems. The same general law prevails very strikingly in measles and scarlet fever; but we have also a law of exception; and the exceptions in one disease seem to hold a steady proportion to those in another. They are most frequent in scarlet fever, fewer in measles, and still fewer in smallpox. In plague, the general immunity lasts but for a few weeks; yet some who have recovered seem to be protected for a much longer time, and several for life. In influenza, it extends through the whole duration of the existing epidemic, but the susceptibility recovers itself against the next visitation. In some remittents, as yellow fever, the patient continues little susceptible for many years, perhaps for the whole of his natural existence: in intermittents, the susceptibility, on the contrary, is very generally increased; for the man who has once suffered from an ague, catches it again more readily than another.

A high degree of fever is not necessary to emancipate the system in any exanthem, and consequently not in smallpox. It is upon this principle that inoculation takes its stand in vaccination, as well as variola. Febrile commotion, as we have observed already, though necessary to throw the morbid poison to the surface, is only necessary in a small, and sometimes an almost imperceptible degree; and if it be urged beyond this, the morbid poison will be increased in quantity, the ferment will acquire a wider assimilation, and hence the fever and the eruption always maintain a balance. Provided the entire system submits to the influence of the contagion, the emancipation is always as perfect under a small product as under a large; and it is wonderful to observe how completely this influence extends through every part of the system, often indeed without any disturbance whatever, upon a deposit of the minutest particle of variolous contagion under the cuticle; for we are perpetually witnessing cases, or rather *were*, when variolous inoculation was more frequent, in which a full change has been operated on the entire frame, though the only pustule has been that excited at the puncture; and the individual, before liable to the disease,

is become liable no longer. And that the blood itself, and therefore every particle of the blood, is equally influenced in such circumstances, and even charged with the nature of the virus, is obvious from the frequent communication of the disease from a pregnant woman to the fœtus; and this too at times where the mother is no sufferer from the disease herself.

A remarkable example of this last fact is given by Dr. Mead in the following words:—"A woman who had formerly had the smallpox, and was near her reckoning, nursed her husband who had caught it. At her full time she was delivered of a dead child, whose body was covered over with pustules; a manifest sign that it died of the smallpox before it was brought into the world."—(*De Variolis*, cap. iv.) Mauriceau has another case or two to the same effect (*Sur la Grossesse, et l'Accouchement des Femmes*, obs. 600, et 576); and others have since occurred.*

In these cases there is no assimilation or multiplication of morbid leaven; and influence is indubitably exercised, and that, too, over the entire current of blood, for it could not otherwise reach the fœtus; yet without any sensible effect on the mother. What is the nature of this influence? Is it by an infinitesimal division of the minute drop of contagion inserted into the skin, or that received by the breath? Whatever be the way, it enables us to be less surprised at the mode by which family taints, as gout, scrofula, and phthisis, are transmitted from generation to generation.

Unborn infants do not always receive the smallpox under the same circumstances, nor in every instance even where the pregnant mother sickens with the disease. Sir George Baker, who was indisposed to credit these singularities, refers to two instances, in which the mothers, having been inoculated, had passed through the eruption favourably, and brought forth infants, both of whom, three years afterward, were also inoculated with good effect.—(*Med. Trans.*, vol. ii., art. xix.) From all which we collect, and we can do no more, that a like variation occurs before birth, as we have just observed occurs afterward; and that different individuals, or even the same individual under particular circumstances, evince a different degree of susceptibility; so that the contagion, though resisted at one time, is readily received at another.

There is another feature in the physiology of smallpox that is peculiarly worthy of notice; and that is the power which all deep-seated organs possess of opposing a lodgment of the pustulous inflammation on their own surfaces,

* During the prevalence of the varioloid in New-York in 1822, a highly interesting case occurred: the patient, a young married lady, had been vaccinated when a child: she was affected with varioloid disease six weeks before her accouchement, and was delivered of a dead child, which was covered with smallpox pustules. Smallpox was communicated by inoculation with virus taken from these pustules.—(Sec Hosack's Essays, vol. iii., p. 472.)—D.

and driving it altogether externally, where it can do least mischief. Dissections have abundantly shown, that the viscera and cavities of the interior are never affected with the eruption : except such as, like the skin, are exposed to the approach or ingress of air, as the nose, mouth, trachea and its ramifications, and the entrance of the meatus auditorius. As a general rule, pustules are never found in the rectum ; but, if there be any prolapse, that part of the rectum which concurs in the exposure will share in the common fate of the external parts.*

To what extent variolous contagion is capable of radiating, as it issues into the atmosphere from a diseased body, has never been satisfactorily determined. In laying down the general rules of febrile miasm I ventured to state, that contagion or miasm, generated in the living body, does not appear to be very volatile in any instance, and soon dissolves in a pure atmosphere. The contagion of smallpox seems fully to be governed by this law. When smallpox was more frequent than at present, medical practitioners, though passing casually from house to house, were rarely, if ever, accused of communicating the disease ; and Dr. Haygarth has appealed to an evidence of facts in proof, that the sphere of variolous contagion does not include a diameter of fifteen hundred feet, and probably not a hundredth part of such a diameter.

As the susceptibility of smallpox varies so considerably in different individuals, it is not to be wondered at that the irritability of the system to its influence should vary also, and consequently that there should be some difference in the period of time between the supposed communication of the disease and its appearance by any manifest tokens. Upon the whole, the interval may be calculated to vary from six to twenty-one days in the natural smallpox ; and in the inoculated, which anticipates the action a day or two, from four days to eighteen.

The writers on this disease have subdivided it into an endless multiplicity of forms ; but the four following varieties are sufficient to include the whole :

<i>a</i> Discreta.	Distinct smallpox.
<i>β</i> Confluens.	Confluent smallpox.
<i>γ</i> Degener.	Crystallized-pox.
	Hornpox.
<i>δ</i> Inserta.	Inoculated smallpox.

The pathognomonic characters of the first variety, or **DISTINCT SMALLPOX**, are the follow-

* Andral asserts (*Anat. Pathol.*, tom. ii., p. 225), that variolous pustules have never been noticed in the bowels, though enlarged follicles have sometimes been mistaken for them, especially in children, in whom these organs are always considerably developed. In what are called putrid or malignant cases, the disease, according to Andral, is complicated with gastro-enteritis more or less severe, that has, on the one hand, modified the eruption, and, on the other, reacted upon the centres of the nervous system. After death the digestive tube presents changes, which vary in different instances from slight congestion to complete ulceration.—*Ed.*

ing :—Pustules pea-sized ; distinct, distended, circular ; the intervening spaces red ; the fever ceasing when the eruption is complete.

The disease opens its battery with the usual signs of a febrile cold fit, accompanied with vomiting, and some degree of soreness in the throat.* About the fourth, sometimes on the third day, the eruption begins to appear on the face, neck, and breast, in minute flea-bite spots (*papulæ*), which multiply every night for the ensuing four days, when there is usually a pretty full crop of them over every part of the body, though the face is, in almost all cases, far more covered than any other part ; and that, according to Camper, in the proportion of five to one.† The head, face, hands, and wherever else the pimples show themselves, gradually swell, and the eyelids are often so much distended as to close the eyes and produce blindness ; the spaces between the pimples are reddish, and continue to grow redder as the pimples become pustules and ripen ; the fever is of the caumatic or inflammatory kind, and the suppuration is complete on the eighth day, or thereabouts. On the eleventh, the inflammation and pustules manifestly abate, and the latter, measuring the diameter of a pea, dry away by degrees and scale off, and wholly disappear on the fourteenth or fifteenth day, with the exception of those on the extremities, which, as they come out later, commonly continue a short time longer.‡

Such is the ordinary course : but the symptoms vary greatly in severity according to the degree of fever and extent of the eruption, which, as already observed, hold a pretty accurate balance. Where the pimples are few and scattered, there is but very little indisposition ; but where they are very numerous, though still distinct, the soreness, swelling, and febrile heat are very distressing : and, under this form, the progress of the disease has often been divided

* The patient is first of all generally seized with languor, drowsiness, vomiting, and pain of the head and loins. The pain in the loins, the sickness, and a tenderness of the epigastrium, present themselves in a strongly-marked degree among the incipient symptoms of smallpox.—*Ep.*

† *Les Avantages de l'Inoculation*, &c., Paris, 1782. The small red spots (*papulæ*) rise, as Dr. Elliotson describes, into elevated pimples, and these again into hard tubercles (*tubercæ*). The pimples become pellucid, and, on the fifth day, counting from the first attack of feverishness, headache, &c., they become pustules, with opaque, white, purulent contents, and those which are large are generally depressed in the centre.—*See Lect. at Lond. Univ.*, as published in *Med. Gaz.*, vol. xi., p. 273.—*Ed.*

‡ According to Dr. Elliotson's description, it is on the eighth day that the face swells, and the eyes begin to be closed from inflammation, if there be much eruption. On the eleventh the pustules are at their height, as full and numerous as they will be ; and the swelling of the face, the running of the mouth, and inflammation of the fauces, subside, and then the hands and feet swell ; first the hands, and afterward the feet. Dr. Good has omitted to mention, in his general description, what is termed the *secondary fever*, which occurs when the suppuration of the pustules is complete about the tenth or eleventh day.—*Ed.*

into four stages, an incursive, an eruptive, a maturing, and declining or scabbing (*Frank*, op. cit., tom. iii., p. 159), at each of which it discovers an exacerbation of pyretic symptoms. And when the patient is an infant, it is at these times, and especially on the incursion of the disease, occasionally attacked with a convulsion fit, or perhaps several in succession.*

The grand principle in the treatment of smallpox, as of all the other exanthems that have passed before us, is to moderate and keep under the fever; and, however the plans that have been most celebrated for their success may have varied in particular points, they have uniformly made this principle their pole-star; and have consisted in different modifications of fresh air, cold water, acid liquors, and purgative medicines: heat, cordials, and other stimulants having been abundantly proved to be the most effectual means of exasperating the disease, and endangering life.

Dr. Mead seems to have been almost indifferent as to the kind of purgative employed, and certainly gave no preference to mercurial preparations. His idea was, that all were equally beneficial that would tend to lower the system: "Indicium," says he, "certè satis manifestum, quæcumque materiæ diminutionem, fomitem igni subtrahendo, huic morbo apprimè convenire." And, in this manner, he accounts for the mildness of the malady after any great evacuation, natural or artificial; after acute diseases, immoderate catamenia, childbirth, and salivation.

Mercury, however, appears to have a specific influence upon the action of variolous matter; perhaps, as in the case of syphilis, upon the quality of the matter itself: for though, when considerably diluted with water, it is still capable of propagating the disease by inoculation, yet Von Wënsel has shown satisfactorily that when triturated with calomel it loses its energy, and in inoculation becomes inert and useless. Mercury has hence been denominated, in Germany, remedium pancreston, and has certainly supported its character as the best corrector of the smallpox we are acquainted with, from a period antecedent to the introduction of inoculation into Europe to the present day. "Physicians who attend hospitals," says Sir George Baker, "have frequently observed the smallpox to be particularly mild in those patients who have happened to receive the infection soon after a mercurial pyalism; and inoculation is said to have been a much more successful practice in some of our American colonies since the use of calomel has been there introduced into the preparative regimen." When given as a purgative, it is usually mixed with the powder or resin of jalap, and in this manner acts more briskly.

* On this subject the following remark by Dr. Elliotson is no doubt very correct:—"It is said that one fit forebodes a mild disease, whereas several forebode a severe disease; but I should suppose, that if the child had no fit at all, it would forebode something still better. When the eruption is taking place, if the individual be an adult, there is frequently a great tendency to profuse sweating."—Ed.

Exposure to fresh and cold air is nearly, if not altogether, of as much service as calomel; and hence the advantages of a cool capacious room. Cold water is usually prescribed in large draughts for the same purpose, and very generally proves highly refreshing. The acids, and especially the diluted mineral acids, have a peculiar influence in diminishing the extent of the eruption; inasmuch that some inoculators have been bold enough to prophecy the number of pustules a patient would produce under a given quantity of the acid. Whether any one of the acids has an intrinsic power beyond the rest has never been sufficiently put to the test of inquiry; nor is it clearly ascertained in what way they operate towards the present effect. They are an excellent refrigerant in fevers of all kinds; but, in smallpox, there seems to be a something beyond this power, and they probably restrain the process of assimilation.

Lemonade may conveniently form the common drink during the fever; or a solution of cream of tartar in water, which, as tending to keep the bowels gently open, will be preferable. When the fever is considerable, the purgative should be repeated at each of its exacerbating stages; and if convulsion-fits arise, the spasmodic irritation is best removed by laudanum.*

The pathognomonic characters of the confluent variety are the following: pustules confluent, flaccid, irregularly circumscribed; the intervening spaces pale; with great debility.

In this variety the eruption assumes, at first, the appearance of a general efflorescence, without any distinctive points; innumerable pimples, however, show themselves about the third day, being a day or two sooner than in the discrete variety. They soon coalesce from their thronging number, and become filled, not with pus, but a yellowish serum, for this variety seldom suppurates regularly.† The fever is violent, and exhibits a synchus or typhous type; and, instead of subsiding on the appearance of the eruption, as in the distinct variety, generally increases. The head is oppressed, the eyes inflamed, the brain comatose or delirious. After the eighth day, the detached plicle, covering a large secretion of this virulent fluid, becomes brown, and not yellow as in the distinct sort. Peculiar to the confluent smallpox are salivation in adults, and a looseness in children; the former always attends, the latter more rarely. The spitting begins as soon as the eruption appears, or within a day or two afterward: the saliva is at first thin, and easily and plentifully

* The utmost cleanliness; plenty of clean linen; a mild antiphlogistic diet, in the first instance; cold or tepid abluion, if the body be hot; washing the patient and room with the chlorides; bleeding in adults, if the head be much affected, or, at any rate, the application of leeches; and aperient medicines, are the means of relief specified by Professor Elliotson.—(See Lecture delivered at London University, as published in *Med. Gaz.*, vol. xi., p. 279.) When debility comes on, he recommends wine and stimulants.—Ed.

† Frequently petechiæ, vibices, and ecchymoses are seen between the pustules—red, dark-coloured spots of various sizes.—Ed.

discharged; but towards the eleventh day, which is the period of the greatest danger, it becomes viscid, and is discharged with great difficulty: the looseness in children, however, continues beyond this period.*

When the disease terminates favourably, the swelling of the face about this time begins to abate, and that of the extremities commences. But if the constitution be incapable of counteracting the weakness under which it is suffering, or the mass of disease with which it is oppressed, and particularly the exacerbating or secondary fever, as it is called, which takes place at the stage of maturation, the cuticle suddenly becomes flattened, the features sink, the pustules are depressed; the coma increases, flea-bite spots are sprinkled over the body, succeeded often by hemorrhages; the pulse flutters, and the patient expires; usually, as already observed, about the eleventh, but sometimes not till the sixteenth day.

In the commencement of this variety, the same reductent plan is to be pursued as already recommended in the preceding variety; and the affusion of cold water may be added to a free use of fresh and even cold air. Bleeding is a doubtful remedy, and its propriety must entirely depend upon the constitution or habit of the individual, and the nature of the prevailing epidemic. In a state of high entonic health, and firm elastic fibre, it may be allowed, and perhaps repeatedly: but we should always bear in mind, first, that the plenitude of the disease does not so much depend upon the strength or weakness of the frame, as upon its susceptibility of the contagion, and irritability beneath its action; and next, that in confluent smallpox the process of maturation does not take place kindly or perfectly, and that the fever, often a synochus, has always a tendency to run into a typhus, particularly when the temperament of the atmosphere predisposes to this type. On this account, it will often be found necessary, and particularly towards the stage of maturation, to support the tone of the system instead of reducing it. Camphire offers us one of the medicines for this purpose; and may be given in solution, or in the form of pills. The latter is generally the most convenient, as it can thus be taken in a larger quantity, and needs not interfere with ammoniacal neutrals, ethereal compounds, the acidulated decoction of cinchona, or the same tonic in a more powerful form. If, indeed, on the accession of the secondary fever, the pulse should suddenly sink, the pustules flatten, and the surface turn pallid or purple, wine must be added to the other remedies, blisters or sinapisms applied to the feet or legs; and, if a diarrhœa should supervene, opium be administered; though, in the earlier stages of the disease, this last symptom should be very cautiously interfered with. Some part of the secondary fever may probably be set down to

* Sometimes there is bloody urine, or blood in the motions. Blindness, phthisis, and diarrhœa, ending in ulceration of the intestines, are more frequent consequences of *V. confuens* than of *V. discreta*.—Ed.

the score of the absorbed virus, now thrown back upon the blood from every part of the surface: and, to disarm this source of exacerbatation, it may be convenient to open the pustules as they ripen, and let them discharge their contents externally. And, to save the face as much as possible from those exulcerations of the true skin that terminate in pits and scars, a piece of fine linen or cambric, over which some cetaceous cerate has been spread, should be applied.

Smallpox, then, may well be contemplated as a fearful disease. It is so at all times from the uncertainty of its prognosis, but especially when it assumes a severe character.* And it is so, moreover, not merely on account of its own ravage, but of the tendency it produces to subsequent evils, after its own course has subsided. In many cases, the constitution is incapable of recovering from the general disturbance and debility it has introduced, and hence atrophy, dropsy, and hectic are by no means uncommon results. But it more frequently proves mischievous by stirring up some hereditary taint that might otherwise lie quiet through life; and, in this way, becomes an exciting cause of scrofula, consumption, and gout.

The HORN or CRYSTALLINE-POCK it is only necessary to notice, as forming a somewhat singular departure from the usual course of the disease, though not often accompanied with danger, or distinguished by an overloading eruption. Its pathognomonic characters are set down in the Nosological Synopsis as follows:—pimples imperfectly suppurating, ichorous or horny, and semi-transparent.

From some unknown cause, the variolous fluid is, in this variety, secreted and thrown upon the surface in the form of lymph, and is never exchanged for that of pus. As the finer part of the fluid is absorbed, it loses its pellucidity, and the vesicular pimples appear whitish, and preserve this hue till they dry and peel off. This is particularly the case in persons of a fair and delicate skin; but, where the skin is darker or coarser, they become brown, hard, and horny: and hence it is always in this way that the present variety terminates among negroes. Whenever smallpox occurs a second time, it usually shows a tendency to this modification.

It is not a little singular, that Professor Frank should have separated this form of the disease from smallpox, and made it, together with varicella, as already observed, a modification of pemphigus,—(*De Cur. Hom. Morb. Epi.*, tom. iii., p. 264.) What landmark can the student find when the boundaries of diseases are thus disastrously broken up?

The fourth variety under which smallpox is to be found, is the artificial modification known by the name of INOCULATION: a most important

* The late Mr. Alcock drew Dr. Elliotson's attention to the fact, that the mucous membrane of the larynx and trachea is frequently much inflamed in smallpox, and that there is an effusion of a very thick tenacious mucus from it, such as produces a degree of obstruction in those tubes, that may have some considerable share in occasioning the fatal result of the disease in children.—Ed.

advantage to mankind before they were acquainted with the equal or nearly equal protection afforded by the virus of cowpox; when, in the language of Professor Frank, “ad illud tandem se reductos viderunt; ut victas huic pesti manus traderent, et sic, quasi dæmoni, quo sibi esset propitior, sacrificarent.”—(Op. cit., tom. 101, p. 334.)

Its peculiar characters are thus described in the volume of Nosology;—orange-coloured areola about the puncture; pain in the axilla about the seventh day; disease mostly mild; and the purulent discharge sometimes confined to the punctured parts.

This mode of communicating the disease, like the natural disease itself, appears to have reached Europe from the east, and especially from China; where, according to the statements of the Jesuits, (*Lettres Edifiantes et Curieuses*, &c., passim), it has been practised immemorably by perhaps the simplest and best means of communication that has hitherto been devised,—that of a needle charged with the contagious matter of a pustule, and introduced transversely under the cuticle. From China the discovery appears to have travelled into India, and thence to Asia Minor. It is not easy to conjecture how it arrived among the ancient native tribes of Africa, as we know so little of their arriving there themselves. It shows, however, that the disease itself is of very high antiquity, though it does not seem to have travelled in a very early period of the world into Europe; unless, indeed, we ascribe to it various sources of origin, which is accompanied with the difficulty of our not knowing where to stop the moment we embrace such a doctrine; for if we once indulge in a plural number, there is nothing to prevent our carrying such number on to infinity. That the disease, however, has from an early period existed in Africa, and has also been counteracted by the employment of a rude kind of inoculation, is now clear from the narrative of Mr. Campbell, whose veracity will not lightly be called in question; and who tells us, that he found both the smallpox and the practice of inoculation in use among the Marootzee, or inhabitants of the city of Kurreechane, about a degree and a half to the northward of De la Goa Bay, or 24½° south latitude. Here the rivers, which before ran westward, were found to flow towards the east, evidently proving, that he had reached the loftiest point of this part of the continent. The natives, it seems, have a tradition that they procured the variolous matter, or rather learned the art, from a people to the northeast called Mahalatyela, who ride upon elephants. They make the incision between the eyebrows. The Booshuanas, however, inoculate also for the smallpox.—(*Travels in South Africa*, &c., 2 vols. 8vo., 1822.)

The first employment of inoculation in our own country seems to have been the result of some fortunate observation, made, like that of cowpox inoculation, in the rudest parts of it; for the practice of “buying” the smallpox, which was in fact a communication of the disease by insertion, was prevalent in Wales at a very early

period, and appears to have been also occasionally resorted to in the Highlands of Scotland, from an antiquity nearly as remote; of which abundant proofs are to be found in various articles in the Philosophical Transactions.—(See vol. xxxii., years 1722–3, and especially Dr. Williams's account.) All such practice, however, and even the knowledge of it, seems to have been confined to the remote quarters in which it accidentally arose, as late as the year 1721, when Lady Mary Montague, who had witnessed its success in Turkey, and had had a son successfully inoculated there, submitted an infant daughter to the same process at this time in London. Yet, so little acquainted with its success were the public, and even the medical profession at this period, and so cautious in giving it credit, that an experiment of its effect was ordered to be made in the same year on six condemned criminals, all of whom were fortunate enough to recover, and who thus redeemed their lives. This gave countenance to further attempts; yet the innovation, like that of inoculation from cowpox, was sharply and pertinaciously opposed, and not more than seven hundred and sixty-four persons, according to Dr. Jurin's calculation, were inoculated all over England from 1722 to 1727.*

Unfortunately, the practice of treating the disease with cordials and a hot regimen at this time prevailed, and was too generally applied to the inoculated as well as to the natural process, by means of which the former was often rendered a severe, and, in many cases, a fatal disease; though it was impossible for the duller intellect to be altogether insensible to its high comparative advantages. By degrees, however, the refrigerant and reducing plan obtained a triumph, and the triumph of inoculation was a synchronous step. Yet half a century afterward the exploded plan was still persevered in by some practitioners, and it is instructive to mark the comparative mischief that still accompanied it. “I found,” says Sir George

* The bold experiment of inoculation for the smallpox was received very differently in North America. About the time this practice was introduced into Great Britain, Dr. Zabdiel Boylston, of Boston, Mass., adopted inoculation at the suggestion of Cotton Mather, who informed him of the Turkish practice. Inoculation was first performed in Great Britain, on Lady Montague's daughter, in April, 1721; and on the 27th of June ensuing, Dr. Boylston inoculated first his own son, then thirteen years old, and afterward his two negro servants, in which he was completely successful. “This had the happy tendency,” says Dr. Thacher, “not only to confirm in his own mind the safety and utility of inoculation, but in some degree to quiet the fears of others. In 1721 and the first part of 1722, Dr. Boylston inoculated two hundred and fifty-seven persons, and thirty-nine were inoculated by other persons in Boston and its vicinity; of this number six only died, and several of these were supposed to have taken the infection before inoculation. In the same period, 5759 took the disease in the natural way, of whom 844 died.”—See Boylston's account of the practice of Inoculation in America, in Thacher's American Biography.—D.

Baker, writing in 1771, "that in the counties of Essex, Norfolk, and Suffolk, many thousands of people, of all ages and constitutions, and some of them of every apparent disadvantage, had been inoculated with general good success: whereas, at Blandford, in Dorsetshire, out of three hundred and eighty-four persons who were inoculated, thirteen actually died, and many others narrowly escaped with their lives from the confluent smallpox."^{*} This gives us a direct mortality of something more than one in thirty; and it is almost needless to add, that, in the successful districts here alluded to, the cooling plan was prevalent, and at Blandford that of hot beds and a warm regimen.

Even this result, however, with all its fatality, offers a wonderful improvement upon the march of natural smallpox; in which one out of every three or four have been computed to die among adults, and one out of every seven among infants; while, wherever the cooling and reducent plan has co-operated with inoculation, the casualties are not more than one in five or six hundred.

Yet, great as is the intrinsic advantage of inoculation, even upon its lowest scale, there is one evil which has always accompanied it, and which, in a nation so justly proud of its civil liberties as Great Britain, it is almost impossible to provide against; and that is, the wider diffusion of variolous contagion through the atmosphere by the indiscriminate use of inoculation in all places. And hence it has been very forcibly observed in our own day, by those who have written most warmly in favour of vaccination, that smallpox inoculation is upon this ground a greater public evil than good; since the multitude who will not consent to be inoculated, receiving the natural disease more generally than they otherwise would do, the total mortality is greater than before inoculation was had recourse to. I was at first induced to think, that this statement was a little too highly coloured for a particular and present purpose. But, on turning to Baron Diinsdale's tables of calculation drawn up nearly fifty years ago, I find him arriving at the very same conclusion; and we may fairly affirm, that the deaths from smallpox, since the introduction of inoculation, have increased in consequence of the more extensive diffusion of variolous contagion in the proportion of fourteen or fifteen upon every hundred. The bills of mortality indeed give us something more than this.

By what means variolous contagion, received by a puncture, becomes so much milder than when received from the atmosphere, is a problem that has never been satisfactorily solved. Something is unquestionably due to the preparatory process of purgatives and a reducent regimen; but as the same mildness of character does not obtain in the natural disease, where the same preparation has been submitted to antecedently, some other power must be sought for. Under inoculation, and with the usual pre-

cautions, the eruption is commonly distinct and widely scattered; yet the most striking character in the inoculated form is, that when the eruption is full, and even confluent, the secondary fever, so alarming in the natural disease, is here for the most part slight, and sometimes altogether absent. This exacerbation is usually ascribed to an absorption of the contagion from the pustules; but the feature before us shows, that there must be a something distinct from absorption, though perhaps acting in union with it. Is the virus from the first less irritant, and less capable of exciting much secondary fever, for the very reason that it was less capable of exciting much primary?

It is on this account that variolous inoculation may be submitted to without danger, by feeble infancy, advanced age, and even cachectic habits in every stage of life; and that the season of the year does not seem to be a matter of great importance. Pregnant women, however, ought never to be exposed to it, nor infants, where there is a choice, till after the irritation of teething.

The operation is perfectly simple: the needle, originally employed in the east, is as good an instrument as any, though the lancet is generally preferred. It is only necessary to deposite a minute drop of the contagion under the cuticle, or at least to make such a wound as may give forth a single drop of blood. It is preferable to take the fluid before the pustule suppurates; as afterward it seems to partake of the nature of common pus as well, and produces a larger circle of inflammation, and, on this account, also, it cannot so fully be relied on. The puncture does not so completely disappear as in that with vaccine fluid, but it is often scarcely visible for three or four days. At this period a minute papula may be traced, a little itching is felt, and sometimes there is a slight inflammation. On the sixth day, a pain and weight are felt in the axilla, proving that the lymphatics of the arm have become affected, and that the virus is conveyed into the system. On the seventh or eighth day, the precursive symptoms of transient shiverings, headache, and pain in the back are perceived, and immediately followed by the eruption itself; though mostly, in this mild form of the disease, the only eruption, as in the inoculated vaccinia, is the pustule on the puncture, or a few which directly surround it. Where the disease spends itself in this manner, the local efflorescence commonly spreads over a larger area than otherwise, and the adjoining lymphatics participating in the irritation, the tenderness and sense of weight are increased in the axilla. Where the symptoms are unfavourable, there is a purplish, instead of a rosy inflammation, or a narrow, deep-red circle surrounding the puncture, with a dip or depression in the pustule.*

The treatment is to be the same as that already pointed out for the natural disease; but

* Med. Trans., vol. ii., art. xix. Compare M. Gatti's *Nouvelles Reflexions sur la Pratique de l'Inoculation*, Paris, 1770.

* Dr. J. D. Fisher, of Boston, has published an excellent work on the smallpox, in which the different stages of this disease, &c., are illustrated by coloured plates.—D.

it should vary with the habit, constitution, or age of the individual. Sufficient attention was not always given to this remark formerly: for the preparatory regimen was a bed of Procrustes, to which every one was alike compelled to adapt himself. Sir George Baker openly complained of this inconsistency in his own day (*Med. Transac.*, vol. ii., p. 282); but notwithstanding his censure, it was very generally continued.*

GENUS IV.

ANTHRACIA.

CARBUNCULAR EXANTHEM.

ERUPTION OF TUMOURS IMPERFECTLY SUPPURATING, WITH INDURATING EDGES, AND, FOR THE MOST PART, A SORDID AND SANIOUS CORE.

THE present genus, denominated ANTHRACIA, from ἀνθραξ, "a burning coal," by its definition embraces two diseases of very different specific characters, though closely according in their generic marks. These are,

- | | |
|----------------------|---------|
| 1. Anthracia Pestis. | Plague. |
| 2. ——— Rubula. | Yaws. |

There have been, however, and still continue to be, great disputes among the nosologists as to the proper station of both these species, many contending that plague ought not to be regarded as an exanthem, and most writers having hitherto contemplated yaws as an impetigo, or some other dysthetic affection. Dr. Cullen has expressed a doubt whether the first should not be removed from the order of exanthems into that of fevers; Vogel has actually introduced it into this last order; Willan has rejected it from the exanthems. Parr arranges it as an exanthem in his article *Nosology*, having previously, like Willan, rejected it from that division in his article *Cutanei Morbi*. In his remarks subjoined to the article *Nosology*, he again acknowledges that "on reflection it appears improper" to introduce it into the list of exanthems; and, in his article *Pestis*, he asserts more roundly that "there is no foundation for arranging plague among the exanthemata, and that it should be reduced to the asthenic

remittents." Sauvages, Linnéus, Sagar, and Macbride, have entered it in the order in which we have placed it in the present system.

In a few words, there appears strong and almost incontrovertible reason for thus placing it. The fever, as will presently be shown, is eruptive, and as specifically so as that of any of the exanthems; it is contagious like most of them, and, although frequently occurring oftener than once in a man's life, we have the concurrent testimony of all the writers who have been eye-witnesses of its effects, that it renders every one less susceptible for a certain period afterward, and some for the whole term of their existence.

With respect to yaws, the diversity of opinion has been quite as considerable as that respecting plague. Generally speaking, it has been placed in the loose and indeterminate class which has been distinguished by the name of cachexies; Sauvages and Sagar arrange it in the order tubera of this class; Cullen in that of impetigines. These writers take little or no notice of any kind of febrile features that accompany it, whether specific or sympathetic. Dr. Young pays as little attention to the febrile symptoms by which it is said to be distinguished, and, at the same time, transfers it from the division of cachexies (*cachochymia*, as he denominates them) to the order of paramorphiæ or structural diseases. Dr. Winterbottom and Dr. Dance, on the contrary, contend that a slight fever is its primary symptom; and Dr. Ludford, to whom we are indebted for, perhaps, the best history which has yet been given of this disease, describes it as a proper eruptive fever, totally unconnected with diet, lues, or any other taint in the blood; commencing with alternations of shivering and heat, lassitude, want of appetite, and pains in the head and loins to so great a degree as to prevent sleep; the fever and every inconvenience diminishing after the eruption, and the appetite returning. So that, like smallpox, it appears to have a regular accession, height, and decline, and, as already observed, may be propagated by inoculation, and is never known to occur a second time. Hence Parr, who seems to have long wavered in his opinion concerning the real nature of this disease, regarding it at one time as a *pustulosus exanthem*, and afterward as a mere *cuticular intumescence*, returned at last with a decided mind to his first opinion, and again asserts that "the detail of symptoms shows that the disease is truly exanthematous."

This view of the subject will therefore abundantly justify the present arrangement of both these diseases, support their pretensions to the character of carbuncular exanthems, and consequently develop the nature of the connexion of yaws with plague, under a nosological method founded on the principle of symptoms. In their individual or specific characters, they are, indeed, highly discrepant; but this is not sufficient to call for a separation, while they agree in the common outline that may form the basis of a generic division. The tall and stately acacia of Egypt, and the delicate sensitive plant of our

* As, in smallpox, the inflammation frequently extends to the eyes, opacity of the cornea, staphyloma, and blindness may be the consequences, especially when a pustule has formed on the eye itself. The smallpox frequently leaves the constitution in a state in which scrofula is disposed to arise; the glands of the neck or mesentery enlarge, or phthisis comes on. Frequently, says Dr. Elliotson, it leaves after it rupia and ecthyma, diarrhoea, and chronic inflammation of the mucous membrane of the intestines.

For the prevention of *pitting*, various plans have been suggested. In the hospital at New-Orleans, in 1830, Dr. Pictou kept the smallpox patients excluded from the light, and not one of them exhibited a pit or mark on the body.—(See *Am. Journ. of Med. Sc.*, vol. x., p. 119.) Pricking the pustules with a fine needle has been favourably spoken of. Mr. George, of Kensington, has published some observations in favour of covering the pustules of confluent smallpox, situated on the face, with calamine.—See *Med. Gaz.*, vols. x. and xi.—Ed.

own green-houses, belong to the same genus in botany, however inaccordant they may appear to the eye of an ordinary spectator.

TUMOURS BUBONOUS, CARBUNCULAR, OR BOTH ;
APPEARING AT AN UNCERTAIN TIME OF THE
DISEASE : EYES WITH A MUDDY GLISTENING ;
FEVER A MALIGNANT TYPHUS, WITH EXTREME
INTERNAL HEAT AND DEBILITY ; CONTAGIOUS.*

It is happy for us that, in describing this dreadful scourge, we are under the necessity of referring to foreign countries, or to remote periods in the history of our own, before the great advantage of public cleanliness and ventilation in our streets was sufficiently attended to, or even known. The earliest visitation of the plague that occurs in English history was in the year 430 ; the last time it appeared as an epidemic was in 1665, and the last notice of it in the bills of mortality was in 1679. In Edinburgh it has not prevailed subsequently to 1645, long since which period it has repeatedly ravaged all the continent of Europe, east, west, north, and south.†

From the diversified and clashing accounts that are given of this disease by different writers and eyewitnesses in different ages, or different parts of the world, we are justified in laying down the three following varieties, which, while they offer the chief points of discrepancy, will be found in their explanation to reconcile the seeming discordances of established authorities.

a Fructifera. The disease extending to
Common plague. about the fourteenth day ;

* "The difficulty of presenting a definition applicable to all cases may be conceived from the fact, that the disease varies greatly in its appearance in different instances ; insomuch, that even fever is by no means invariably present ; and, in rapid cases, death terminates their course before a sufficient time has elapsed to admit of the formation of buboes and carbuncles."—(Bateman, in Rees's Cyclop., art. PLAGUE.) The following is Dr. Joseph Brown's definition :—"An exanthematous disease, consisting of buboes, carbuncles, and pustules, white, livid, or black, distributed in various parts of the body, and generally attended with malignant and very fatal fever."—Cyclop. of Pract. Med.

† Marseilles, which had previously suffered twenty severe visitations in the course of seventeen centuries, was ravaged by it again in 1720. Moscow suffered cruelly from it in 1771 and 1772 ; and it prevailed at Noja, in the Neapolitan territories, as late as 1815 and 1816. It appeared in the Lazaretto of Venice in 1818 ; and at Gressenberg, in Silesia, in 1819. In the year 1813 it raged at Malta. With these exceptions, it has of late generally been confined to the northern parts of Africa, the reputed land of its origin, and to those portions of Asia and Europe which are, or have been, under the dominion of Turkey.—See the art. PLAGUE, by Dr. Brown, in Cyclop. of Pract. Med.—Ed.

and relieved by the appearance of the eruption.
β Infructifera. The eruption imperfect or
Unruptive plague. suppressed ; transferred to some internal organ ; or superseded externally by stigmata and vibices.
γ Erythematica. The body covered over with
Erythematous trails of vesicular erythema, producing deep, sanious, and gangrenous ulcerations as it spreads, often to the loss of one or more limbs.

The whole of these varieties have sometimes been exhibited in the same epidemic ; the last, however, is the least frequent, whether alone or in conjunction with the rest. All of them appear to have been present and intermixed in the Aleppo plague of 1660–1–2, so clearly and strikingly described by Dr. Patrick Russell, physician at the time to the British factory established at that city ; for he speaks of the pestilential eruptions appearing under the form of buboes, carbuncles, or other exanthemata ; among which last he takes particular notice of an erysipelatous redness, forming streaks of a reddish purple or livid colour, intermixed with vibices and wheals, or large blue and purple spots, the maculæ magnæ of authors ; while, in some cases, he observes that an extraordinary concurrence of these eruptions took place, which, however, was chiefly remarked among children under ten years of age.

In the Barbary plague of 1799 and 1800, so fully and excellently described by Mr. Jackson (*Account of the Empire of Morocco, &c.*, 4to., 1809), who was an eyewitness to its effects,—the first and second of the two varieties here offered, the fructiferous and infructiferous, were intermixed, while the erythematic seems to have been absent. It was probably absent also in the plague of Moscow of the year 1771, as it is not noticed by Dr. Mertens, who gives a full description of both the other modifications. In the London plague of 1665, all of them seem to have occurred occasionally ; the first and the second, however, most frequently, examples of which are to be found in Hodges, Sydenham, Sir Gideon Harvey (*City Remembrancer*, passim), and indeed all the writers ; while, in allusion to the last, Sydenham compares the inflammation of the plague, as it often appeared, to that of an ignis sacer, by which he means an erysipelas ; in which nature, he tells us, expels the matter of the disease from the blood to slightly elevated tumours dispersed over the surface in broad red patches : only that this *ignis*, says he, is more violent than the ignis sacer (*Febbris Pestilens, et Pestis Opp.*, sec. ii., class ii.) :—"ignis noster isto sacro longè divinius est." They seem also to have co-existed in the Neapolitan plague, or rather that of Noya, in 1815, for the police regulations,* as well as the med-

* Giornale di tutti Atti, Discussioni, e Determinazione della Sopra-intendenza Generale e Su-

ical descriptions, have a reference to each of these in very distinct terms.*

In the plague of Athens, on the contrary, as described by Thucydides and Lucretius, we are not sure of the existence of buboes, as not being distinctly noticed, though probably included in the inflammations that are stated to have fallen upon the privities (*τὰ αἰδοῖα*), while the last two varieties were perpetually intermixed; the chief eruption, however, being that of the vesicular erythema, the sacer ignis, or holy fire, as observed by Sydenham. In consequence of which, Thucydides tells us, that "the surface of the body was neither violently hot nor wan; but reddish, livid, and covered over with an efflorescence of minute vesicles and ulcers,"—*φλυκταίναις μικραῖς καὶ ἰλκείν*:—but that the interior parts were so burning that the sick could not endure the lightest covering or clothes, and eagerly threw themselves into cold water. And he adds, that the disease, in its ulcerative progress, commencing in the head or the upper parts of the body, migrated over the entire frame, and often fixed itself permanently on the sexual organs, the hands, or the feet (*Hist.*, lib. ii., 50): the whole of which course is by Lucretius described under the express name of *sacer ignis*, or *holy fire*.—(*De Rer. Nat.*, vi., 1164.)†

"Et simul, ulceribus quasi inustis, omne rubere Corpus, ut est, per membra SACER quom diditur IGNIS."

One of the severest attacks of plague which Rome was ever afflicted, was that which made its appearance about the middle of the second century of the Christian era, and is supposed to have been introduced into Italy by the army of Lucius Varus, on its return from Parthia. It is loosely but frequently glanced at by Galen, who adverts on different occasions to various cases in which he was consulted. It was

* Ragguaglio Istorico della Peste sviluppata in Noya nell'anno 1815. Napoli, 1816.

† The descriptions given by Thucydides and Lucretius, being very imperfect in a medical point of view, certainly will not justify a positive inference that the fatal disorder at Athens was the plague. Dr. Bateman believed that the account, as far as it goes, even proves that the epidemic was not the true plague, since glandular swellings are not enumerated among the symptoms. The description of the state of the skin, indeed, seemed to him, as well as Dr. Willan, to convey the suspicion of smallpox: for it is said to have been reddish or livid, with an eruption of small pustules, or sores.—(Thucyd., lib. ii., sect. xlix.) Some of the plagues mentioned by Livy do not appear to have been accompanied by the glandular tumours and carbuncles of the true plague.—(Rees's Cyclop., art. PLAGUE.) Now although a few examples of true plague are not attended with buboes and carbuncles, the editor believes, that, in modern times, if any fatal epidemic or contagious disease were to originate, generally or invariably unattended with those symptoms, it would not be regarded by any medical men of the present day as the true plague. Hildebrand adopts the opinion of Haller, that the Athenian plague of Thucydides was only a malignant typhus.—Über d. Ansteck. Typhus, p. 22.—Ed

a direct counterpart of the Athenian plague, and hence we meet with all the characteristic symptoms just enumerated. "The body," he tells us, "was stigmatized with ulcerating eruptions (*Meth. Med.*, lib. ii., cap. xii.), (*ἕξανθρον ἰλκείν*), which were often livid, and ramified in every direction; while there was no increase of heat to the touch, even when the patient felt as if burnt up with an internal fire. The discharge from the bowels was, at the beginning, and during the augmentation of the disorder, yellow or reddish, but afterward black, like dregs of blood.—(*De Præsg. ex Pulsu*, cap. iv.) The pulse was in many instances not much affected, but there was great thirst, and an urgent desire for cold water." And he adds, shortly afterward, a symptom distinctly noticed by Thucydides and Lucretius, "that from the peculiar stupor of the head, the patient, for a long time afterward, knew neither himself nor his friends around him."—(*De Præsg. ex Pulsu*, cap. v.)

Eusebius has given us a similar account of the tremendous plague which raged over Syria, A. D. 302, in which, however, he more expressly notices, that the SACER IGNIS was intermixed with the CARBUNCLES, and made a dreadful havoc on the bodies even of the few who lived through the disease; very generally fixing upon their eyes, and rendering them totally blind.—(*Hist. Eccles.*, lib. vii., cap. xvii.; ix., cap. viii.) In the correct rendering of his interpreter Rufinus, "Aeris quoque temperies in tantam corruptionem versa est, ut humana corpora ulceribus pessimis, quæ IGNIS SACER appellantur, necnon et his qui dicuntur CARBUNCULI, replerentur, ita ut ora hominum atque oculos occuparent, et ut siquis forte ex his effugisset mortem, luminibus orbaretur."

In the still more severe and extensive plague which prevailed in the reign of Justinian, A. D. 540, and which ravaged the greater part of Europe and Asia for at least half a century, all the varieties enumerated in the present classification appear to have either co-existed or alternated. It commenced, however, according to Agathias, "in its old form," or with buboes as a prominent and early symptom; which chiefly appeared, as Procopius tells us, in the groins, the armpits, or behind the ears, and were attended with violent fever and stupor, or phrenitis. "The carbuncle," he adds, "did not always show itself, but, on opening a patient's body after his decease, it was detected in an incipient state." Yet, from the diversity of character the disease at length assumed in different individuals, and after it had spread to an illimitable extent, we are informed by Evagrius, that though it still continued to be regarded as one and the same malady, it seemed to consist of numerous disorders. In some, like the Athenian plague, as already copied from Thucydides, it commenced in the head, inflamed the eyes, and tumefied the face, then descended into the throat, and destroyed them. In others, there was a violent flux; and in others again, buboes arose, accompanied with a most malignant fever. Not unfrequently, the patient died on the second or third day, with little mental or corporeal suffer-

ing. Some became comatose, and suddenly perished in this state; while an efflorescence of the ignis sacer destroyed multitudes.

Dr. Willan, in his posthumous volume published by Dr. Ashby Smith, has taken great pains to show that the last or erythematous variety, which, by the Greek physicians, was often distinguished by the specific name of ANTHRAX or ANTHRACES, was the confluent and ulcerative smallpox of the present day, which he conceives was as well known to the Greeks as to ourselves. It is not necessary to go over this question again, as the author has already examined it at large in the section on VARIOLA; where he has endeavoured to prove, that we have no real ground for believing that either the Greek or Latin physicians were acquainted with this last disease under any form. It is sufficient for the present purpose to remark, that, even in what may be called our own times, both these diseases, the smallpox and erythematous plague, have made their appearance at different dates in the same countries, and under the eye of the same physicians—men whose skill and judgment have received the homage of universal assent—who have never dreamed of confounding or amalgamating them, but have distinctly described the one as a variety of proper plague, and the other as the smallpox, in the ordinary sense of the term; each produced by its own specific contagion, and keeping true to its own symptoms and progress. Such are both the Russells, Forestus (Lib. vi., obs. xi., xii., Schol.), Diemerbroeck, Geoffroy of Provence (*Traité de la Peste*, pp. 1, 436), Gotwald of Dantzic, Hodges, and, as already observed, Sydenham. The trailing vesications, which constitute the erythematous variety, are called PAPULÆ ARDENTES by Gotwald, in describing the Dantzic plague, which term Dr. Goodwin has correctly translated FIRE-BLADDERS. In their origin, however, they were often as minute as a millet-seed, and when large were, in Holland, denominated GRANUM PIPERIS.

When they were of larger magnitude, there was sometimes a difficulty in distinguishing them from proper carbuncles; whence, by many writers, the two are confounded or described under a common name. Hodges very properly made a distinction between them, but Forestus and Gotwald arrange them as only modifications of one and the same eruption, and Dr. Patrick Russell seems partly inclined to contemplate them in a similar light, though he speaks doubtfully. "The same eruption," says he, "appears under various forms, as it happens to be viewed in its different stages; and hence, perhaps, the varieties of the carbuncle have sometimes been erroneously multiplied. I will not be confident of not having fallen into the like mistake."—(*Treatise of the Plague*, book i., chap. iv., p. 121.)

Gotwald makes not less than four varieties of the carbuncle, as he traced it in the plague at Dantzic in 1709. It is the last of these that constitutes the erythematous form before us. "It is," says he, "the most curious, as Purman, in his Treatise of the Plague, has well observed. Sutorius calls them pale, livid, ulcerous papulæ:

they appear with a high, yellow blister, which seems full of corruption: the circle round it is first red, then of an ash colour; the blister soon falls, and with the carbuncle, appears scarce so big as a pepper-corn, continually eating deeper and wider."—(*Hist. Account of the Plague*, &c., p. 49, by N. Goodwin, M. D., London, 1743.)

To the same effect Forestus:—"Carbunculus ferè autem oritur ex pustula exili, milii seminis magnitudine: interdum vero multi prosiliunt, primò quidem pruritù, deinde rubore, ardore, doloreque vehementi. Hoc verò sensim incremente, pars uritur, crustosumque ulcus quasi candenti ferro inducitur, idque vel nigrum, vel cinereum."—(Lib. vi., obs. xi., Schol.) To which he adds, in another place, "et in ore eorum cernes aliquid pestilentis coloris cum partim *erysipelatosum*, partim colorem habent *depasscentibus serpentibus similem per plures partes diffusam*."—(Forestus, obs. xii., Schol.) And in proof that the same variety of eruption did occur also in the plague of London, to the testimony already offered of Sydenham, it will be sufficient to add the following of Hodges. "There were occasionally," says he, "vesications, of size from a pea to a nutmeg, encompassed with a variegated circle, generally reddish. They arose with exquisite and shooting pain, and contained an ichor of a yellowish or straw colour, which was so acrid or caustic, that it soon corroded the vesicle and burst out, of a colour yellowish, livid, or black. These pustules broke out in many parts of the body; their station and number being uncertain: sometimes few, sometimes many: in one case, the whole body was covered all over with them."—(Loimolog., p. 110.)

It is impossible that these writers could be mistaken in the nature of the complaint, and have regarded that as plague which was really smallpox: and as they describe, in these passages, the very lineaments of the Athenian plague and other erythematous forms of it among ancient nations, there is no reason whatever for conceiving the physicians of Greece and Rome to have been more deceived than those of recent times.

The greater part of these passages precisely correspond with the character of the *erysipelas pestilens* of Lorrain, delineated under this name by Sauvages, who has copied freely both from Sydenham and Hoffmann; but which, though he calls it an erysipelas, had, as he admits, the closest affinity with plague in its most malignant form,—"*cum atrocissimo morbo pestilenti summam affinitatem habet*;" and was in reality this disease in the form before us. "Each," says he, "commences with horror, burning heat, delirium, prostration of strength, vehement pain of the back and head; in each, the burning matter of the disease breaks forth, on the fourth day, on the axillary or inguinal glands, and spreads to the feet in the form of the ignis sacer; in the glands it produces abscesses; in the extremities gangrene." It is the *mal des ardens* of the French writers; and, in its malignant variety, the *erysipelas gangrænosum* of Willan. Much of this difference,

however, seems to be dependant upon local or accidental circumstances, and especially upon the state or constitution of the atmosphere. Thus we are told by Sir James M'Grigor, that when the plague first broke out in the Indian army in the course of its laborious expedition to Egypt, the cases sent from the crowded hospitals of the 61st and 88th regiments were, from the commencement, attended with typhous symptoms; while those from the Bengal volunteer battalion, and the other corps encamped near the marshes of El-Hamed, evinced uniformly an intermittent or remittent type; and those that occurred in the cold and rainy months of December and January, an inflammatory character; after which, as the weather became warmer, the disease at Cairo, Ghiza, Boulac, and the isthmus of Suez, wore the form of a mild continued fever.—(*Med. Sk. of the Expedition, &c.*)

The plague of London in 1665, was, in like manner, distinguished by a peculiar constitution of the atmosphere, which excited an epidemic synochus of great violence and danger, often accompanied with symptoms of rheumatism or pleurisy, and which seems to have added considerably to the progress and mortality of the plague. Sydenham expressly calls it a pestilential fever, *febris pestilentialis*; and adds, that the fever of the plague, after it had broken out, so completely assimilated itself to its character, that, in the second or infructiferous variety, it was extremely difficult to distinguish between the one and the other.—(Sect. ii., cap. i.)

In like manner Thucydides expressly tells us, that whatever incidental complaint any person was labouring under during the plague at Athens, it was sure to run into this disease, which swallowed up every other. Yet he adds, that at the commencement of the plague, complaints of all kinds were peculiarly uncommon; insomuch that, by the acknowledgment of every one, the year seemed to have enjoyed a general immunity.—(*Hist.*, lib. ii., 49.)

The plague at London first attracted attention about midsummer, and augmented in its destructive ravage till the autumnal equinox, at which time about eight thousand died within the bills of mortality in the space of a week, though two thirds of the inhabitants, at least, had fled into the country to avoid the infection. From this time, it suddenly put on a milder character, and made fewer attacks; nearly ceased, as is uniformly the case, with the cold of the winter; and totally vanished by the spring; the epidemic fever, nevertheless, remained for a twelve-month longer, though this also was both less common and less virulent.

As Sir Gilbert Blane observes, it is uncontestedly established by the experience of ages, that the disease of the plague cannot co-exist with a heat of atmosphere above 80°, nor a little below 60°.—(*Select Dissertations, &c.*, p. 314,

8vo., 1822.) It never fails to disappear in Egypt at the summer solstice, the heat being then pretty uniformly at 80° or upwards. Its chief prevalence, therefore, is in Lower Egypt. It is almost unknown in Upper Egypt; totally so in Abyssinia, in Mecca, and the southern parts of Arabia.* On the contrary, it appears, from the history of all the plagues of which there is any account in England, that they have never begun to appear epidemically but in the end of June, or about the beginning of July: that they proceed increasing till September, when they are at their acme, and then decline until they entirely subside in winter, with the exception of a few sporadic cases.—(*Select Dissertation*; also, *Russell on the Plague*; and *Bancroft on Yellow Fever*, p. 579.) The influence of temperature is, indeed, striking in numerous diseases, and even in many of those that issue from a specific contagion, of which we have already given an impressive example in its effects on syphilis in the West Indies.

[Dr. Bancroft has brought forward various observations, made by himself, in proof of the influence of atmospheric heat and cold, in both their extremes, in rendering the contagion dormant, or in suspending that susceptibility or affinity of the human body, without which it cannot produce disease in ordinary circumstances. Pestilential contagion, he observes, probably exists at all times in Lower Egypt, Syria, and many of the great cities of the Levant, and it is frequent on board Turkish and Greek vessels. When he was in Egypt he remarked, that the obvious effect of heat in lessening the susceptibilities of individuals, or their aptitudes for taking the disease, was most evident in those who had lately arrived from cold climates, and who were comparatively most affected by the summer's heat. "There were, however, persons in Egypt," he adds, "who had been long accustomed to greater degrees of heat, and who were therefore not rendered insusceptible of the disease; and some few of these caught it after it had become extinct in the British army, and when a person landed from England would not receive it, though he slept in an infected bed; and it was from this cause that, in the autumn of the same year, the disease began at Rosetta nearly two months before the usual time, i. e. on the 13th of September, when I first discovered it in two natives of the East Indies, attached to the Indian army; and it was propagated with some rapidity for six or eight weeks, among persons who were either born in or had just come from a climate much hotter than Egypt."—(*Bancroft on Yellow Fever*, p. 591.)]

The same controlling circumstances take place all over the world; and, in studying the history and progress of the disease, we must allow for the changes they effect. Dr. Mertens has well described this progress in the plague

* The plague, therefore, may be said to be endemic in Egypt, where it arises every autumn, and prevails till the beginning of June in the ensuing year. By some the vernal equinox is said to be the period of its greatest fatality; by Sir John Webb, however, the month of November. In the

spring, the southerly winds, which pass over the deserts and the lakes left by the waters of the Nile, blow three or four hours a day for several weeks. In June the country is refreshed and rendered healthy by cool breezes from the north.—See Larrey, *Mém. de Chir. Mil.*, tom. i.—Ed.

of Moscow of 1771, at which time he presided over one of the largest hospitals of the imperial capital, and was an eyewitness to its ravages. —(*Obs. Med. de Febr. putr. de Peste, nonnullisque aliis morbis*, Vindobon., 1778.) Having noticed its liability to modifications from several of the above causes, he tells us, that, in general, it begins with headache, giddiness, horripilation, prostration of strength, fever, nausea, vomiting, redness of the eyes, a dejected countenance, and a white foul tongue. A tickling, attended with slight pains, is perceived in the parts where the buboes and carbuncles afterward break out. "The former," says he, "are glandular swellings, not acutely painful, and more or less elevated; usually seated in the groins or armpits, but occasionally occurring in the neck, checks, and other organs of the body." The latter he describes very nearly in the words already employed in the specific definition of the carbuncle or anthrax in the preceding pages of this work, though he observes that "in the plague, this tumour evinces somewhat less prominence, pain, and inflammation, than when it arises as an idiopathic affection."

"Many," he tells us, "died on the first or second day of the attack, before either of these kinds of tumours made their appearance." In such cases, an eruption of petechiæ, maculæ, or vibices, like what occur in putrid fevers, usually took place a few hours before death; but sometimes the disease was so sudden as to outstrip the march of these active precursors of dissolution. Almost all who died were cut off on or before the sixth day, insomuch that those who reached the seventh were pronounced to be out of danger.

The disease was introduced into Moscow by a communication with the Turkish army; it made little progress during the earlier part of the year, but became fearfully fatal with the advance of summer, and gradually died away with the frost. The mortality was tremendous. Seventy thousand inhabitants were cut off in a few months, twenty-two thousand in a single month, and sometimes twelve hundred in twenty-four hours. Notwithstanding which, by cautiously blocking up every avenue except one to the large hospital over which he was appointed physician, and keeping a strict and constant guard at the entrance thus left open, although the building was in the midst of the city, it was maintained perfectly free from infection, while the disease raged around it in every quarter.

Mr. Jackson's account of the plague at Morocco is in perfect consonance with this description, though it contains a feature or two in addition, which probably became more prominent from the higher temperature of the atmosphere. "The symptoms of this plague," says he, "varied in different patients; the variety of age and constitution gave it a like variety of appearance and character. In some, it manifested itself by a sudden and violent shivering; in others, by a sudden delirium, succeeded by great and unquenchable thirst. Cold water was eagerly resorted to by the unwary and imprudent, and proved fatal to those who indulged in its mo-

mentary relief. Some had one, two, or more buboes, which formed, and became often as large as a walnut in the course of a day; others had a similar number of carbuncles; others had both buboes and carbuncles, which generally appeared in the groin, under the arm, or near the breast. Those who were affected with a shivering, having no bubo, carbuncle, spots (vibices or maculæ latæ), or any other disfiguration (eruption), were invariably carried off in less than twenty-four hours; and the body of the deceased became quickly putrefied, so that it was indispensably necessary to bury it in a few hours after dissolution.

"The European merchants shut themselves up in their respective houses, as is the practice in the Levant. I did not take this precaution, but occasionally rode out to take exercise on horseback. My daily observations convinced me that the epidemic was not caught by approach, unless that approach was accompanied by an inhaling of the breath, or by touching the infected person."

This last remark is in strict agreement with the observations of the best medical writers of modern times who have witnessed the disease in different countries and climates; and the wholesome practice of drawing a line of demarcation, and thus cutting off all communication with the sick, is founded upon the same view. Assalini traces the progress of the plague among the French army in Egypt with great care, and asserts, that even those who associated with the sick were seldom affected unless in-mated in their rooms, and instances the small degree of danger there is from casual intercourse by showing how very rarely the medical attendants suffered. Dr. Frank the younger, who was with the French army at the same time, visited his patients closely and frequently, but never ventured to feel their pulse.—(*De Peste, Dysenteria, &c.*, 8vo., Vienn.) Baron Larrey (*Mém. de Chir. Militaire*, t. i.), however, who distinguished himself so much by his medical services in that expedition, declares that when the disease is slight, there is little or no danger, either in touching the patient's pulse, "du bout des doigts," or in opening buboes or carbuncles, or touching small portions of his body or his clothes, "par des petites surfaces;" nor even in going into his apartment, if well ventilated.]

Yet fresh persons are far less safe than the stated inhabitants of an infected place, who have been gradually inured to the influence of the morbid miasm. "Families," says Mr. Jackson, "who had retired to the country to avoid the infection, on returning to town, when all infection had apparently ceased, were generally attacked and died. After the mortality had subsided at Mogadore, a corps of troops arrived at the city of Terodant, in the province of Suse, where the plague had been raging and had subsided: these troops, after remaining three days at Mogadore, were attacked with the disease, and it raged *exclusively* among them for about a month, though they were not confined to any particular quarter, many of them

having had apartments in the houses of the inhabitants of the town."

As in the plague of Athens and of London, "the mortality," continues the same author, "was so great that the living, not having time to bury the dead, the bodies were deposited or thrown together into large holes, which, when nearly full, were covered over with earth. Young, healthy, and robust persons, with strong stamina, were for the most part attacked first, then women and children, and lastly, thin, sickly, emaciated, and old people." The depressing passions of fear and grief had also a strong predisposing effect: a few suffered twice. Morocco lost a thousand upon an average daily, when the infection was at its height, being about the maximum that fell at London; Old and New Fez from twelve to fifteen hundred; Terodant about eight hundred. The total loss sustained in these three cities and in Mogadore was estimated at one hundred and twenty-four thousand five hundred souls: not quite equalling, however, the mortality that desolated the coast of Provence from the same disease in 1720-1, and particularly the three towns of Marseilles, Toulon, and Aix, in which the first of these lost half of its inhabitants in a short time, and the second sixteen thousand out of a population of twenty-six thousand, the destruction throughout the entire province amounting to two hundred thousand souls: but this was before the laws of quarantine were perfected and rigidly carried into execution. Dr. L. Frank calculates the average population of Cairo at three hundred thousand, and its annual mortality from plague at seven thousand: yet, when the disease proves very mild, he thinks it may not be more than a fifth part of this number.

In the regular progress of the disease, buboes make their appearance first, and about the second or third day from the attack; then carbuncles and ignis sacer, if either of these occur at all; and lastly, as the danger increases, petechiæ and vibices. But, as already observed, where the plague shows great malignity from the first, it opens with petechiæ and vibices, and sometimes kills in a few hours, even before buboes have time to appear.

Buboes, in the opinion of all the practical writers, or nearly without an exception, are a critical mark of the disease, and the natural means of conducting it to a favourable termination: "but in order," says Mertens, "to their proving beneficial, they must undergo perfect suppuration." In many instances, they neither inflame nor become painful; and in others, they suddenly disappear after having reached the size of walnuts. In the former case, they afford no relief; in the latter, death is almost sure to follow speedily. [Dr. Bancroft's mode of accounting for these facts will be hereafter noticed.] The earlier buboes make their appearance the better; and upon a free suppuration, they certainly render the patient less susceptible of the disease afterward. In the opinion of M. Sotira, indeed, and of most of the French medical staff appointed to the Egyptian expedition, they prove an indemnity for life:

yet, the examples of a second attack are too numerous to allow us to adopt this opinion as a general rule.

[The fact of the occurrence of the plague in the same individual more than once, is, indeed, fully established upon the best authorities, although the point has been sometimes disputed. Meriten says of the plague at Moscow, "Experientia comprobatum sit, hanc (pestem) illos non solum in variis vitæ periodis, sed et eadem epidemia, bis aut sæpius occupare potest."—(*Obs. Med.*, p. 123.)]

Mr. George Smith, surgeon of the Russian Imperial Land-Cadet corps of nobles, was twice a sufferer from the plague at Bucharest in the year 1772, as I think, and had the rare privilege to recover from both assaults. But that an exemption for a considerable term of time is hereby very generally obtained, is established by innumerable examples, of which M. Mathias Degio, one of the surgeons attached to the same establishment, affords us a striking instance in his own person. "Perceiving," says Dr. Guthrie, "the gentlemen of his profession condemned, in a manner, to death, if punctual in their duty, he had the resolution to inoculate himself for the plague, in a full confidence of its efficacy; and ever afterward found himself invulnerable, while his companions around him were falling victims to its fury."—(*Guthrie on the Plague, &c., in Edin. Med. Commen.*, vol. viii., p. 348.) And to the same effect we are informed by Dr. P. Russell, that, in four thousand four hundred cases of infection, he only met with twenty-eight of a well-ascertained renewal of disease.—(*Treatise, &c.*, p. 190.)

[The contagion of the plague, like that of typhus, and unlike that of smallpox, may infect a person a second time, though his chance of being so attacked is very considerably diminished. Dr. Bancroft says, "Two cases of reinfection, or second attacks of plague, fell under my observation in Egypt; one occurred in Mr. Webster, then an assistant surgeon, and the other in a soldier of the 27th regiment, each of whom had a bubo: they were, however, but slightly indisposed, the weather having become hot. Dr. Buchan had a second attack, but with only a small carbuncle, as he informed me. Dr. Price had also a second attack, without either a bubo or carbuncle, but, according to his own account, with a violent affection of the head and nervous system. In general (he adds), I think second attacks are milder than the first, though Dr. Price informed me of his having seen a lad, who, under such an attack, died on the second day. Pugnet says, that reinfections, when they occurred, were most frequent in persons who had been mildly treated by the first attack; and that several of these had the disease very violently the second time, immediately after using the bed or blanket of persons who had died of it."—(*Bancroft on Yellow Fever, &c.*, p. 599.)]

Looking at the general tenour of the evidence on the point before us, it may be concluded that a second infection is not a common event, at least during the same epidemic. In above 120 pestilential cases recorded by Diemerbroeck,

there are only two in which the patients had been infected twice during the same season.—(*De Peste*, lib. iv., hist. 37, et 45.)

Thucydides, in his account of the plague at Athens, mentions, "that those who recovered had much compassion on those who were dying and those who lay sick, as having known the misery themselves, and were now in a secure condition, for it never seized the same person twice, so as to be fatal." This confidence of the convalescents in their security (which is not usual in cases of the true plague when epidemic), is sometimes regarded as a confirmation of the suspicion, that the plague of Athens was the smallpox; against which inference, however, our author has zealously adduced every reason that it is possible to urge.]

Of the efficacy of inoculation from the virus of a bubo there can be no question, and we have hence a sufficient proof of the specific character of the eruption; but it is not always a successful efficacy; and even where it is so, as the extent of the immunity is not sufficiently ascertained, inoculation for the plague is by no means to be recommended. We are told by Sir John Webb of a bold experimenter, in the person of a young physician and hospital surgeon attached to the British army at Rosetta in 1802; who, to determine the question whether the bubonous virus of the plague be or be not a specific and propagable poison, inoculated himself at El-Hamed, on January 3d, twice by friction from the matter of a bubo, and once on the ensuing day, by incision. He was attacked with rigour and other symptoms of fever on the evening of the 6th of the same month, which proved to be the plague, became delirious on the 8th, and continued in this state till the evening of the 9th, when he expired.—(*Med. Trans.*, vol. vi., art. viii.)

I gladly avail myself of this authentic narrative of the Director General of the Ordnance Medical Department, in confirmation of the general statement here offered; and as containing, if a feeling of high esteem and friendship have not unduly biased my judgment, one of the most valuable documents we possess on the subject, particularly in respect to the best practical means of opposing the influence of this desolating scourge upon a large scale.

Sir John Webb's narrative embraces the history and progress of the plague, as it appeared in the British army employed in the conquest of Egypt in the years 1801, 1802, and 1803, during the whole of which time he was present, and actively engaged in arresting its course: and it justifies us in drawing the following conclusions:—Firstly, that the disease is specifically contagious. Secondly, that the atmosphere of contagion is very limited, and that hence it is by no means difficult to avoid being infected. Thirdly, that the disease makes its attacks with very different degrees of malignity, at different seasons of the year, and on different constitutions. And, fourthly, that those who reside in a place in which the plague exists, and have been gradually inured to the influence of the pestilential miasm, are less disposed to be

affected by it than those who are fresh to its poison; and, as in the case of the jail-fever, may carry about them, in their clothes, effluvia enough to infect those who come within its atmosphere, while they themselves remain in a state of health.

The first position is sufficiently proved, not only by the test of inoculation just adverted to, but by numberless other facts, of which one of the most forcible is the following. A lieutenant of the 10th regiment of foot, residing in Alexandria, was attacked with the disease, and conveyed within the boundary of the quarantine. A rent having been made in a moscheto curtain, it was taken without his knowledge, by John Lee, a private, and servant to the lieutenant, who prevailed on the sentinel to let him pass, in direct violation of orders, to another private of the same regiment, of the name of William Bower, to be repaired; after which, Lee immediately carried it home, and, at his own request, accompanied his master into the pest-hospital, and attended him till he recovered. On the fourteenth day after this visit of Lee to Bower, the latter was taken ill with very suspicious symptoms, which, on the idea that it was an attack of plague, could be accounted for by no one till the application to repair the moscheto curtain was recollected by the patient. The suspicions were confirmed on next morning, and in the evening he died.

So long, however, as the line of separation was faithfully maintained, and the sound and the diseased were thus kept distinct, there was scarcely an instance in which the disease broke out among the former. I say scarcely an instance, because an anomalous case or two occurred occasionally. But such was the judgment and the vigilance exerted from first to last, that the Board of Health were able to trace almost every instance of fever to the source from which it was derived, notwithstanding the difficulty of maintaining a rigid and permanent prohibition of all communication whatever. And hence it is most probable, that the few exceptions to the general fact proceeded from a disobedience of orders which the Board were not able to detect.

In general, Sir John Webb observes, that the course of the disease is nearly the same every year, and equally varies in different seasons of the year. In Egypt it commences in November, at which time it rages with its mostly deadly malignity, "and those who are affected by it sink into the grave almost without complaint." It continues its ravages with little abatement through the winter and the earlier part of the spring, when, as the weather becomes warmer by the approach of summer, its attacks are less frequent, its symptoms much milder, and it subsides into a manageable malady; still, however, retaining the characteristic test of glandular affection: and, on the 24th of June, the Turkish government announces to the public its supposed cessation by a discharge of cannon; the atmospheric temperature being now acquired, in which the matter of plague ceases to operate.

Sir John, however, with great judgment, en-

tertain doubts of its entire cessation, even then or at any time; and brings a proof or two of its existence during the period of official emancipation. In few words, he conceives the plague to exist in Egypt as the smallpox exists in England; only, from a greater regularity in the atmospheric changes of the country, evincing a greater regularity of epidemic flux and reflux, operated upon at the same time by contingencies often difficult to be developed; and hence equally varying in violence and extent.

That the miasm of plague, like that of typhus, is sometimes inert upon those habituated to its influence, is obvious from the following fact. "When our pest establishment at the camp was broken up, I discovered that the Arab servants who had been employed in it had secreted a great part of the clothing of the men who had died of the plague; some of which they wore with great satisfaction and *perfect impunity*." I have noticed this effect of habit in the preceding view of the plague at Mogadore: and to the same cause Sir John Webb ascribes it that the Chasseurs Britanniques, on their first arrival at Alexandria from Trieste, suffered far more severely from the disease than the troops that had been stationed there for some months.*

[Dr. L. Frank (*De Peste, Dysenteria, et Ophthalmia Aegyptiaca*, Vindob., 1820) has published several striking examples of the sudden disappearance and occasional inertness of plague contagion. The French army arrived at Cairo in 1793, only thirty days after the cessation of a severe plague; and though, in the hospitals, the beds, clothes, &c., of the Mamelukes were made use of, not a single case of plague occurred during that year. Upon this subject, as Dr. Winterbottom has noticed, Dr. Wolmar informs us, that about the summer solstice the south winds and sirocco, which had prevailed during the time of the plague, ceased, and were succeeded by north and northeast winds. A heavy dew fell every night, and the disease disappeared. The Europeans, many Christian merchants, and the Cophts, now opened again their enclosures, and many days were passed merely in visiting. The Turks, also, visited to congratulate each other, and to renew their commercial ties. The Europeans and native Christians paid visits of condolence to the Turks in their houses; on which occasion they seated themselves, without dread, upon sofas covered with cotton, which, but a few days before, would have infallibly communicated to them the plague; though, at this time, such an occurrence was not heard of—a sufficient proof how great the influence of the atmosphere is over this disease.† Moreover, soon after the battle of the pyramids, Bonaparte and his staff

occupied the quarters of Murad Bey; in which, a short time previously, sixty men had died of plague, yet none of the French suffered from contagion. Pugnet also informs us, that Bonaparte, in order to lessen the fears of the soldiers, used to touch the bodies infected with plague. Upon this subject, Desgenettes more particularly says:—"Se trouvant (le général-en-chef) dans une chambre étroite et très encombrée, il aida à soulever le cadavre hideux d'un soldat, dont les habits en lambeaux étoient souillés par l'ouverture d'un bubon abscedé."—(*Hist. Méd. de l'Armée d'Orient*, p. 49; and *Winterbottom, in Edin. Med. Journ.*, vol. xxx., p. 331)]

How slightly the disease makes its assault upon some constitutions may be inferred from the case of one of the sailors of the Major transport, who was attacked towards the end of March with an inguinal bubo, but was otherwise in *perfect health*. "The man," says Sir John Webb, "declared he had had it three days, and attributed it to cold. I was, however, satisfied, after a careful inquiry into his case, and an examination of his leg and thigh of the same side, that it was an effect of pestilential contagion, but in its mildest form. He was therefore placed in a separate tent, and a gentle aperient was administered, which was all the medicine he required. On the 2d of April I found the swelling had begun to diminish, which it continued to do until it entirely disappeared."*

The following description is of a different character. It is written with a touching simplicity that does credit to the author's heart, and will not be read without feeling by the most torpid. "As I approached the beach to examine them (the sick and suspected of the Major transport), the first object that presented itself was a young woman supported in a chair (Francisca Kennis,) moaning under oppressive disease. She stared wildly about, quite insensible to every object around her, and there was a muddy glistening in her eyes, which I had seen described but had never before observed. Her husband stood over her in the deepest distress, and held a lovely infant to her breast, who tranquilly sucked the poison that soon afterward destroyed him. I feared, at first, that force would be necessary to separate the father from his wife and child, but he at length yielded to entreaty, and was removed from the infection, though too late to save his life. She was conveyed to the pest-hospital, where she soon expired; and the child was confided to an Arab, who fed and watched over it with the greatest care. On the 28th of March, the fifteenth day after the separation took place, the infant was attacked with plague, and languished until the

* Compare Dr. Patrick Russell's Treatise on the Plague, book i., chap. iv. (Aleppo), p. 19, 4to., 1791.

† Enrico di Wolmar, Abhandl-ueber die Pest, Berlin, 1827. This work, according to Dr. Winterbottom, is extremely interesting, and contains the author's remarks on the plague, made during four epidemics, which occurred in a residence of fourteen years at Cairo and Constantinople.—See *Edin. Med. Journ.*, vol. xxx., p. 64.—Ed.

* Where buboes or carbuncles constitute the main symptoms, the patients are sometimes able to walk about and follow their usual employments, unless prevented by the degree of inflammation in the groin. Among the French soldiers whom Bonaparte led into Syria, several, while ill of plague, were able to march a considerable time.—(See Fodéré in *Dict. Des Sciences Méd.*, vol. xli., p. 77.) Similar facts are recorded by Diemerbroeck.—Ed.

14th of April, when death terminated its sufferings."

Upon an average, from a table of the general return of the loss sustained by the British army from the plague, during the conquest and evacuation of Egypt, from the 8th of March, 1801, to the 8th of March, 1803, comprising just two years, it appears that the whole number of sick was 660:—of whom 361 died, and 299 were discharged cured: making the deaths rather more than half the number attacked. And further, that of the above 660, 612 were seized between March 8th, 1801, and June 30th, 1802, being nearly sixteen months; and only 48 between July 1st, 1802, and March 8th, 1803, including the remainder of the time: a result which reflects a very high degree of credit on the means resorted to on the occasion, and on the vigilance and activity with which they were carried into execution: 361 being the entire loss sustained from this fatal scourge operating through a period of two years: while in the French army in the same quarter, as we learn from M. Desgenettes, not more than one in three of those that suffered were fortunate enough to recover; and, according to Dr. L. Frank, not more than one in five.

Such is the history of plague, as it has shown itself in different ages and parts of the world, collected from the writings of unimpeachable eyewitnesses of its progress. In the midst of many discrepancies, it exhibits a sufficient identity of character; and I have dwelt upon it the more largely, because, from the time of Dr. Cullen to the present day, its discrepancies have been chiefly attended to. And hence, while some writers of respectability have attempted to divest it of one, and others of another of its peculiar and most striking attributes, as that of contagion,* or that of atmospheric influence (*Sir Brooke Faulkner; Tully, Hist. of Plague in the Islands of Malta, Goza, Corfu, &c.*, 8vo., 1821), some, and especially Professor Frank (*J. P. Frank, De Cur. Morb. Hom. Epit.*, tom. i., p. 136, 8vo., Mannh., 1792), have been equally inclined to sweep the whole away at once, and to reduce it to a mere modification of typhus, or some other fever of great malignity;† on which account, in Swediaur's Nosology, it is placed next to typhus in the class of continued fevers, instead of in that of exanthems; and is distinguished by the name of loimopyra.--(*Nos. Med. Syst.*, i., 23.)

From its history, then, let us endeavour to collect its pathology, or the laws by which it is

governed, and which connect it with or separate it from other exanthems.

In the first place it is obvious, that the plague, like many other febrile eruptions, is under the occasional influence of various concomitant circumstances that give a considerable diversity to many of its features. Its proper fever is an acute typhus; but even this, by the constitution of the individual, or the peculiar state of the atmosphere, sometimes changes to a remittent, and even to an inflammatory type. So the measles and smallpox, whose proper fever is a cauma, sometimes change, as we have already seen, into a typhus or synochus. The final end of the fever in plague, as in other exanthems, is to restore the body to health by throwing the morbid ferment to the surface in a specific way. And, as in other exanthems also, a very small degree of fever is requisite for this purpose. And hence we find, that, wherever the disease runs through its progress kindly, the fever is slight in degree and short in continuance; and the specific eruption shows itself in its perfect character. Dr. Frank the younger tells us of a patient, who even danced and was merry at the very time when he had a bubo forming in the right axilla.—(*De Peste, Dysenteria, &c.*, 8vo., Vienn.) In the smallpox we sometimes find scarcely any eruption, and very little disturbance of the system; and the same benign disposition is occasionally found to attend the plague; for the soldier who is struck while in the ranks with a sudden shock, or *m'drop*, as the Arabians call it, and is taken to the hospital on one day, has, in a few instances, by proper treatment, passed through the febrile assault in three or four hours, and resumed his station the day after (*Edinburgh Med. Commentaries*, vol. iii., p. 352): the disease, in such cases, evincing the same rapidity of attack and recovery which we have already noticed in that tremendous and fatal scourge, the spasmodic cholera of India.

Next, the proper eruption of plague is that of buboes; and where these alone arise, and in their proper period, the disease is not accompanied with much danger. They are always a favourable sign, and seem to afford the longest indemnity against future attacks. When the fever is more considerable, carbuncles, the jimmerat حماريات of the Arabians, are thrown out at the same time over different parts of the body; and there is in this case always great debility, which is probably the cause of their appearance, and a considerable degree of danger. And, if the fever run still higher, the danger will be proportionably increased, the proper eruption of buboes may perhaps be suppressed, and carbuncles alone be found highly malignant, and secreting a most acrid and corrosive ichor, which, as it oozes and spreads about, occasionally forms extensive trails of painful and distressing sores.

But the fever is often still more acute, and especially, for a reason we shall presently notice, when the disease first appears among a people; and the danger may be imminent from the first

shock. The typhous symptoms are here of the most malignant nature: there is a sudden and almost utter exhaustion of sensorial power without the smallest means of recruit: all the larger viscera are disturbed in their functions; the head, the heart, the lungs, the stomach, and the liver: some overwhelmed with congestion, others sinking and powerless, as though the morbid virus were translated from the surface to themselves; the only active principle throughout the entire system being that of fever itself, which increases with the increase of the general mischief, and, like a house on fire, gathers fuel from the downfall of the fabric. All the symptoms of putrefaction make an early appearance, and appear at the same time under these circumstances: the animal spirits fail and are despondent; the respiration is anxious and feeble; the stomach faint and sinking, or the brain comatose; purple stigmata and vibices are scattered over the body, and the patient is destroyed by the incursion of the eruptive fever, as often happens in the smallpox, before the specific toxins have time to show themselves.

Of the primary source of plague we are in as much uncertainty as in respect to that of any other exanthem: it appears, however, to have a just claim to a higher antiquity than any of them; for we have already seen that it was known in an early era to the Greeks, and that histories of it, as it has shown itself in different ages and countries, have descended in a regular stream of Greek, Arabic, Roman, and neoteric writers down to our own day. We might, indeed, if it were necessary, ascend to a far remoter period, and prove its existence in the earliest ages of the Jewish history, for it is very frequently referred to in the Pentateuch under the name of DEBER (דִּבֶּר), (*Exod. v., 3, et alibi*), and is more particularly described in the prophetic writings as DEBER MIZRAIM (מִצְרַיִם דִּבֶּר, (*Amos iv., 10*), the PLAGUE OF EGYPT, THE PLAGUE PROCEEDING FROM EGYPT; thus pointedly adverting to what was equally regarded as its indigenous soil by the Greeks (*Lucr. vi., 1139*, who quotes from Thucydides) and Barbarians, as well as by the Jews; while the carbuncular variety is also peculiarly distinguished and characterized by the name of Shechin perech (שְׁחִין פֶּרֶח), (*Exod. ix., 9*), "BURNING CARBUNCLE," and Shechin Mizraim (מִצְרַיִם שְׁחִין), (*Deut. xxviii., 27*), CARBUNCLE OF EGYPT. That, like other exanthems, it consists in and is propagable by a specific virus, is unquestionable; for we have already seen that it has often been put to the test of inoculation; and, like most other exanthems also, it appears to be dependant for an extensive spread upon the same accessories as give rise to febrile miasm or contagion, and which, as before noticed, are, for the most part, the common auxiliaries of putrefaction. Whether any combination of these be capable of originating it of themselves, either without or within the human body, or whether it be only propagable by a stream of hereditary descent from primary matter communicated from place to place, is a problem to the present hour, though it is probable

that the principle which in this respect governs most of the other exanthems, as measles, smallpox, and scarlet fever, governs the miasm of plague also: for all of them, while derivable by communication with the affected, seem at times to have assumed the form of epidemics.

In deducing the more obvious laws that regulate febrile miasm, I observed at some length, that, whenever originating from the human body itself, this miasm does not seem to be very volatile, and is soon dissolved or decomposed in an atmosphere of pure air: and we have since had occasion to apply the same remark to the specific miasms of all the preceding exanthems. I have now to observe that it applies especially to that of plague, whose sphere of infection in pure air seems to be more limited than any of the rest; on which account, indeed, it has been held by many who have practised in the field of this disease to be communicable by contact alone. Such, in truth, seems to be the surest way of communication, and may, in all common cases, be regarded as a way altogether irresistible: but it is not the only way. In the pure and healthy air of Malta, during the visitation of the plague in 1813, it was almost the only mode of transmission; and hence the readiness with which it was subdued by the rigid line of quarantine which was so wisely proposed by the medical officers, and enforced by Sir Thomas Maitland. But several of the most intelligent residents on the spot, and even Mr. Tully himself, who, in his work on the subject, has held up contagion as the sole means of propagation, have admitted to me, in conversation, that the disease might be received by the breath of the infected, without contact, upon a very close intercourse. Sir B. Faulkner's opinion upon this point is in perfect union with Mr. Tully's: "It is communicated," says he, "only by contact or close association with the person or thing infected."—(*Minutes of Evidence before the Select Committee of the House of Commons.*) And, in consequence, they admit that the air, even in its purest state, may become a vehicle of communication, though to a very short distance, and probably for a short period after being impregnated; since, as already observed, the miasm of plague dissolves in pure air with great rapidity.*

When, however, the atmosphere is stagnant, or already loaded with foul effluvia of any other kind, especially such as proceed from the filth of close or crowded rooms, or the putrescent decomposition of animal or vegetable substances, no modification of febrile miasm, as we have had reason to state antecedently, dissolves readily; and consequently the seeds of such disease may continue floating for a considerable period of time, and be driven by currents to some distance in full possession of their specific mischief; and

* Whether the plague can be received by means of respiration, must yet be regarded as an unsettled point. The celebrated Omodei observes: "A tutti è noto che il valoroso Valli, ricco d'esperienza su di questa materia, sosteneva non essere contagiosa l'aere respirata dagli appestati."—*Peste di Sirmie del 1754.*—Ed.

hence, even a sporadic fever may be converted into an epidemic.

It is in this way that plague appears in many cases to have extended itself; for it would be unjust to the character and good sense of a cloud of intelligent witnesses, to deny that this disease sometimes also assumes the form of an epidemic. But I believe it would be found a universal fact, that it has never exhibited itself in this form, except when aided by the above auxiliaries. Thus much is certain, that it has always raged with most violence, and to the greatest extent, in cities and districts where the atmosphere has been least pure, the human frame most debilitated, and the tendencies to putrefaction strongest and most multiplied, as in times of famine or any other general distress, and in the close and squalid quarters of the poor of every city into which it has found an entrance, if it have not even originated there.

This fact, indeed, is so common, that while many writers have contended that plague can only be propagated by actual contact, others, of equal authority, have maintained that the disease is altogether an epidemic, as directly dependant upon the state and constitution of the air as any epidemic whatever, and that to attempt to cure it by a mere interdict of communication between individual and individual is equally weak and wicked. The view now taken of the disease is calculated to reconcile these conflicting opinions, and to bring into a state of amity the most sturdy adversaries in the contest.* In enforcing the line of quarantine at Malta (*Treatise on the Plague, by Sir Arthur Brooke Faulkner, M. D., 8vo., 1820*), Sir Brooke Faulkner most wisely took especial care to enforce at the same time a rigid attention to purification of every kind; and I shrewdly suspect that, without the latter, his cordon would have been but of little avail.

Thus far, the ordinary course of plague does not essentially vary from that of most of the exanthems already considered. The general laws of any one are those of the whole: they are all deflected, and exhibit some variety of features by particular circumstances; but each, to an attentive eye, gives sufficient proofs of identity in the midst of every modification, and is specifically distinguished from the rest.

There are two or three properties, however, which, if not peculiar to the plague, are indented upon it far more strikingly than upon any other

disease of the same order, or perhaps of any order whatever: and we will next proceed to a brief examination of them.

The ordinary mode of infection, on exposure to an exanthematous patient, is by inhalation or deglutition; probably by the former; for various contagion has been swallowed in the way of experiment without producing any influence. How far any other virus, besides that of the plague, is receivable by the pores of a sound skin, is to this hour a matter of doubt. In the case of plague, however, there ought not to exist the shadow of a doubt; for though the miasm is probably communicable within the sphere of its activity, by the mouth or nostrils, direct contact or absorption by the skin forms the ordinary means of its conveyance. Upon this point, almost all the writers of authority, who have been professionally engaged in opposing its progress, are concurrent. And hence again, whatever obstructs or corrugates the mouths of the cutaneous absorbents becomes a certain anti-loimic. Oil seems to do this most effectually; it was accounted "the sovereignest thing on earth" in the last pestilent ravage at Noya, where the physicians, inspectors, and commissaries uniformly wore oil-skin caps, mantles, masks, and gloves.—(*Giornale di tutti Atti, Discussioni, &c., Napoli, 1816*.) At Malta, it was in equal favour: and Mr. Tully has informed me, that there was no instance of an attendant on the infected having received the contagion so long as he was regular in thoroughly rubbing himself with oil, wearing a dress soaked in oil, or a covering of oil-skin. And to the same effect is the evidence of Sir Brooke Faulkner, physician to the forces at Malta in 1813, before the Select Committee of the House of Commons, June 14, 1819, who, in answer to the question, "How were the military attendants preserved?" replied, "With respect to the pest-hospital in which I attended, they were in my opinion preserved by wearing a dress of oiled silk, which prevented the possibility of any contact of infected matter with the skin, and probably also by its promoting free and copious perspiration, and in consequence preventing absorption."—(*Copy of Minutes, &c. Asat Sir A. B. Faulkner's Treatise on the Plague, &c., Appendix, p. 16, 8vo., 1820*.)

To the same effect it has been asserted by Mr. Baldwin, of Cairo, that among upwards of a million of inhabitants carried off by the plague in Upper and Lower Egypt during the space of four years, not a single dealer in oil, so far as he could learn, had fallen a sacrifice to it.—(*Travels, &c., chap. xvii.*) A similar remark is made by Mr. Jackson, respecting the crolies or labourers in oil-warehouses during the Barbary plague. In that of London in 1665, it is specially observed by Baynard and most of the writers, that the trades chiefly exempted were those of oilmen, fishmongers, tanners, barge-men, and watermen: the first three evidently protected by the greasy viscosity that covered the hands and dress generally; and the last two by living separate from the scene of contamination, as though cut off by a quarantine.

* The principal difficulty in the way of an unqualified admission of the contagious nature of the plague, is the complete and often speedy eradication of the disease, in a place where no particular means of purification have been employed for the removal or destruction of the contagion. "But," as Dr. Bateman observes, "this difficulty is not insurmountable, as might be illustrated by a reference to the progress of those contagious diseases which admit of no dispute, such as the smallpox and measles. For even these are only widely epidemic and severely fatal at particular seasons, when circumstances that are not always cognizable give a peculiar virulence to the contagion, or a predisposition to the human constitution to receive its influence."—(*Roes's Cyclop., art. PLAGUE.*)

While, on the contrary, it has been quite as generally remarked, that the description of persons most exposed to infection are bakers, cooks, and smiths, the pores of whose skin are kept in a state of perpetual irritation and relaxation from their respective employments.

How far an habitual exposure to the miasms of other exanthems torpifies the skin to their action, or whatever other organ affords them an inlet; or how far the system at large may be thus torpified, has not been determined with any degree of satisfaction. That stimulants of most kinds have a tendency to produce such torpitude and inirritability is unquestionable; and that the miasm of jail fever has occasionally done it, will not soon be forgotten in the courts of judicature of our own country. It is hence probable, that the effluvium of exanthems in general is possessed of a like power. But in the case of plague, the fact seems to be unequivocally and most strikingly established; for we find in every country, after it has raged for a certain number of weeks or months, that the disease is both caught more sparingly, and exercises far less violence, at least upon those that have been exposed to its aura; for upon newcomers, or strangers, it still retains its virulence. The history of almost every plague may be taken in confirmation of this remark; but it is particularly established by numerous facts already quoted from Sir John Webb and Mr. Jackson. It is highly probable, that if the corps of troops which, after the mortality had subsided at Mogadore, arrived there from the city of Terodant in the province of Suse, *where the plague had been raging* and had subsided, had remained at Terodant, it would have continued to escape. But it lost its immunity by an exchange of contaminated for pure air in the course of its journey, and the organs having acquired their wonted irritability and susceptibility, were as open to infection as those of fresh persons.

The acquisition then of a growing torpitude to the action of the pestilential effluvium beneath a habit of exposure to its influence, seems unquestionable; and puts us in possession of one means of the progressive subsidence of this tremendous scourge, after having occupied a town or district for a certain period of time.

But there is an additional cause of its cessation, which is equally striking, and forms another of the peculiar features of this complaint. As a particular state of the atmosphere, such, for instance, as its being saturated with foreign corpuscles from decomposing animal filth, renders it a bad solvent of pestilential miasm, and consequently a ready vehicle for the spread of the disease, a particular state of the atmosphere of some other kind seems to possess a power of dissolving the effluvium instantaneously, in many cases, and of diluting or disarming its virulence in others. Of the immediate nature of this atmospheric change, we are in a considerable degree of ignorance, but of the general fact there is not a quarter of the world that does not furnish us with examples: so that, all of a sudden, the scourge that had hitherto been sweep-

ing off one or two thousand inhabitants of a city every day, either totally vanishes, or drops its mortality, and only continues in a form so mild as to excite no alarm. Dr. Hodges notices this sudden change very particularly in the plague of London. "In the beginning of November," says he, "people grew more healthy, and many came into the city without fear; so that in December they crowded back as thick as they fled: and such confidence was now inspired, that many went into the beds where persons had died, before they were cold, or cleansed from the stench of the diseased; *for the nature of the disorder was changed.*"—(*Loimol.*, p. 27.) "Even the physicians themselves," says another eyewitness of the same pestilence, "were surprised: wherever they visited, they found their patients better. Either they had sweated kindly, or the tumours were broken, or the carbuncles went down, and the inflammation round them changed colour, or the fever was gone, or the violent headache assuaged, or some good symptom was in the case: so that in a few days whole families that expected death every hour were revived and healed, and none died at all out of them."—(*Journal by H. F.*, p. 250.)

Alpinus speaks in the same manner of the sudden decline of mortality in the plague of Egypt: "In the month of June," says he, "to whatever degree pestilence may be raging in Egypt, as soon as the sun enters Cancer, it ceases entirely." And Dr. Russell confirms this remark as follows:—"It is agreed on all hands, that about the 24th of June, at Cairo, there is a remarkable sudden alteration in the contagious property of the plague, as well as in the malignity of the disease itself, to whatever cause it is to be ascribed: and Alpinus's remark, that at the same time it ceases, the furniture in infected houses suddenly loses all power of communicating the disease to the inhabitants, so that health and tranquillity are at once restored, agrees in some measure with the general experience of other places in Turkey, where, it is well known, houses or goods undergo little or no purification."—(*On the Plague*, b. iii., ch. v.) Mr. Bruce speaks to the same effect:—"The Turks and Moors, immediately after this day, expose in the market-places the clothes of the many thousands that have died of the plague during its late continuance; and though these consist of fur, cotton, silk, and woollen cloths, which are stuffs the most retentive of the infection, no accident happens to those who wear them, from their happy confidence." And we are hence able to enter more fully into the meaning of a passage already quoted from Sir John Webb, in which he tells us, that, on the approach of summer, the plague subsides into a manageable malady, and that, on the 24th of June, the Turkish government announces to the public its supposed cessation by a discharge of cannon.

Unless, therefore, we withhold, most unjustly, all belief in this accumulation of unimpeachable evidence, it seems impossible not to admit that the state, or, to speak more definitely, the

temperature of the atmosphere is connected with the decline of the plague, and consequently with its previous progress; and that, as already observed, it cannot maintain its energy, nor perhaps exist under an atmospheric heat of 60°,* nor above that of 80°; while its dependence upon a specific miasm seems equally clear from its occasionally commencing in the healthiest, as well as in unhealthy seasons; though most frequently, and most fatally, in the latter. In the plague of London, as we have already seen, the disease followed a malignant epidemic; in that of Athens, the preceding year had been so peculiarly healthy, that mankind seemed to have acquired an exemption from complaints of every kind. In that of Egypt it makes a regular return, whatever be the constitution of the season. Dr. L. Frank, in one place, ascribes the diminution of the fatal power of the plague to a periodical return of the north wind: but he afterward observes, that winds, at times, or even moisture, seem to have little influence upon it. That the change in its degree of activity is connected with the change which takes place in the temperature of the atmosphere, is unquestionable; and it is highly probable, that it is dependant upon this alone. That below 60°, or in the cold of the winter months, the miasmatic corpuscles lose their volatility, and gradually become decomposed; while above 80°, as in the summer months of Egypt and Arabia, they become almost immediately dissolved; so that clothes and bedding, however loaded with them, are rendered harmless. And hence the reason why it has never been known either in the tropical or arctic regions.

Respecting the proper plan to be pursued, there is still some controversy. Early, copious, and even repeated venesection was at one time, and by very high authorities, recommended in this disease, and especially by Sydenham at the commencement of the plague of London, in 1665 and 1666, before the appearance of any eruption. Like Dr. Rush, in North America, respecting the yellow fever, he was stimulated by the bold determination of quelling this formidable enemy in its very onset, and before it should have made a fatal breach in the constitution. This practice, however, has been far less successful, and therefore less persevered in, with regard to the plague, than with regard to the yellow remittent. Dr. Mergens says, he would never advise its being resorted to; and even Sydenham hesitated as he became more experienced. "But though," says he, "I ap-

prove, and have often experienced the utility of bleeding, yet, for several reasons, I prefer the dissipation of the pestilential ferment by sweat, because sweating does not in the same degree prostrate the patient's strength." Bloodletting and purgatives, Dr. L. Frank assures us, prove equally hurtful in the plague of Egypt. During the plague at Noya, the doctrines of Dr. Brown were in high vogue, and the disease was divided into sthenic and asthenic; free bleeding and large doses of calomel being prescribed for the former; and acids, opium, ether, and other stimulants for the latter. But, in general, the medical practice was here as confused and inconsistent as the precautionary means of the police were excellent and effective, so that Romani was right in affirming that, after all, their real alexipharmic was to be found in God alone.—(*Ricordi sulla Peste, da F. Romani, M. D., Napoli, 1816.*) Wherever there is great and threatening congestion in a large or vital organ, early bleeding should certainly be employed; and is, in such cases, wisely recommended by the elder Frank.—(*De Cur. Hom. Morb. Epit.*, tom. i., p. 136.) But the practice must form an exception to the general rule, and not the rule itself. In general, as Dr. Bancroft says, very bad effects have resulted from this evacuation.

The use of external cold by the application of sheets of pounded ice to the body generally, has been also tried, but with no satisfactory result. It has, indeed, been chiefly confined to Russia, under the vigilant eye of M. Samoilowitz. How far it might succeed in warmer climates is uncertain, but ablation with cold water offers a fairer promise. [According to Dr. Bancroft, however, the unsuccessful trials of the cold bath in Egypt afford no encouragement to repeat them.] A brisk emetic, given at the commencement of the attack, has often proved of the utmost advantage. M. Degio, to whom I have already adverted, affirms that he has seen men suddenly cut down by the disease when on duty, as though shot by a musket ball, so completely recovered by an emetic given instantly, as to be on duty again within twenty-four hours afterward.* If the nausea and bitter taste in the mouth be not removed by a first emetic, a second, and even a third are often prescribed; and where the symptoms are urgent, at a distance of not more than four or five hours from each other. And this plan is found to produce far less exhaustion than that of purging, which the patient is often unable to support.

After evacuating the stomach, and hereby exciting a determination towards the skin, the cutaneous action is to be maintained by active and cordial sudorifics, which, indeed, constitute the ordinary plan of the present day. For cordials, there is the utmost necessity: the debility is, from the first, extreme and threatening, and

* The only fact with which the editor is acquainted, in opposition to this doctrine, is that of Mindererus, who was an eyewitness of the plague of Ismail, during the most severe winter ever remembered there.—(Account of the Turkish Empire.) Dr. Winterbottom, in noticing the differences between the plague and yellow fever, says, that the former can maintain itself in excessive degrees of cold, while, on the contrary, a changeable temperature, inclining to cold, is destructive of yellow fever.—See *Edin. Med. Journ.*, vol. xxx., p. 340.

* Substance of notes taken at the Russian army during the prevalence of the plague.—See *Edin. Med. Comm.*, vol. viii., p. 352.

the vascular action must be supported at all adventures. Even Sydenham, who at one time hesitated as to the use of them upon theory, in which he did not often indulge, was obliged to admit their beneficial effects, though he regarded the practice as hazardous. With respect to sudorifics, the concurrent voice of all physicians in all countries is in their favour. Diaphoresis is, indeed, the evacuation that relieves most certainly and most effectually; and it should be maintained by warm, diluent, and supporting drinks. James's powder employed without cordials does not appear advisable. It was very largely administered at Moscow, but according to Dr. Mergens, with no particular advantage. In many cases the warmer opiates, as the opiate confection, have been found serviceable, assisted with camphire and ammonia, and blisters repeated in succession.

As oils of all kinds, applied to the surface of the body, have been found a good preservative against the absorption of the contagious miasm, it has been also had recourse to, and employed in the same manner as an antidote when the disease is present, and particularly in the east, where the zeit jagghy زيت يانغى, or olive-oil, has been regarded almost as a specific. Mr. Baldwin affirms, that he made use of it in this form very extensively at Cairo, and with great success: and it is usually employed in Barbary and at Constantinople. The French physicians, however, do not seem to have relied much upon its virtue. M. Sotira suggests, that Mr. Baldwin's benevolence in the distribution of oil for this purpose was occasionally abused, and the cures by oil exaggerated and multiplied by those who wished to have oil gratis. Assilini, however, inclines to a belief that it may be useful: it is most pointedly recommended by Father Louis of Padua, director of the hospitals at Smyrna: and quite as strongly by Dr. Pauvini of Palermo, who had practised indeed at Malta, but whose work was reprinted during the plague at Noya, and gave a character to the medical practice pursued in that city.* The application should be accompanied with a long-continued friction; and, when successful, is followed in about half an hour by a perspiration profuse and general, and which affords immediate relief. Sir Brooke Faulkner admits its sudorific power, but is by no means friendly to its use: believing that even by this very power it has often proved highly injurious. Yet he does not speak from much personal acquaintance with its effects; but tells us that "a gentleman who superintended the health of one of the districts of Valetta assured him that, although he had constant opportunities of seeing oil frictions used by those under his immediate orders, he was satisfied that it was not merely useless as a defence, but hurtful to the general health, by the debility which succeeded to the profuse perspirations which it occasioned."

[Pugnet says, that oil frictions, so extensively employed by the French physicians in Egypt, were not only useless, but caused anxiety and disturbance to the sick; and that of fifteen patients to whom they were applied, under Dr. Carrie, one recovered with difficulty, and all the rest died; and that where they seemed to do good, the disease was always mild. With so much reason to doubt of their efficacy, there is a strong objection to their use, arising from the very great danger of communicating the disease to the person by whose hands they may be applied.—(Bancroft on Yellow Fever, &c., p. 623.)] Sir Brooke, in the passage of his book above referred to, estimates its prophylactic virtue as low as its remedial (*Treatise on the Plague*, &c., pp. 231, 232), and is thus far in a state of direct antagonism, not only with Mr. Tully, who was afterward inspector of quarantine on the same station, but with himself at the time of delivering his evidence before the Select Committee of the House of Commons; an extract from which we have already quoted. Dr. L. Frank employed oil, according to his own statement, with great and decided success. In his hands it proved a most salutary sudorific; and to sudorifics he principally trusted. He used it in the form of friction, six ounces at a time, and a single friction a day.

In the remissions of the fever, the bark is used in great abundance, commonly intermixed with port, or other generous wines. During the fatal plague which depopulated the whole of Western Barbary in 1799, the Emperor Sidî Soliman is said to have had the disease twice, and in both cases to have derived his cure from a free use of the bark; in consequence of which he was never afterward without a large supply of it. When buboes or carbuncles appear, they are always to be promoted and matured by warm cataplasms.

[With respect to the management of buboes, although it may be right to promote their supuration by emollient cataplasms, where a natural tendency to that issue is evident, it is fully ascertained that there is no danger in favouring their dispersion by the usual means, when they show a disposition to recede. Dr. Bancroft says, "I know that the sudden retrocession of buboes, previous to supuration, and while other symptoms indicating danger subsist unabated, is often followed by death. But, this mortality is not in such cases produced by any change in the bubo itself, or by the retention of any matter which ought to be discharged, but by such an extreme diminution of the living power, or other injurious effects of the disease, as is incompatible with the continuation of a suppurating process, and also with the patient's recovery; and, therefore, this retrocession is to be considered not as the cause of death, but as an indication and consequence of that condition of the patient, from which death necessarily resulted; and, on the other hand, when these glandular swellings rise and suppurate favourably, they indicate such a state of the living power and of the system as is likely to overcome the

* Chiara Dimostrazione de veri Preservativi della Peste e de Remedi, &c., del Sacerdote P. Pauvini. Dottore in Medicina, &c., Palermo, 1813.

disease, without the supposed benefit of an evacuation of morbid poison by that suppuration. The same reasoning appears applicable to carbuncles, though in their gangrenous state, and, when not surrounded by concentric inflamed rings, they require hot stimulant applications, and afterward such as will promote a suppuration, and a separation of the carbonaceous crust.”—(*Bancroft on Yellow Fever, &c.*, p. 617.) These observations are important, as connected with the theory, prognosis, and treatment of the disease.]

Camphire, smoking tobacco, fumigation with gum sandrac, and the vinegar of the Four Thieves, are still largely employed as preventives. But the contagion, as we have already observed, is not peculiarly active, and the best prophylactics are cleanliness, pure air, freedom from actual contact, a liberal diet, and cheerful spirits. I may add that vaccination has been repeatedly tried; but has answered no good purpose. Sir Brooke Faulkner, indeed, gives a striking example of its failure, for “in a numerous family,” says he, “who had been recently vaccinated, the whole fell sacrifices to the prevailing contagion, with the exception of the parents, who had never undergone the operation.”—(*Treatise on the Plague*, p. 233.)

[In relation to this part of the subject, the editor mentions with admiration the name of Valli, who, as Dr. Winterbottom observes, “appears to have been a man of a cultivated mind, and overflowing with ardour for his profession. Being an enthusiastic admirer of vaccine inoculation, and imagining that the prevalence of natural smallpox and plague was influenced by a kind of mutual repulsion between the two diseases, he flattered himself with having discovered a specific for the latter disease in the vaccine matter. To prove the truth of his opinion, he went to Constantinople, and shut himself up in a pest-house, from which he narrowly escaped with life. He made many experiments by inoculating with mixtures of smallpox, vaccine, and pestilential matters, which he promised to publish, but which it is feared are lost. Dr. Valli inoculated himself with impunity with a mixture of vaccine and plague matter. In consequence of these trials, a nostrum was advertised for sale as a preventive of plague; but it is not clear that Dr. Valli had any concern in it, at least, not from sordid motives. But an apothecary at Constantinople was accused of preparing, as a specific for plague, an ointment, composed, it was pretended, of plague and vaccine matter. The apothecary was strangled, as a just reward for his knavery. Dr. Valli ultimately went to the Havana to investigate yellow fever, the contagious nature of which he denied, where he died a few days after his landing, and where the Medical Society of that city have erected a monument to his memory. A republication of Valli’s works on plague, now out of print, with a biographical sketch of the author, would, as Dr. Winterbottom says, be an interesting present to the medical world.”—(*Edin. Med. Journ.*, vol. xxx., p. 332.)]

SPECIES II.

ANTHRACIA RUBULA.

YAWS.

TUMOURS NUMEROUS AND SUCCESSIVE; GRADUALLY INCREASING FROM SPECKS TO THE SIZE OF A RASPBERRY; ONE AT LENGTH GROWING LARGER THAN THE REST; CORE A FUNGUS EXCRESCENCE: FEVER SLIGHT;* OCCURRING ONLY ONCE DURING LIFE; CONTAGIOUS.

THE term RUBULA, by which this disease is distinguished in the present work, is derived from the Latin *rubus*, “a blackberry or raspberry,” in French *framboise*, whence the common but barbarous name of *frambæsia*, quite as objectionable as that of *scarlatina*; and which the author has thus attempted to exchange for a euphonious and strictly classical term, in perfect concordance with the ordinary law of diminutives, which seems to prevail through the general nomenclature of exanthematous diseases, as rubeola, variola, varicella. Perhaps morula, from morus, a mulberry, a diminutive used in an approximating sense by Plautus, might have been somewhat more appropriate, since the eruption seems to bear a nearer resemblance to small mulberries than to raspberries. But as this last plant has laid a foundation for the vernacular name both on the African and American coast, on the former of which it is called *yaw*, and on the latter *pian* or *epian*, both importing raspberry; and as the earliest writers have, upon this authority, denominated it *framboise* or *frambæsia*, I have not felt myself at liberty to deviate from the original idea. Swediaur has denominated it *thymiosis*, but with less attention to the external character of the eruption. He arranges it, indeed, under the division of cachectic ulcers, and has made it synonymous with the *synochus* of the Greeks, as described by Celsus (Lib. vi., cap. iii.); to which it has only a few casual resemblances, while in its essential signs it is widely different.—(*Nov. Nosol. Meth. Syst.*, vol. ii., p. 180.)

The disease, as it occurs in Africa and America, exhibits some diversity, and lays a foundation for two varieties, as follow:—

- | | | |
|---|-------------|---|
| a | Guineensis. | Attacking infants and young persons chiefly; and subsiding as soon as the eruption appears. |
| β | Americana. | Depascent; and destroying progressively both muscles and bones.† |

* It is alleged by Mr. David Mason, that fever, so far from being necessarily connected with yaws, seldom occurs, and perhaps never, except as an adventitious disorder. Hence he prefers the arrangement of yaws in the class tubera, as adopted by Sauvages, and not Dr. Good’s classification of it with *Exanthematica*.—See *Edin. Med. and Surg. Journ.*, No. cvi., p. 54.—Ed.

† Mr. David Mason’s observations, published in the *Edin. Med. and Surgical Journal*, No. cvi., he informs us, refer to the African variety of Dr. Good; but he thinks that there is no good foundation for the division into the African and American kinds. The disease, he believes is of a uniform

In the precursory remarks to the present genus, I have stated the reasons for introducing this species into the list of exanthems, or febrile eruptions; and the history of the disease will still further show, that it could not with propriety have been placed under any other division. It is singular, that we have no decided account of this malady among the early writers; nor, indeed, any account whatever till after the appearance of syphilis; whence, as several of its symptoms, and especially where the bones become affected, bear a resemblance to those of syphilis, yaws have been supposed by some writers to be a species of lues, and especially of that which in Scotland is denominated sibbens or sivens, of which we shall treat in the ensuing order: but the eruptive fever and consequent efflorescence, the indemnity from a second attack, as well as other symptoms, draw a sufficient line of distinction.*

The FIRST VARIETY will often run through its course favourably without any medical assistance whatever: and is, indeed, often rendered worse by the injudicious interposition of it. This seems to be the primitive form, and that under which it chiefly shows itself in Guinea, and some other parts of Africa, where, as just observed, it is vernacularly called yaw, or morbus RUBULUS.

It commences, like the other exanthems, with the ordinary symptoms of fever, although they are usually more tardy in their progress. Hence the precursory symptoms are languor, debility, headache, loss of appetite, rigour, and pain in the back and loins, which continue for a few days, with evening exacerbations. To these succeeds the specific eruption; consisting of successive crops of papulæ, at first not larger than a pin's head, but increasing in size with every series, till they acquire the magnitude of a raspberry or mulberry. The smaller papulæ become real pustules, and discharge an opaque whitish fluid when broken, and concrete into dense scabs or crusts. The larger are fungous excrescences, and, in their granular surface, as well as in their size and colour, bear a near resemblance to the fruit from which they derive their name. These sprouting tumours have but little sensibility, and suppurate very imperfectly; discharging rather a sordid ichor than a matured pus. They originate in scattered groups over different parts of the body, but are chiefly found, like the eruption of plague, in the groins, parotid glands, axillæ, and about the arms and pudenda: though they often disfigure the neck and face. The colouring matter of the hair, wherever they are seated, is obstructed in its secretion, and, as in old age, the hairs themselves, from a brown or a nature, the malignant and anomalous symptoms sometimes presented by it being the result of internal constitutional, or accidental external circumstances.—Ed.

* Speaking of yaws, Mr. Mason observes:—"It has some resemblance to syphilis, being slow in its progress, and only communicable by contact; but its after-effects are not so destructive, and it leaves the constitution invulnerable to future infection."—Edinburgh Med. and Surg. Journ., No. cxi., p. 54.—Ed.
VOL. I.—T t

black, become a dead white. Dr. Thomas, who has given a very accurate account of this variety, apparently from personal knowledge, observes that, "in general, the number and size of the pustules are proportioned to the degree of eruptive fever. When the febrile symptoms are slight, there are few pustules; but they are mostly of a larger size than when the complaint is more violent and extensive."—(*Pract. of Phys.*, p. 643, edit. 1819.)

The duration of the eruption is uncertain, and seems to depend considerably upon the state of the habit, and its power of promoting their maturity. They sometimes acquire full perfection in four or five weeks, and sometimes demand two or three months. In their progress to this state, there is usually some one that appears larger and more prominent than the rest, and is called the master-yaw. It is, in truth, a broader and more sloughy fungus, and discharges a larger portion of erosive sanies, which, if not washed off as it issues, will spread widely, and sometimes work its way to an adjoining bone, and render it carious. When the tumours point from the soles of the feet, they cannot press through the thickness of the skin, and hence form imperfectly, and produce highly elevated calluses, which are called tubba or crab-yaws: and often very much impede the power of walking. As soon as the eruption has attained its height, the tumours, when the disease proceeds favourably, become covered with crusts or scabs, which fall off daily in whitish scales; and, in the course of a fortnight, the skin is left smooth and clean; the master-yaw alone remaining and demanding attention.

In attempting the cure of this disease, the first step should consist in separating the patient from his associates, to whom he will otherwise assuredly communicate it by contagion. He should then take freely of decoction of sarsaparilla or some other warm diluent. And it is highly probable that the warm aperient bolus, composed chiefly of a scruple of sublimed sulphur and five grains of calomel, as recommended by an anonymous writer (*Edin. Med. Essays*, vol. v., part ii., art. lxxvi.), may be found serviceable, continued every night. [In a good practical paper on yaws, Loeffer recommends sarsaparilla; and, for the purpose of promoting the eruption, small doses of ipecacuanha, camphire, warm baths, friction, and blisters.*] The master-yaw must be attacked with escharotics; for it is to be destroyed in no other way. The callous tumours on the soles of the feet (termed crab-yaws) should be softened by warm water, or cataplasms of some gentle stimulant; and, when on the point of breaking, are best subdued by a slight application of the actual cautery. The diet should be nutritious and liberal, so as to support the strength during the progress of the disease. And, under this mode of treatment, it is rarely that a patient fails to do well.†

* Meckel's Neues Archiv. der Pract. Arzneykunde; Richter's Chir. Bibl., vol. xii., p. 340; and Winterbottom's learned paper in Edinburgh Med. Journ., vol. xxx., p. 322.

† The following is Mr. Mason's description of

Mercury was at one time given in great abundance from the commencement of the complaint, under an idea that it would prove as beneficial as in the case of lues. But it is now sufficiently known to be productive of great mischief, and particularly when carried, as it used to be, to a state of salivation. It retards the cure, and generally aggravates the symptoms. It is often given in small doses as an alternative, when the disease is on the decline, and perhaps with advantage; but it ought never to be employed in any other form.

When the excrescences discharge a sordid ichor, they may also be stimulated with the nitric-oxyde mercurial ointment: but the natives themselves, who rigidly abstain, also, from the internal use of mercury, employ, instead of this, a liniment of the rust or subcarbonate of iron and lemon-juice, which proves a very useful application; though probably a solution of sulphate of zinc might answer better. And during the maturation of the eruption, they excite a profuse sweat by what may be called a warm air-bath, which consists in putting the patient into a cask with a fire at the bottom in a brazier or small firepan; the top being covered over with a blanket. Under this mode of treatment, a cure is said to be often effected in three weeks, and the funguses thoroughly healed.—(*Edin. Med. Comm.*, vol. ii., p. 90.)

The SECOND, or AMERICAN VARIETY, is a far more terrible complaint; or rather is the same complaint in an exasperated and chronic form; and hence, though incomparably slower in its progress than the plague, is accompanied with a carbuncular eruption, quite as mischievous and disgusting, and more certainly fatal in its issue. It was first distinctly described by M. Virgile, of Montpellier, who had practised with great reputation at St. Domingo. There can be little doubt of its being imported into the West Indies along with the slaves from the African coast; and is here called, as already observed, pian or epian, precisely synonymous with the African term yaw: the master-fungus being named mamma-pian, or mother-yaw, as supposed to be the source or supply of the rest. The fungous berries, in this form, precisely correspond to the carbuncle already described under the trivial name of *terminthus*, which

consists of a "core or fungus, spreading in the shape, and assuming the figure and blackish-green colour, of the fruit or berry of the pine-nut, or terminthus of the Greeks."* And it

* CL. III., ORD. II., vol. i. Several of the febrile eruptive diseases are capable of affecting the same person only once during life; but, according to Mr. Mason's belief, the yaws is a solitary instance of a slow chronic disorder, producing similar constitutional changes, tending to future exemption. The time that elapses between the inoculation with yaw matter and the first appearance of a yaw tubercle on the spot where the matter was inserted, was found to be about three weeks. A dry scab was first formed, that remained stationary, and under it the yaw fungus became perceptible at the end of about three weeks, and soon afterward other tubercles appeared on the body. In the instances referred to by Mr. David Mason (*Edin. Med. Journ.*, No. cvi.), there was no obvious constitutional disturbance. The following is the description given by him of the American yaws:—"The first appearance of this disease is usually indicated by a foul ulcer, variously and fortuitously situated, and which is ultimately ascertained to be the spot of inoculation, the skin having been previously broken, either by accident or design. At an early stage this sore resembles a simple cutaneous ulcer, and only becomes suspicious by not healing with the use of common dressing. In a short time, however, the edges become spongy, and of a whitish colour. The poison now begins to act on the constitution, and, in most cases, circular patches of minute papulæ appear in various parts of the skin, giving it a granular appearance. In time some of these papulæ enlarge, become elevated, and covered with a crust. When this scab is cautiously removed, the whitish, spongy, granular yaw is distinctly seen. When the tubercles are left to themselves they attain a considerable size, and a diameter for them of two inches is not uncommon. They are easily destroyed by caustic, without any mark or depression being left. For a few days the spot is distinguished by a deeper black colour than the surrounding skin, but it gradually fades into the natural colour. Mr. Mason has never seen a yaw tubercle on a mucous surface; sometimes at the angles of the mouth, but not on the lips, or in the nostrils. All yaw tubercles, he says, are composed of irregular circular segments, cutting each other more or less acutely, and forming waving lines around the base. The summit is often flat and depressed in the middle. Those of the strawberry shape are considerably elevated, and exhibit an irregular granular surface. In some parts, where the tubercles are numerous, they unite in clusters. Occasionally they appear in the form of a ring or semicircle, with a depression of sound skin in the middle. Whatever be their figure, they all discharge the same sort of matter, which is condensed into a similar scab, and which, being cautiously removed, shows the dingy granular surface underneath. Among healthy negroes, exposed to the simple action of the yaws, Mr. Mason noticed little constitutional disturbance. A tingling or itching sensation in the skin, and slight pains in the joints, were common, but not constant symptoms. The mother-yaw, or that caused by inoculation, which generally ulcerates, sometimes gives considerable pain. As the disease advances, and the yaws become large and numerous, the constitution shows more evident signs of disorder, debility, emaciation, &c.; but never, in ordinary circumstances, causing confinement, or, under proper care and regimen, depressing the spirits.

the crab-yaws:—"Like the other yaws, they seem to arise from the true skin; but, being confined during their growth by the hardened cuticle, its resistance, together with the pressure in walking, creates intolerable pain, and inability to move except in a singular and awkward way, whimsically fancied to resemble that of the movements of a crab, whence the origin of the term. As the tubercles enlarge, the upper covering gives way, and they appear above the surface in the shape of granular yaws. They are easily removed by paring away the hardened skin around them, cutting off the projecting tubercle, and touching its root freely with caustic. It seems that the dangerous practice of keeping the feet immersed in a medicated and nearly boiling bath for nine days, is sometimes tried in the West Indies: Mr. Mason has known of some instances in which the method proved fatal.—*Ed.*

has hence been conjectured, but without sufficient foundation, that the disease of yaws is referred to by Galen and Dioscorides under this name.

The erosive secretion from the carbuncles of this variety generally, but especially from the mother-yaw, spreads widely, and, in its meandering, destroys all the surrounding parts, not excepting the bones.* [Conradi is wrong in asserting that the pains in the bones affect only negroes, and not Europeans.—(*Grundriss des Pathol.*, b. ii., §26.) Dr. Winterbottom knew a European in Africa, a slave-dealer, who was dreadfully tormented with pains in his bones, in consequence of yaws.†] Nothing can exceed the revolting scene of a yaw-house, or hospital for the reception of slaves suffering under this disease, in the West Indies. "Here," says Dr. Pinckard, "I saw some of the most striking pictures of human misery that ever met my eyes. Not to commiserate their sufferings is impossible, but their offensive and wretched appearance

creates a sense of horror on beholding them. Of all the unsightly diseases which the human body is heir to, this is perhaps the worst. Some of these diseased and truly pitiable objects were crouching upon their haunches round a smoky fire; some stood trembling on their ulcerated limbs; others, supporting themselves by a large stick, were dragging their wretched bodies from place to place; while many, too feeble to rise, lay shivering with pain and torture upon the bare boards of a wooden platform."—(*Notes on the West Indies*, vol. ii., letter xxii.) Dr. Pinckard adds, that, "unhappily, this most odious distemper has not hitherto been found within the power of medicine: that it often exists for years, and, even where it sooner yields, its removal is more the effect of time and regimen than of medical treatment."

This view of the case is too generally true: but, from the length of time which, under the best treatment, is required to effect a cure, it seldom happens that these miserable wretches receive all the attention which their situation deserves; and they are rarely sufficiently heedful of personal cleanliness, which, even alone, is of the utmost importance. This, with a generous diet to support the strength, pure air, regular hours of rest, and such exercise as can be used without fatigue, with warm balsamic applications to the sores, have not unfrequently succeeded where the bones have not become extensively carious. But the latter stages of the disease are horrible when it proves fatal; for the pains are excruciating, the debility extreme, and the bones are covered with foul exostoses and corrupt ulcerations.*

It is happy for the European inhabitants of the West Indies that they are less liable to this miserable malady than their slaves; probably from using a better diet, and being more attentive to cleanliness. As yaws is communicated

The eruption continues more or less numerous, until the disease is entirely extinguished, occasionally increasing and diminishing without any apparent cause. Towards the termination, the large tubercles often disappear, and a few others, after a considerable time, come out. Yet, during this interval of apparent recovery, the skin is seldom free from clusters of small papular yaws, which sometimes remain for weeks or months after every return of the larger yaws has ceased."—See *Edin. Med. Journ.*, No. cvi., p. 57.—Ed.

* This does not agree with Mr. Mason's description, who informs us that the morbid secretion produces no immediate change on the surrounding skin, unless the cuticle happen to be broken.—(*Edin. Med. Journ.*, No. cvi., p. 56.) He bears witness, however, to the bones of the legs and arms becoming affected with simple enlargement; to the extension of ulceration down to the periosteum; and to the bones becoming carious. These affections of the bones seem, like those of syphilis, often to continue for years after the other symptoms have ceased, and, in some instances, to prove fatal. The membranes of the nasal cavities sometimes ulcerate, and the adjacent bones become diseased, followed by frightful and incurable ulceration of the nose, palate, and throat.—Ed.

† *Edin. Med. Journ.*, vol. xxx., p. 323. As already noticed, Mr. David Mason denies that the American form of the disease is necessarily connected with fever, and maintains that, when febrile disturbance is present, it is only an adventitious circumstance. From his investigations, it appears that the poison or infectious matter of yaws is never, under any circumstances, conveyed through the medium of the atmosphere. Actual contact or inoculation is essential to the production of the disease. With the design of avoiding any labour, the negroes in Jamaica, he says, often purposely inoculate themselves, and mothers their children about the period of weaning, as is done also in Africa. Yet, according to Mr. David Mason, it is proved by experience that this disease is not milder in childhood, but, on the contrary, more unmanageable, and liable to be conjoined with infantile disorders, and to prove dangerous. Although the disease is often propagated by intentional inoculation, no doubt it is in numerous instances communicated by the accidental contact of the matter with an abraded part of the skin.—Ed.

* Mr. Mason suspects, from what he has observed, that the mother-yaw might not only be healed by means of caustic, but the constitutional disease prevented, by inoculation before the system has been tainted. The aggravated effects of the disease he refers to neglect, and to accidental unfavourable states of the general health. An ample supply of nourishing diet, frequent bathing, and moderate or equable warmth, seem to him to be requisite in the treatment. He is also in favour of tonic and diaphoretic medicines. Mercury, he says, affords no decided benefit, and, in alterative doses, is prejudicial. The plan which he prefers consists in frequent abluion in the tepid bath; clean linen and clothing; decoction of sarsaparilla, with small doses of tartarized antimony; and, in a later stage, tonic medicines, especially preparations of iron, with full diet, and a liberal allowance of animal food. Anasarous debility and functional derangement of the digestive organs, require frequent calomel purges, chalybeates, and proper diet. As a topical application, he commends the nitrate of silver, with which he not only destroys the crab-yaw, but others of long standing, which often linger in the skin after all signs of constitutional disease have ceased; and its effect on them was still more immediate and complete. Before the caustic is applied the scab must be removed, in order to let the caustic touch the spongy granular substance.—Ed.

in the same way as the venereal disease or the itch, it is just as much endemial in Africa as lues or itch is in this country. Were it not for the circumstances adverted to, Bertrandi's be-

lief, that negroes are more disposed to this disease than whites, perhaps might not be correct. The same exposure might produce the same effects in the European as in the negro.*

* Winterbottom, in *Edin. Med. Journ.*, vol. xxx., p. 322. On this point the following observations are made by Mr. Mason:—"There is no foundation for Dr. Darwin's observation, that the yaws is hereditary; nor is it exclusively confined to the negro or African race. Neither Europeans nor Creoles are invulnerable, although it occurs very rarely among them. These classes, and also people of colour, view the disease with peculiar dis-

gust; and as they are not exposed to intermingle with the infected, but are careful to avoid such intercourse, nor have the same motives which so often prompt negroes to inoculate themselves and their offspring, we may find, in these considerations, sufficient ground for the above exemption. Something, however, may be allowed to the European constitution being less susceptible of yaws than the African."—*Op. cit.*, No. cvi.—ED.
